Alternatively, extremely soft, or even paramagnetic, coatings may be used (Hopkins *et al.* 1996). The interaction between the sample and the tip is then mostly if not solely attractive. A point-like paramagnetic tip probes the square modulus of the stray field generated by the sample and allows for an accurate stray field mapping under specific conditions (Proksch *et al.* 1996).

## *4. Applications of MFM*

The need for fast observations of recorded bit patterns fostered the development of MFM. Perpendicular media have been widely studied. Figure 6 shows an example of dense periodical flux changes in a CoPtCrO(12nm)/RuCr(4nm)/CoPtCrO(12nm) granular-type perpendicular recording medium, which demonstrates a recording performance of 4 Gbit $cm^{-2}$ (26 Gbit $in^{-2}$). Atomically ordered alloys with an $L1_0$ type phase, such as FePd or FePt, are known to exhibit an abnormally large uniaxial anisotropy with a perpendicular to the plane easy axis. Over a wide thickness range, a stripe pattern develops (Fig. 7(a)) with domains magnetized alternately up and down.

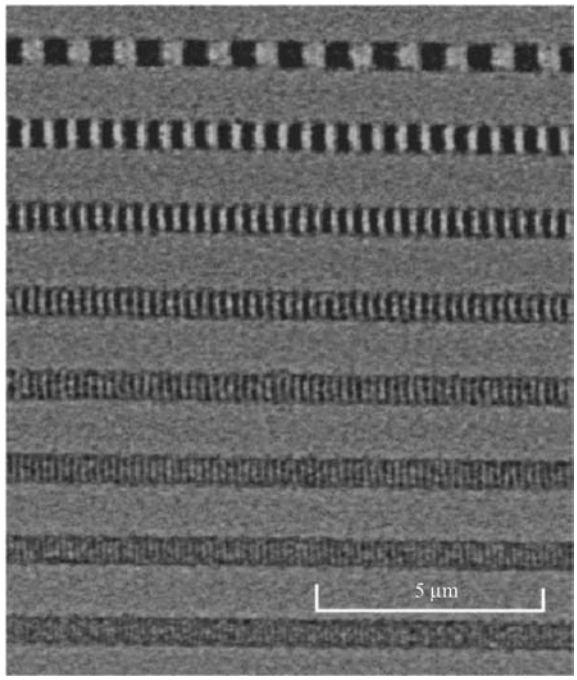

***Figure 6***
Recorded bits in a granular-type perpendicular recording medium along tracks with densities ranging from 50 kfci (kilo flux change per inch) to 400 kfci in steps of 50 kfci (courtesy of Takao Suzuki and A. Ehsan, Toyota Technological Institute).

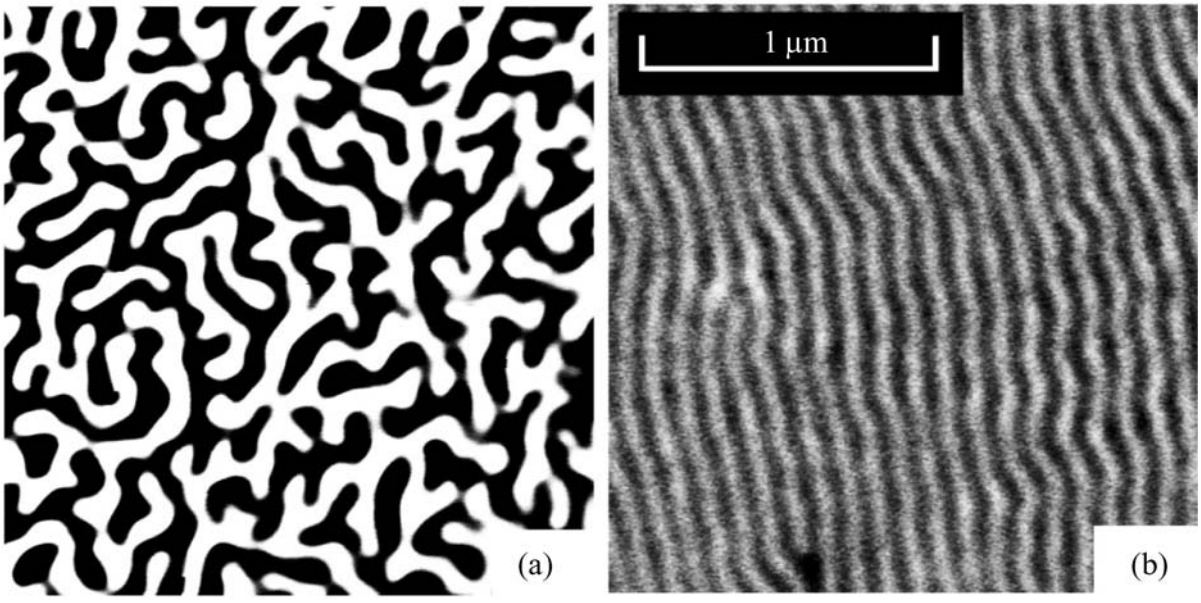

***Figure 7***
MFM images of (a) (fragmented) ''strong'' and (b) ''weak'' stripes in chemically ordered FePd alloy thin films. Domain widths as low as $\sim 35$ nm have been observed in such materials (courtesy of Y. Samson).

As the thickness increases, the stripe width first sharply decreases and then slowly increases as the result of the competition between wall and demagnetizing field energies. In samples grown at room temperature the chemical ordering is imperfect resulting in a reduced perpendicular anisotropy. So-called ''weak'' stripe domains (Fig. 7(b)) as narrow as $\sim 35$ nm have been observed for such samples (Samson *et al*. 1999) thereby setting an upper limit to MFM resolution in the favorable case of a periodic domain pattern. MFM also proves sensitive as clear initial domain pattern observations in cobalt layers as thin as three monolayers with the smallest features in the 400 nm range have been reported.

Patterned magnetic layers are viewed as possible future high-density recording media. Shape anisotropy now relays growth or chemical ordering-induced anisotropy. Figure 8 shows a partially demagnetized array of iron pillars with a large height-to-diameter aspect ratio, fabricated by scanning tunneling microscopy-assisted chemical vapor deposition (Wirth *et al*. 1999). In this study, the smallest periodicity of particles was 80 nm corresponding to a data storage density of $\sim 15\,\mathrm{Gbit\,cm^{-2}}$ ($\sim 100\,\mathrm{Gbit\,in^{-2}}$). As a prerequisite to applications, a precise physical understanding of reversal processes in nanometer-scale particles proves necessary, such as the size threshold between a pure thermally activated Stoner–Wohlfarth-type behavior in weakly interacting particles and the emergence of more complex nucleation modes.

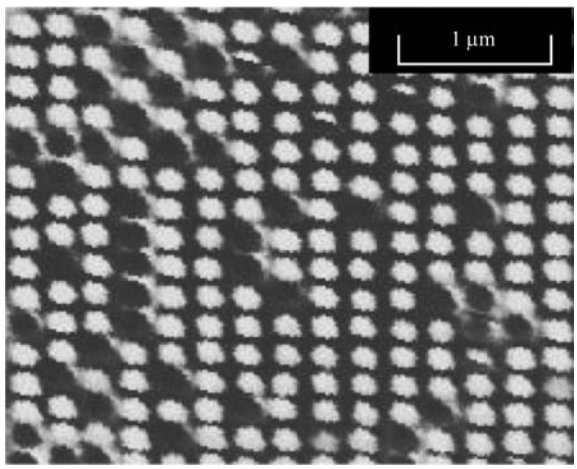

***Figure 8***
MFM image of part of an array of iron pillars grown on gold. A pulsed field of 66 mT has caused reversal of some of the pillars (color change from bright to black) (courtesy of S. Wirth).

Because of its ability to handle complex topographies and of its spatial resolution and sensitivity, MFM appears, in this context, singular among magnetic imaging techniques. Similar arguments prevail in the observation of magnetic nanowires. One of the most illustrative observations in 80 nm diameter

nanowires is shown in Fig. 9 (Belliard *et al*. 1998). In spite of a rather unpromising geometry, submicrometer-size domains are clearly revealed. Image analysis leads to the picture of axially magnetized wire segments separated by off-axis magnetized domains, in agreement with knowledge of the growth properties of such wires. As the diameter is reduced to $\sim 30$ nm, the magnetization distribution remains axial owing to shape anisotropy, with, because of magnetic history, the possible occurrence of head-to-head or tail-to-tail charged walls (Ebels *et al*. 2000).

If MFM offers unprecedented imaging capabilities in systems displaying localized charge densities, it proves much less efficient in the high-resolution observation of soft magnetic materials, owing to their very specific ability to screen and/or spread magnetic charges. In low saturation magnetization soft magnetic materials such as Permalloy ($Ni_{80}Fe_{20}$), the domain wall contrast in micrometer-size elements proves diffuse, as shown in Fig. 10 (Gomez *et al*. 1999), whereas large wall distortions are commonly observed in larger-size elements. Numerical simulations shed light on the underlying physical phenomena (Fig. 11): magnetic charges gather in the soft material under the influence of the tip stray field. Their associated demagnetizing field opposes the tip field (screening). Tip-induced charges interact with charges already present in the soft magnetic material along walls, for instance, thereby modifying the shape of the wall (Fig. 11(a)). As the tip moves above the surface of the element, the overall charge pattern evolves and so does the tip–sample interaction energy, hence the force or force gradient acting on the tip (Eqns. (7), (9), and (10)).

If MFM was mapping the charge distribution inside the sample without perturbation, then the image would mirror perfectly the wall symmetry, here a set of four 90° walls building a perfect flux closure (Landau–Lifshitz) pattern (Fig. 11(b)). When tip perturbations are duly accounted for, the MFM image resembles that of distorted walls (Fig. 11(c)) although it is the result of a complex convolution process. Simulations performed with realistic tip field distributions properly predict the existence of a global attractive force between the tip and the soft element as well as the right order of magnitude for "wall contrast." Interestingly enough, noticeably stable images of naturally pinned magnetic structures such as 360° walls have been produced in a number of laboratories (e.g., Cho *et al*. 1999).

Numerical simulations: (a) local perturbation in a Permalloy platelet (size 1 μm × 1 μm) under the action of a tip representative of standard MFM probes; (b) simulated MFM image in the "no perturbation" limit; (c) simulated MFM image taking account of tip on sample perturbations.

## 5. Outlook and Perspectives

Further development of MFM needs to include better magnetic tip calibration and repeatability as well as environment cells (e.g., temperature and field). Modulation techniques allow the analysis of phenomena occurring at a time scale much shorter than the resonance period of cantilevers (Proksch *et al*. 1999b). Besides, a finer interpretation of the mechanics of force microscopes is also highly desirable: an independent monitoring of both the frequency shift and the cantilever motion amplitude vs. position are key factors towards a full analysis of dissipation (Proksch *et al*. 1999a) and nonlinear oscillations in the high $Q$ regime (Aimé *et al*. 1999).

## Magnetic Hysteresis

When a magnetic field acts on a demagnetized ferromagnetic body, the component of the macroscopic magnetization along the field direction increases nonlinearly. In general, the increase takes place with a low initial slope, a drastic increase of this slope at intermediate fields, and a new decrease at higher fields up to the technical saturation (total saturation requires 0 K or applied fields with strength tending to infinity). When the field is removed, the macroscopic magnetization decreases along a curve located well above the initial magnetization curve. For zero field a noticeable magnetization generally remains that is called remanence or remanent magnetization, $M_r$. After reversal of the field, the magnetization drops and vanishes for a reversal field known as coercive field, $H_c$. Further increase of the field leads to the saturation. When the field is cyclically applied, the magnetization curve is a hysteresis loop as that shown in Fig. 1. If the maximum applied field is not high enough to get saturation, the loop is called a minor loop.

The coercive field permits the scaling of the applied fields as weak, lower than $H_c$, intermediate, those of the order of $H_c$, and high fields, stronger than $H_c$. If superimposed to a constant field, a cyclically varying field is applied, and we obtain a hysteresis loop around a point of the hysteresis loop, generally known as a shifted loop. It is important to remark that the field acting on a magnetized sample is the sum of the externally applied field and the demagnetizing field due to the magnetization itself. As the demagnetizing field can be roughly approximated by $-NM$, where the demagnetizing factor, $N$, is geometry dependent, the shape of the hysteresis loop of any material depends on its geometry. Customarily, it has been well established in the textbooks that the ideal shape of a magnetic sample is either toroidal or a long narrow bar, both exhibiting negligible demagnetizing factors. For a more detailed discussion of the hysteresis in ferromagnetic materials the reader is referred to the book of Bertotti (1998).

### *1. Technical and Fundamental Importance of the Magnetization Curve*

Ferromagnetic materials are used for two main technological applications: (i) as flux multipliers forming the nucleus of electromagnetic machines, and (ii) as stores of either energy (magnets) or information (magnetic recording). The technical requirements to improve the material performance for both functions are related to the characteristics of the hysteresis loop and magnetization process. Flux multiplication requires high permeability and narrow hysteresis loop or low

coercivity, $\mu_0 H_c$. These properties are characteristic of the so-called "soft" magnetic materials. Storage requires high remanence and wide hysteresis loop in order to prevent demagnetization. Both properties are characteristic of "hard" magnetic materials.

Even though for all types of applications the higher the spontaneous magnetization, $M_s$, the better the performance, the difficulty of increasing $M_s$ artificially yields coercivity as the key parameter to be controlled by the material scientist. In fact, the history of the magnetic material research is the history of the progressive increase of the available coercivity spectrum. The maximum spontaneous magnetization is that corresponding to 0 K and it is known as saturation magnetization; its value is roughly given by the atomic magnetic moment, of the order of Bohr magneton, $10^{-23}\,\mathrm{JT}^{-1}$, times the number of atoms per unit volume, typically $10^{29}$, that leads to $\mu_0 M_s$ of the order of 1 T. At the beginning of the twentieth century, just as in Plato's time, the harder material, "hard steels," had a coercivity $\mu_0 H_c = 10^{-2}\,\mathrm{T}$, only two orders of magnitude larger than that of the known softer material, "purified iron." At the beginning of the twenty-first century, the softer material is nanocrystalline $Fe_{84}Zr_7B_9$ with coercivity $\mu_0 H_c = 10^{-7}$ T whereas the harder material is nanocrystalline $Fe_{84}Nd_7B_9$ with coercivity $\mu_0 H_c = 1\,\mathrm{T}$.

Seven orders of magnitude separate the coercivity from the harder to the softer ferromagnetic material which compositionally differs only in 7 at.% of atoms, zirconium for the softer and neodymium for the harder. This result summarizes the best achievement of the science of magnetic materials. It has been the control of the magnetization curve, made possible from the deep understanding of its governing parameter, anisotropy, which has allowed the outstanding enhancement of the required properties. Anisotropy can be tailored through both composition and microstructure. Since $\mu_0 M$ and $\mu_0 H$ have the same units it is possible to compare the hysteresis loops of soft and hard materials, taking into account that the height of the loop of soft materials is seven orders of magnitude larger than its width, whereas the hysteresis loop of the best hard materials are square, exhibiting the same height as width, typically 1 T.

The central characteristics of ferromagnetic materials, the magnetization curve and the hysteresis loop, depend on the macroscopic magnetization measured along the direction of the applied field as a function of the field strength. We have seen that magnetization curve features are of maximum relevance for material application. From the fundamental point of view, the problems involved in the physical processes underlying hysteresis, such as relaxation, nonlinearity, metastability, energy dissipation, irreversibility, domain wall nucleation and propagation, coherent rotation, or incoherent modes, are the more attractive issues for basic scientists.

## 2. Magnetization Processes

Ferromagnetic materials do not generally exhibit macroscopic magnetization. Even though exchange interactions tend to align all spins along the same direction, the minimization of the magnetostatic energy tends to break the spin directional order achieving a demagnetized macroscopic state. As crystalline ferromagnets contain a discrete set of easy directions for the magnetization, the more common spin configuration minimizing the sum of exchange, magnetostatic, and anisotropy energies becomes the domain structure, as that schematically illustrated by Fig. 2. Domains, within which the spontaneous magnetization, $M_s$, is oriented along an easy axis, are separated by domain walls with thickness $\delta$ corresponding to the exchange correlation length. $\delta$ is of the order of $(A/k)^{1/2}$ where $k$ is the anisotropy constant and $A$ is the exchange constant $A = 2JS^2/a$, $J$ being the exchange interaction between two adjacent magnetic moments, $S$ the spin value in h units and $a$ the interatomic distance (see Magnets, Soft and Hard: Domains). In general, $A$ is around $10^{-11}\,\mathrm{J\,m^{-1}}$. Since $k$ varies from $10^7$ to $10^2\,\mathrm{Jm^{-3}}$, $\delta$ ranges from 1 nm to a few micrometers (Cullity 1972 pp. 290). The energy of the configuration, anisotropy and exchange, is stored in the walls with a surface density $\gamma = (Ak)^{1/2}$. However, in sufficiently small ferromagnetic particles the minimum energy corresponds to the single domain structure. This fact is due to the different geometrical dependence of the magnetostatic energy that increases with the sample volume, compared to the wall energy that increases with the wall area. In the following the case of multidomain structures will be analyzed.

In multidomain samples each domain is a magnetic moment. At the demagnetized state the vectorial sum of the magnetic moments corresponding to each domain vanishes. When an external magnetic field, $H$, is applied along the positive $z$-direction the Zeeman energy of the $i$th domain becomes $\mu_0 M_s H v_i \cos\theta_i$, where $v_i$ is the volume of the $i$th domain and $\theta_i$ the angle formed by $M_s$ of the $i$th domain with the $z$-axis,

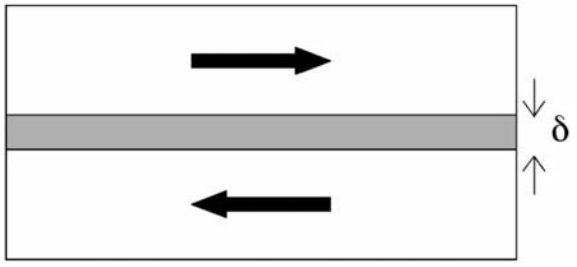

***Figure 2***
Schematic representation of two magnetic domains separated by a domain wall of width $\delta$.

respectively. Since the Zeeman energy changes from domain to domain there is an energy gradient through the walls and, therefore, a pressure exerted on them. On the other hand, under the torque $\mu_0 M_s H v_i \sin\theta_i$ the magnetization tends to rotate from the easy axis to the field direction. Under the field effect, if the temperature is above 0 K, there is also a tendency to increase the spontaneous magnetization. This is the so-called para-effect that is observable in the approach to saturation. Therefore, the changes in the macroscopic magnetization, $\Delta M$, can generally be expressed in the following schematic way

$$\Delta M = M_s \cos\theta_i \Delta v_i + M_s v_i \Delta\cos\theta_i + \cos\theta_i v_i \Delta M_s \quad (1)$$

The first term is known as domain wall motion contribution, the second corresponds to rotations of the spontaneous magnetization, and the third describes the para-effect or increase of the spontaneous magnetization strength induced by the field against the disordering thermal effect. It has been customarily assumed that domain wall motion takes place at lower fields whereas rotations seemed to require higher applied fields. In fact, one of the historically more attractive objectives of researchers in order to increase coercivity was the production of single domains to avoid the wall motion contribution to the magnetization process. The subsequent development of materials and experimental techniques pointed out that domain wall motion in high anisotropy samples could require field strengths as large as that required for magnetization rotation (Becker 1970). However, it can be accepted that generally domain wall motion is the main magnetization process at low fields, whereas rotations become preponderant for higher fields. As stated above, the character of "low" or "high" fields should be related to the coercivity and, therefore, depends on the nature of each sample. As shown in Fig. 1, the initial region of the initial magnetization curve, the Rayleigh region, corresponds to applied fields much smaller than the coercivity and is due to almost reversible processes. For applied fields of the order of coercivity the maximum contribution of irreversible processes takes place. Finally for applied fields higher than coercivity that region known as "approach to saturation" is reached.

For a given pressure exerted by the field on the wall, the wall displacement depends on the resistance that the solid presents to such displacement. Let $p$ be the pressure acting on a wall initially located at $x_0$, that for a 180° domain wall with the field parallel to one domain is of the order of $2\mu_0 M_s$. Under a pressure $p$ the wall moves to a new position $x$ at which the pressure exerted by the solid that is due to the position dependence of the wall energy, $d\gamma/dx$, exactly counterbalances $p$. Many models have tried to account for the spatial dependence of the wall energy density $\gamma$. Fluctuations due to modulation of residual stresses, point defects, dislocations, and grain boundaries affecting either $A$ or $k$ have been invoked and many times evidenced as sources of discontinuities in the domain wall displacement (Néel 1978). Nevertheless, it should be emphasized as the more relevant fact that the correlation length of the fluctuation, $l$, must be scaled to the domain wall width. When $l < \delta$ the wall energy does not depend on position and therefore the hindrance to displacement disappears.

This is the case for amorphous materials for which the structural or topological disorder has a typical correlation length shorter than $\delta$ and therefore the energy of the wall, though high, does not depend on position. Note that at any relative equilibrium position $x_i$ of the wall at $H = 0$ it is verified $(d\gamma/dx)_{xi} = 0$. Around $x_i$, $\gamma$ allows a quadratic Taylor expansion that yields to a reversible linear displacement for sufficiently low fields. When the field rises leading to an effective pressure $p$ that overcomes the maximum $(d\gamma/dx)$ the wall undergoes an irreversible jump and disappears and provides an order of magnitude for the coercivity. But note that the derivative $d\gamma/dx$ has only sense for $dx > \delta$, therefore the maximum $d\gamma/dx$ means the maximum $\Delta\gamma/\delta$ which is of the order of $(Ak)^{1/2}/(A/k)^{1/2}$ , a ratio that becomes proportional to $k$. In other words $H_c$ in this case should increase proportionally to $k$. Figure 3 illustrates a typical dependence of the wall energy density with position.

The rotation process has also reversible and irreversible steps. Consider a uniaxial anisotropy, of constant $k$, that in first order can be described by an energy density term $F_k = k(\cos^2\varphi - 1/3)$, where $\varphi$ is the angle formed by the spontaneous magnetization and the easy axis, see Fig. 4. As the easy axis forms an angle $\theta_i$ with the applied field the magnetization

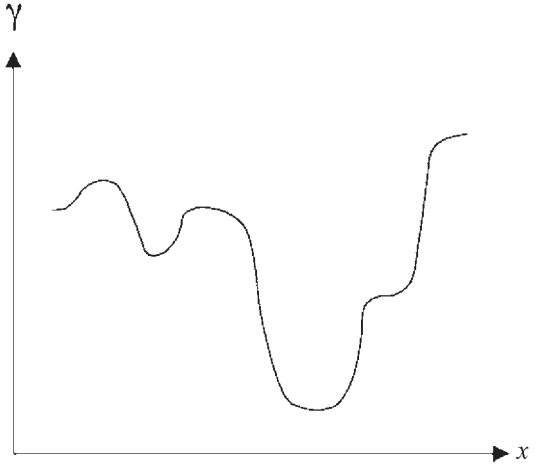

***Figure 3***
Typical dependence of the wall energy density ($\gamma$) with position ($x$).

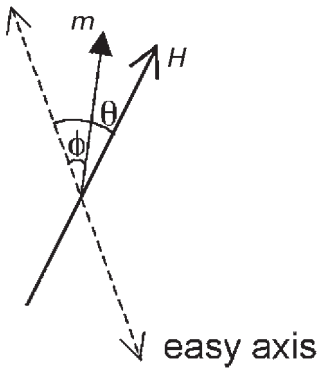

*Figure 4*
Rotation of the magnetization from the easy axis under the influence of an external magnetic field.

would rotate by an angle $\varphi_i$, from the easy axis towards the field direction, for which the sum of the anisotropy and Zeeman energy densities vanishes. Therefore, at the stable equilibrium position, the total energy should be a minimum and thereby, it is verified for the first derivative

$$\left[\frac{\mathrm{d}}{\mathrm{d}\phi_i}\right][k(\cos^2\phi_i - \tfrac{1}{3}) - \mu_0 M_\mathrm{s} H\cos(\theta_i - \phi_i)] = 0 \quad (2)$$

and for the second derivative

$$\left[\frac{\mathrm{d}^2}{\mathrm{d}\phi_i^2}\right][k(\cos^2\phi_i - \tfrac{1}{3}) - \mu_0 M_\mathrm{s} H\cos(\theta_i - \phi_i)] > 0 \quad (2a)$$

The component of the magnetization along the field direction $M_z$, that initially at zero field was $M_\mathrm{s}\cos\theta_i$, increases with $H$ to $M_\mathrm{s}\cos(\theta_i - \varphi_i)$. The dependence of $M_\mathrm{s}\cos(\theta_i - \varphi_i)$ with $H$ can be obtained from relations (2) and (2a). The solutions are known as Stoner–Wohlfarth model for coherent rotation in uniaxial materials (Stoner and Wohlfarth 1948). Figure 5 summarizes some of the corresponding hysteresis loops. It is worth noting that the hysteresis depends on $\theta_i$ being maximum for the $\theta_i = \pi$ case for which only two stable or metastable states corresponding to $\varphi_i = 0$ or $\varphi_i = \pi$ are allowed and the coercivity corresponds to the so-called anisotropy field $\mu_0 H_\mathrm{c} = 2k/M_\mathrm{s}$. In contrast, for $\theta_i = \pi/2$ the magnetization curve is reversible and linear with slope $M_\mathrm{s}^2/2k$ for applied fields smaller than the anisotropy field, i.e., the field at which the magnetization finishes its rotation reaching the applied field direction. For a random distribution of the easy axes orientation the coercivity increases with $k$ as well as the field required to reach saturation.

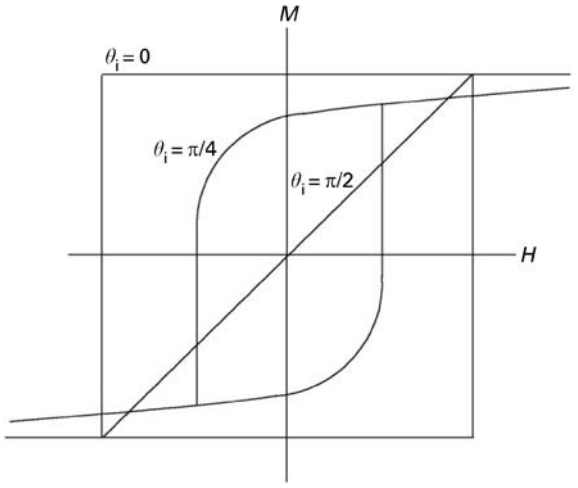

*Figure 5*
Schematic representation of the hysteresis loops of a uniaxial material according to the Stoner–Wohlfarth model for coherent rotation. $\theta_i$ is the angle between the easy axis and the external magnetic field.

## 3. Dissipation and Irreversible Processes

One of the more important features of the magnetization process is its irreversibility due to the fact that for a given field there exist many wall positions for which the energy is a relative minimum. In other words, for a given applied field the macroscopic magnetization is not a single-valued function of the applied field. For rotation processes also the anisotropy barrier that should be overcome in order to reverse magnetization yields irreversible jumps and hysteresis. Note that the magnetization energy or work supplied in an adiabatic magnetization process during which, under the action of an increasing applied field, $M$ increases from zero to $M_\mathrm{f}$ is given by the integral between zero and $M_\mathrm{f}$ of $\mu_0 H\mathrm{d}M$ (see Fig. 1). If after removing the field the magnetization evolves to the remanent state the expended energy has not been restored and the process of increasing and decreasing the applied field had the energy cost indicated in Fig. 1.

During a complete hysteresis loop the energy irreversibly lost is that given by the area enclosed by the loop (see *Magnetic Losses*). This energy, according to the $M$ and $H$ scales indicated above, ranges from $10^6\,\mathrm{Jm}^{-3}$ to $10^{-1}\,\mathrm{Jm}^{-3}$ for hard and soft materials, respectively. The magnetic energy that a magnet can store is of the order of the energy dissipated during a complete hysteresis loop. Where does the electromagnetic energy go? It is dissipated as heat. Suppose that the magnetization process of a metallic ferromagnet is completely reversible at very low frequency

of the applied field. As the field frequency increases the electric field as well as the eddy currents induced through the Faraday law rise. The increase of frequency leads to a dissipation of Joule energy as heat and to the appearance of hysteresis or phase shifts between field and macroscopic magnetization. These types of losses are known as eddy current losses. Suppose now that the frequency of the applied field is almost zero. The losses now result only from the hysteresis of the macroscopic magnetization. In metallic materials the main source of hysteresis losses is that of the eddy currents.

The walls are locally pinned and suddenly jump as the field varies producing local eddy currents associated to these processes known as Barkhausen jumps (Barkhausen 1919). Local or microscopic eddy currents located around the pinning centre are induced. Structural relaxation, driven by motion and rearrangement of atoms, and magnetization relaxation through interaction between the spin and lattice systems also contribute to introduce delays between magnetization and field. All these considerations outline the complexity of the magnetization process as a thermodynamic transformation far from equilibrium, with time-dependent behavior and irreversible steps leading to energy dissipation.

## 4. Anisotropy as the More Important Factor Determining Hysteresis

From the point of view of the material physicist, the important conclusion of this overview is the importance of the anisotropy in the control of coercivity (see *Coercivity Mechanisms*). Anisotropy is related to technical magnetism, magnetization process and hysteresis loop just as exchange is to basic magnetism and magnetic structures. The structural anisotropy is due to the combined effect of the spin–orbit coupling and the non-spherical charge distribution around the magnetic atom. Thus, anisotropy can be increased by introducing magnetic atoms with large atomic weight, as rare earth elements. Nowadays, we know that the average or macroscopic anisotropy can be controlled from the local or structural anisotropy through the control of the nanostructure. In particular, for nanostructured multiphase random anisotropy systems, with the exchange correlation length larger than the structural fluctuation, the macroscopic anisotropy undergoes a noticeable reduction with respect to the local anisotropy by the smoothing effect of the exchange energy (Herzer 1989). The importance of the anisotropy on the coercivity is illustrated by taking into account that different theories of coercivity lead to the expression

$$H_c = \alpha\left(\frac{2k}{\mu_0 M_s}\right) - \beta M_s \qquad (3)$$

where the meaning of the $\alpha$ parameters depend on the particular theory and magnetization process (Kronmüller *et al*. 1988, Givord *et al*. 1991) and $\beta$ is a local demagnetizing factor.

## 5. Single Domains

An important question rises in the case of single domains corresponding to saturated multidomains as well as in the case of stable single domains; that is, how can the magnetization reversal take place when no wall exists over the sample? This is a fundamental question for the understanding of magnetization reversal. Let us suppose that a sample is completely saturated under an applied field along the positive $z$-axis that is an easy axis. If after removing the field the macroscopic magnetization decreases, it is because some domains oriented along the negative $z$-axis have been formed. But to nucleate a reversed seed a field of the order of the anisotropy field is required. Therefore the demagnetizing field acting on the sample when the applied field is removed should be higher than the anisotropy field. It is well known that coercivity is generally much lower than that expected from the value of the anisotropy field. This fact, known as Brown's paradox, has been interpreted by using two types of main arguments. (i) Existence of defects yielding local anisotropy effective constant fluctuations. Such fluctuations would decrease at some regions the reversal barrier height. (ii) The saturated state is not a completely saturated state but it contains a few very small domains oriented along the negative $z$-axis.

These domains, as observed in Fig. 6 in a saturated Co–Ni multilayer (González *et al*. 1999), would grow under the reversal field up to a critical size (reached at the growing field) and then propagate through the whole sample. For this case the nucleation of reversed domains is not necessary for the magnetization reversal. There are two important fields, nucleation and propagation fields, governing the shape of the hysteresis loop. The concept of nucleation field is generalized to that of growing field, when reversed domains are frozen. The hysteresis shape is smoothed if the propagation field is higher than the nucleation one. On the other hand, the hysteresis loop is rectangular when the propagation field is smaller than the nucleation, which is a condition of bistability. This property allowed Sixtus and Tonks (1931) to evidence the contribution of domain wall motion to the magnetization reversal. A nice example is shown in the experiment described by Fig. 7. A positive magnetostriction amorphous wire keeps closure domains at its end in the saturated state.

If a uniform field larger than the propagation field is applied along the direction opposite to $M_s$ and an extra field located at one end is superimposed in such

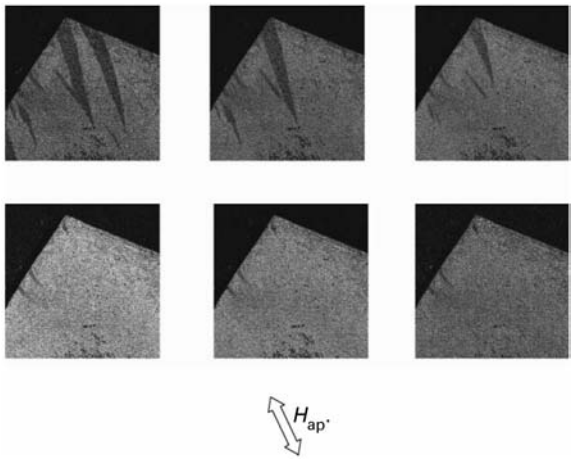

***Figure 6***

a way that at this end the field is higher than the growing field, the wall propagates (Reininger *et al.* 1993). As in the classic Sixtus and Tonks experiment, two small pick-up coils, separated by $z$ along the axial direction $z$ will collect the induced voltage due to the magnetization reversal with a relative delay, $t = z/v$, where $v$ is the wall speed during its propagation. When the length of the wire becomes short enough to allow overlapping of the closure domains the bistability disappears since the growing field decreases below the propagation field. Nowadays theoreticians and experimentalists proceed the research on magnetization reversal mechanisms that form an open framework for the technical magnetism.

Let us now take into account the case of single domains. If we focus our interest on small ferromagnetic particles the nonequilibrium character of the hysteresis loop can be easily illustrated. Suppose a set of $N$ uniaxial single domains with their easy axis perfectly oriented along the $z$-direction. If this assembly has been saturated under a field applied along the positive $z$-direction, the system is expected to remain saturated just immediately after the field was removed. If we call $N^+(t)$ and $N^-(t)$ the number of particles with the magnetization oriented along the positive or negative $z$ axis respectively, the condition at $t = 0$ is $N^+(0) = N$. This configuration corresponds to an equilibrium situation only at $T = 0$ K. For $T$ above 0 K any remanent magnetization at equilibrium is zero. The free energy ($F = U - TS$) minimization requires minimum energy and maximum entropy. If we assume the magnetization to lie along either the positive or negative $z$-direction the energy at zero applied field is minimum for both cases, since only anisotropy energy contributes. Therefore, we have to consider only maximum entropy as equilibrium condition. The maximum entropy clearly corresponds to $N^+ = N^- = N/2$. To reach this equilibrium configuration it takes a time, which is typically the relaxation time of the system (see *Magnetic Viscosity*).

Conceptually speaking it is important to remark that remanence is always relaxing to demagnetized state. The hysteresis is due to the fact that the measuring time is much smaller than the relaxation time. As the relaxation time of a particle of volume $v$ and anisotropy constant $k$ is of the order of one minute for $kv = 25K_BT$, $K_B$ being the Boltzmann constant, it is inferred that a system of particles with $kv$ lower that $25K_BT$ should behave as a paramagnetic (superparamagnetic) material without exhibiting any hysteresis in the field dependence of magnetization (Cullity 1972 pp. 410–18). However, by decreasing the temperature the relaxation time exponentially increases and the system becomes ferromagnetic exhibiting hysteresis. The magnetic field acts on the magnetization by increasing or decreasing the macroscopic magnetization in times smaller than the relaxation time, whereas the thermal motion tends to demagnetize the sample overcoming the anisotropy barriers and eliminating the hysteresis phenomena. Therefore, for systems formed by small particles for which, at reasonable temperatures, it may be verified from $kv = 25K_BT$—for usual $k$ values of the size of a few nanometers—a

new term should be included in the general expression of the coercivity (3) that becomes

$$H_c = \alpha\left[\frac{2k}{\mu_0 M_s}\right]\left[1-\left(\frac{25K_B T}{kv}\right)^{1/2}\right] - \beta M_s \qquad (4)$$

The thermal term tends to decrease coercivity by decreasing the relaxation time. Superparamagnetism or disappearance of the hysteresis was a surprising and amazing experimental observation found by Bean and Livingston (1959) just while they tried to decrease the particle size in order to prevent domain wall contribution for "improving" hard properties (Jacobs and Bean 1963). In 1949, Néel had predicted superparamagnetism (Néel 1949). Nowadays, the nanostructures formed by different amorphous and nanocrystalline phases with different Curie temperatures have lifted superparamagnetism and, in general, relaxation processes (García del Muro *et al*. 1997) to an outstanding position of interest.

## 6. *Effect of the Nanostructure*

Finally, three examples, based on fairly recent experiments and illustrative of the influence of the nanostructure on the magnetization curve are summarized.

Nanocrystalline materials, composed of ferromagnetic Fe(Si) nanograins embedded in an amorphous matrix with lower Curie temperature, $T_c^{am}$, exhibit a noticeable thermal dependence of magnetization as shown in Fig. 8 (Hernando and Kulik 1994). For $T < T_c^{am}$ the coercivity is very low due to the exchange coupling between the crystallites transmitted by the matrix. As the temperature rises the magnetization of the matrix drops and the grains are less coupled giving rise to a progressive increase of the coercivity that reaches an abrupt maximum at $T_c^{am}$, since at this temperature the grains behave as single domains. Further increase of the temperature leads to a superparamagnetic transition and the coercivity falls to zero.

An example of the influence of the domain wall width, $\delta$, on the coercivity and magnetization curve is illustrated by Fig. 9 (Arcas *et al*. 2000). In a sample composed of iron nanocrystallites embedded in a FeZr amorphous matrix, $\delta$ depends on the number of crystallites. The influence on $\delta$ of the exchange

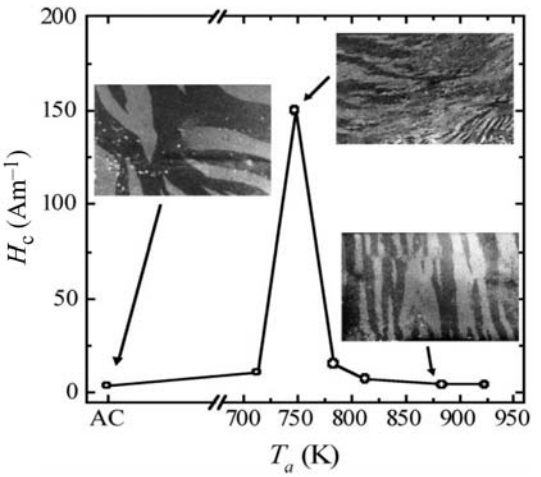

***Figure 9***

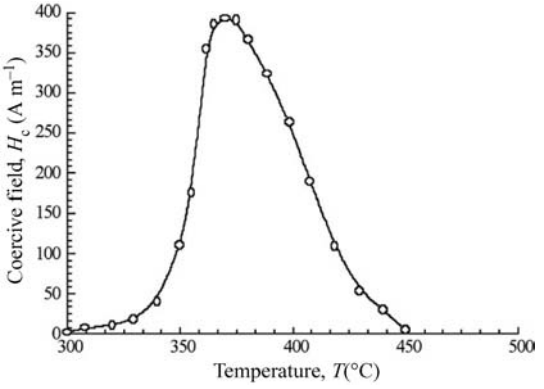

***Figure 8***
Temperature dependence of the coercive field for a nanocrystalline material. Notice the drastic increase of the coercive field as we approach the Curie temperature of the amorphous matrix ($T_c^{am} \approx 370$ °C).

coupling between the grains analyzed by Herzer (see *Amorphous and Nanocrystalline Materials*) is reflected in the coercivity.

Finally an example of minor hysteresis loops obtained around a fixed point of the hysteresis loop, shifted loops, is outlined. Spin–valve systems allow the shift of the hysteresis loop through the coupling between an antiferromagnetic (hard) layer and a ferromagnetic (soft) layer. Figure 10 shows a typical shifted hysteresis loop (Dimitrov *et al*. 1998). The minor loop corresponding to the reversal of the magnetization at the soft layer takes place under the effective exchange field exerted by the hard layer.

## Magnetic Layers: Anisotropy

A dictionary definition of anisotropy is "a difference of property or of effect in different directions." Magnetic anisotropy in materials is concerned with the observation that the magnetization prefers to point parallel or antiparallel to a particular direction or axis. A detailed treatment of the fundamentals of magnetic anisotropy is given by Chikazumi (1997).

Anisotropy can be related to the crystal structure of the material and, in the case of thin-film materials, to the form of the material, to the importance of the break of symmetry at the surfaces of the thin layer, to any strain in the thin film, to the morphology of the microstructural units making up the film, to any directional atomic ordering in the film, and to any other interface effects at the junction of overlaid films. It is clear that perpendicular anisotropy, i.e., anisotropy favoring an orientation of the magnetization normal to the plane of the film, is one of the most important materials requirements in MO recording technology.

To a sufficient approximation the effective anisotropy, $K_{EFF}$, can be written phenomenologically in terms of a volume term, $K_V$, and a surface term, $K_S$:

$$K_{EFF} = K_V + 2K_S/t_F \qquad (1)$$

where $t_F$ is the thickness of the magnetic element. $K_V$ necessarily contains a magnetocrystalline anisotropy term, any stress term, any shape anisotropy term, any growth-induced anisotropy term, and any other volume sources of anisotropy. The demagnetizing energy for a film magnetized normal to its surface is also included as the last term:

$$K_V = (K_{MC} + K_{ST} + K_{SH} + K_G \cdots - \mu_0 M_S^2/2) \qquad (2)$$

In the case of a thin film the surface term, which accounts for the two surfaces, is only of significance if $t_F$ is of nanometer dimensions. This can occur practically in multilayer systems. $K_{EFF}$ is positive for perpendicular magnetization.

### 1. Magnetocrystalline Anisotropy

The microscopic origin of this anisotropy is related to the spin state of the magnetic moments and by the symmetry of their arrangement in the crystal lattice that involves spin–lattice coupling. It occurs in all crystalline ferro- and ferrimagnetic materials.

The anisotropy can be describe phenomenologically in terms of the direction cosines of the magnetization with respect to rectangular coordinate axes or in terms of spherical harmonics. Any perpendicular magnetization will realistically occur in an effectively uniaxial system. The latter representation gives, for a simple hexagonal symmetry:

$$E_{MC} = K_1 \sin^2\theta + K_2 \sin^4\theta + \cdots + K_4 \sin^6\theta \cos 6\varphi \tag{3}$$

in terms of the anisotropy constant $K_i$ and the polar and azimuthal angles $\theta$ and $\varphi$ between the magnetization and the $c$- and $a$-axes. In an oriented film with an easy axis normal or close to normal to the surface of the film, perpendicular magnetization can be achieved, in the absence of any other sources of anisotropy, if the magnetocrystalline anisotropy energy is greater than the demagnetizing energy. This requires, following Eqn. (2), to a sufficient approximation neglecting higher terms $K_1 > \mu_0 M_S^2/2$.

### 2. Stress Anisotropy

This anisotropy comes from stresses produced in the film by the deposition process or by thermal expansion differences between the substrate and the magnetic film. The magnetoelastic energy produced by a stress $\sigma$ is essentially the product of this stress and the resulting value of magnetic strain or magnetostriction, $\lambda$. Again, assuming a uniaxial system the volume magnetoelastic energy is given by

$$E_{ML} = -3\sigma\lambda_S \cos^2\theta/2 \tag{4}$$

where $\lambda_S$ is an isotropic magnetostriction coefficient and $\theta$ is the angle between the magnetization $M_S$ and $\sigma$. Stress can therefore create uniaxial anisotropy with a relevant stress-induced anisotropy constant given by

$$K_{ST} = 3\sigma\lambda_S/2 \tag{5}$$

The stress axis is an easy direction of magnetization if $\sigma\lambda_S > 0$, i.e., positive magnetostriction will promote perpendicular magnetization for a compressive stress in the film while a negative constant requires a tensile stress.

### 3. Shape Anisotropy

In general magnetostatic energy in a thin film acts to orient the magnetization in the plane of the film as suggested above. However, many deposited films can contain microstructural units that by their shape and orientation favor magnetization normal to the film. This is very possible in films that contain columnar grains or directional voids. In a prolate spheroid the magnetostatic energy can be written as

$$E_{ME} = \mu_0(N_a - N_c)M_S^2 \sin^2\theta/2 \tag{6}$$

where $N_a$ and $N_c$ are constant factors known as demagnetizing factors related to the semiminor and semimajor axes, respectively, and $\theta$ is the angle between $M_S$ and the $c$-axis. In analogy to the case of stress, a shape anisotropy constant can be written as

$$K_S = \mu_0(N_a - N_c)M_S^2/2 \tag{7}$$

If $N_a < N_c$ then the shape anisotropy is a minimum with $M_S$ along the $c$-axis.

### 4. Growth-induced Anisotropy

Thin films essentially condense and grow in a unidirectional manner from the substrate surface. This can lead to particular growth morphologies and also directional ordering of atoms and a so-called growth-induced anisotropy. This source of anisotropy is important in ferrite and garnet films and in amorphous alloy films.

In amorphous films single magnetic ions may have a particular atomic coordination, say in the plane of the film, which gives rise to a directional magnetic coupling and perpendicular anisotropy. Also, atom pairs may order preferentially parallel or normal to the surface, and in mixed oxide crystalline films atoms may occupy lattice sites in a preferential manner, so reducing the magnetic symmetry of the system. The anisotropy may be represented phenomenologically in terms of the direction cosines of the magnetization with respect to any lattice and the normal to the growth surface. Again, for a uniaxial system

$$E_G = K_G \sin^2\theta \tag{8}$$

where $\theta$ is the angle between the growth direction and the magnetization.

### 5. Surface or Interface Anisotropy

Interface or surface anisotropy is related to the reduced symmetry, lower coordination numbers, the presence of localized near-surface and interface states, and other effects at a surface (Bayreuther 1989). The reduced symmetry at the surface modifies the magnetocrystalline anisotropy and this contribution can, in fact, be positive or negative encouraging out-of-plane and in-plane magnetization. There can also be a contribution to the interface anisotropy that is magnetoelastic in origin. This is related to stress

relief by defect formation at interfaces. It is inversely related to the layer thickness and may therefore be significant at small thicknesses.

Phenomenologically the effect of surface anisotropy can be represented by a term $K_S$ added to the volume anisotropy in an equation for the total anisotropy, as shown in Eqn. (1). Conventionally, a positive $K_{EFF}$ signifies a perpendicular anisotropy and a plot of $K_{EFF}t_F$ against $t_F$ gives a slope of $K_V$ and an intercept of $2K_S$.

There is one further anisotropy that will be mentioned only briefly as it is not important here: exchange anisotropy. This effect is unidirectional and involves the pinning of moments in a ferromagnet layer by an adjacent antiferromagnet layer on cooling through the Néel temperature of the antiferromagnet in an applied field. Exchange anisotropy is of growing importance in several magnetic thin-film devices such as giant magnetoresistance sensors.

## 6. Materials

### 6.1 Rare Earth–Transition Metal Alloy Films

The generic materials that form the various layers in the storage medium in MO recording are amorphous rare earth–transition metal alloy (RE–TM) films. RE–TM films are treated in a review by Grundy (1994). In brief, the deposition and alloying of the heavy rare earths gadolinium, terbium, and dysprosium with cobalt and/or iron produces thin ferrimagnetic films with the necessary magnetic coercivity, in relation to the compensation phenomenon, and perpendicular anisotropy to store stable magneto-optically written bits in the memory layer. The perpendicular anisotropy is composition dependent and, more than any other magnetic parameter, it can be strongly dependent on fabrication conditions and microstructure. For example, early measurements showed that $K_{EFF} > 0$ for bias sputtered GdCo and evaporated GdFe films, whereas $K_{EFF} < 0$ for evaporated and zero-bias sputtered GdCo and GdFe sputtered at relatively high biases. In most situations several sources of anisotropy may be active. Measured values of the principal perpendicular anisotropy constant for compositions of interest are of the order of $5 \times 10^5$ J m$^{-3}$.

Magnetocrystalline anisotropy is not relevant in amorphous films and the potential sources of anisotropy therefore come from any growth-induced structural anisotropy, atomic ordering, stress, or shape effects. The first growth-induced anisotropy to be considered is single-ion anisotropy (Suzuki *et al.* 1987) that may be present with non-S state ions such as terbium and with dysprosium but not with gadolinium. An anisotropic distribution of atoms is assumed with more nearest neighbors in the plane of the film. Interactions such as that between the RE 4f electrons and the surrounding ions give perpendicular anisotropy in such a "bond-order" anisotropy (Prados *et al.* 1997).

The second ordering effect, that of pair ordering (Mizoguchi and Cargill 1979), has also found favor in explaining the perpendicular anisotropy in RE–TM alloy films. The atomic arrangement in amorphous films is only pseudorandom and may include slight chemical order in which some TM–TM or RE–TM pairs are oriented parallel or normal to the plane of the film. There appears to be experimental evidence for such an arrangement in TbFe films (Hufnagel *et al.* 1995) and good correlation between modifications of such an anisotropic local atomic arrangement on annealing with loss of magnetic anisotropy (Harris *et al.* 1993). Calculations of anisotropy from such arrangements suggest that only a few percent of atoms need be coupled in this way to promote perpendicular magnetization. The large anisotropies observed in some substituted TbREFe alloys may only be explained by a pair ordering mechanism, but the complete picture is not always clear.

Stress in thin films is related to the deposition process and deposition conditions, e.g., the argon pressure during sputtering and the substrate temperature. A change from compressive to tensile stress with increasing argon pressure has been observed in sputter-deposited RE–Fe. In general, RE–TM films deposited at ambient temperatures should not suffer much thermal stress due to mismatch of the expansion coefficients for the film and the substrate. Any residual stress will couple with magnetostriction and produce stress-induced anisotropy. Magnetostriction in Gd–TM alloys is relatively small at $\sim 10^{-6}$–$10^{-5}$, whereas measurements for TbFe and TbFeCo and TbDyFe films find values of $\sim 2 \times 10^{-4}$–$7.5 \times 10^{-4}$ (Williams and Grundy 1994). Clearly, in terbium-based alloys magnetostriction can play a significant role in providing stress-induced perpendicular anisotropy (Prados *et al.* 1997) and residual values of the order of $3 \times 10^4$ J m$^{-3}$ have been measured (Cheng *et al.* 1989).

PVD techniques, particularly sputter deposition, can create anisotropic microstructures in thin films, e.g., the well-known columnar structure, which are dependent on factors such as surface mobility in the growing film and the inclusion of sputtering gas. These factors appear to be mainly dependent on the argon pressure and substrate temperature during deposition and on any target bias. Thermalization of the sputtering process at higher pressures, the use of heavier sputtering gases, and reduced bombardment of the growing film lead to coarser microstructures. The maximum possible value for shape-induced anisotropy would be $0.5\mu_0 M_S^2$ or typically $10^3$–$10^4$ J m$^{-3}$, and in general this is not sufficient to support perpendicular magnetization. This model of anisotropy also does not fit with observations that the anisotropy can vary smoothly through the compensation point, where $M_S$ is zero or at least very small,

and that it reaches its largest values in dense, microstructurally featureless films.

### 6.2 Magnetic Oxides

Other candidates for MO recording that have been investigated are garnet and uniaxial ferrite films. In most cases films prepared on ambient temperature substrates are amorphous and must be crystallized to produce the magnetic mixed oxide. The deposition conditions and the subsequent nucleation and growth process on annealing affect the microstructure and magnetic properties of the film. Magnetic properties can also be tailored in cubic $RE_3Fe_2Fe_3O_{12}$ garnet films by substitution with particular ions; dysprosium typically enhances perpendicular anisotropy and bismuth and cerium substitutions improve the magneto-optic interaction.

Any perpendicular anisotropy in polycrystalline cubic films must originate in stress, growth-induced ordering, or microstructural inhomogeneities. Measured $K_{EFF}$ values for substituted garnet films can reach $\sim 5 \times 10^3\,J\,m^{-3}$ at the compensation temperature. Calculations of any stress-induced anisotropy from the thermal mismatch between film and substrate give values of this order. Such anisotropy values are relatively low but, coupled with reduced magnetization values near compensation, are sufficient to support perpendicular magnetization and reasonable coercivities.

Cubic and hexagonal ferrite films also have useful magneto-optic properties and can be prepared with perpendicular anisotropy. The intrinsic uniaxial magnetocrystalline anisotropy in hexagonal Ba,Sr–$Fe_{12}O_{19}$ ferrites of the order $5 \times 10^6\,J\,m^{-3}$ is sufficient to ensure $K_{EFF} > 0$ in (0001) textured polycrystalline films. The high anisotropy ensures high coercivities in films in which the value of $M_S$ can be controlled by substitution, typically cobalt, titanium, lanthanum, or zinc (e.g., Atkinson *et al.* 1994, Ogata *et al.* 1999). Cubic ferrites, e.g., $CoOFe_2O_3$ also have large intrinsic anisotropies that are a disadvantage in attempts to create a stress-induced preferred direction normal to the film plane.

### 6.3 Multilayer Films

In nanoscaled multilayered thin films the contribution of any surface anisotropy to the total anisotropy can become significant. Typical systems in which this is the case are Co,CoNi/X, where X can be Ni, Cu, Ru, Pd, V, Pt, and Au, and RE/TM multilayers such as Tb/Fe.

In the first group attention has focused on Co,CoNi/Pt,Pd multilayers for MO recording investigations. These systems have increased Kerr rotations at short wavelengths. A rough calculation for a Co/Pt multilayer using the values of $K_{MC}$ for f.c.c. cobalt (the cobalt layers in these systems are in the cubic phase), a value of $1400\,kA\,m^{-1}$ for $M_S$ and a typical value of $K_S$ of $0.5\,mJ\,m^{-2}$ in Eqn. (1) shows that the cobalt layers should be less than about 1 nm thick. A plot of any experimentally determined $K_{EFF}t_{Co}$ against $t_{Co}$ gives an intercept at $t_{Co} = 0$ of the surface anisotropy and the slope gives the volume contribution. Several sources of anisotropy may be present and it has been shown that magnetostrictive stress-induced anisotropy makes a significant contribution to the volume anisotropy in Co/Pd multilayers but not in Co/Pt multilayers (Umeda *et al.* 1996). In practice the cobalt layer is maintained below $\sim 0.4$ nm in the multilayers whereas the thickness of the platinum layer is not critical in affecting the effective anisotropy but values below 2 nm are usual.

The effective anisotropy of the multilayer can be affected by the growth conditions. The use of different substrates, the inclusion of underlayers, the use of different sputtering gases at different pressures, and different substrate temperatures have all been shown to affect the microstructure of multilayer films. A volume contribution can be obtained by a preferred texture, which is usually $\langle 111 \rangle$ in polycrystalline cubic films, and the surface contribution is dependent on the form and sharpness of the interfaces in the system. This fits well with the observation of improved $\langle 111 \rangle$ texture with underlayer thickness. Investigations of the effects of the sputtering gas show that thermalization of the deposition process and the reduction in bombardment of the growing film can increase interface roughness but lead to increased interface anisotropy (Carcia *et al.* 1993).

Other multilayer films explored for their anisotropic properties and their potential for MO recording investigations are RE/TM systems with the basic compositions Gd,Tb/Fe,Co (e.g., Jamet *et al.* 1996). For example, perpendicular anisotropy is observed in sputter-deposited Tb/Fe and Tb/Co multilayers, as in Co/Pt systems, when the thickness of the layers is below 1 nm or 2 nm. Again, the value of $K_{EFF}$ depends on the thickness of the TM layers and indicates the presence of a significant surface anisotropy. Typical values of $K_{EFF}$ can vary between $5 \times 10^4\,J\,m^{-3}$ for Tb/Co multilayers and $10^6\,J\,m^{-3}$ for Tb/FeCo.

However, these values can be dependent on the details of the coupling between the RE and TM layers and an additional property of these systems is that they can show antiferromagnetic coupling and ferrimagnetic ordering and a compensation temperature. This behavior can be tuned by varying the relative thicknesses of the two layers and also in proportion to the composition of the equivalent alloy. Magnetic spin reorientation effects also occur as a function of temperature, in which the system is dominated by the RE and TM magnetization in different temperature ranges as in homogeneous alloys. The crystal structure of the layers is also unusual in that for the thinner layers the RE and TM are amorphous but for thicker layers the TM is crystalline.

Exchange coupled layers are the basis of media for super-resolution MO storage techniques. Although not multilayers in the usual sense, temperature-dependent spin reorientations occur also in these bi- or trilayer structures that are used in the read-out process (e.g., Nishimura *et al*. 1996). The perpendicular anisotropy in the memory layer, e.g., TbFeCo, the mediating effect on exchange coupling of any intermediate layer, and the in-plane anisotropy in the read-out layer, e.g., GdFeCo, can clearly be controlled by adjustment of compositions for the required temperatures (Stavrou *et al*. 2000) (see also *Magneto-optic Recording: Overwrite and Associated Problems*).

### 6.4 Other Materials

The first requirement of a thin-film material for MO recording is significant magneto-optic activity at wavelengths of interest. As already made clear, the second requirement is perpendicular anisotropy that is sufficiently strong to maintain magnetization normal to the plane of the film. This first property has been the trigger for successful investigations of many metallic alloys, oxides, and composite materials but the second property has often not been realized. Several materials of the many that have been investigated can be addressed.

The relatively high Kerr rotations observed for CoPt alloys, rather than multilayers, has suggested their possible use as MO recording media. Growth on oriented platinum underlayers at temperatures $\sim$200–500 °C can result in films with a perpendicular $K_{EFF}$ greater than $10^6$ J m$^{-3}$ (Lin and Gorman 1992). Equiatomic CoPt films grown at $\sim$500 °C show ordered face-centered tetragonal (f.c.t.) and disordered cubic phases with $\langle 111 \rangle$ and $\langle 200 \rangle$ preferred orientations and $CoPt_3$ films grown at $\sim$200 °C are also f.c.t. The large effective anisotropies have been associated with the large $K_{MC}$ along the tetragonal *c*-axis that is oriented normal to the film plane (Iwata *et al*. 1999).

Alloys related to the Heusler alloys have very interesting MO properties. PtMnSb, with the $C1_b$ structure has a very large Kerr rotation of $\sim 2^\circ$ at 633 nm. This is related to its semimetallic nature and unusual band structure. Unfortunately the compounds have cubic symmetry and deposited films show in-plane anisotropy and low coercivities (Attaran and Grundy 1989, Carey *et al*. 1993). MnBi, MnSb, and related compounds, such as MnGaGe, have also been investigated for MO applications over many years but have not been adopted because, although their magneto-optic properties are very attractive, difficulties in thin-film fabrication and magnetic and structural instabilities make them unsuitable.

# Magnetic Levitation: Materials and Processes

Magnetic levitation is one of the most outstanding properties of superconductors, which in addition has launched the development of several electromechanical systems. The simplest experiment consists of a single permanent magnet levitating in a stable position over a superconducting pellet refrigerated with liquid nitrogen.

It is indeed the characteristic of stable levitation that gives rise to great interest in devices such as magnetic bearings, rotating machinery, linear transport systems, etc.

The axial vertical force of a permanent magnet over a superconductor stems from the flux exclusion associated with materials with high critical currents (Moon 1994). In this case, the following can be written:

$$\vec{F} = \int_V (\vec{M} \cdot \vec{\nabla}) \cdot \vec{B}_{\text{ext}} \, \mathrm{d}V$$

where $M$ is the magnetization of the superconductor, $B_{\text{ext}}$ is the magnetic field generated by the permanent magnet, and the integral is extended over the whole volume of the superconductor.

Therefore a body may magnetically levitate if the vertical gradient of the magnetic induction displays a positive $F_z$ component, which eventually overcomes the weight of the permanent magnet. From the superconducting material point of view, the generation of a large magnetization requires current loops shielding the magnetic field generated by the permanent magnet. According to the critical state model, a partial flux penetration occurs in which the flux gradient obeys the Ampere law $\mathrm{rot}\mathbf{B} = \mu_0 \mathbf{J}_c$, where $\mathbf{J}_c$ is the critical current of the superconductor. Hence, the magnetization of the superconductor increases only if $|\mathbf{J}_c|$ or the area of the corresponding current loop increases.

Consequently, applications based on the magnetic levitation phenomenon require large quasisingle-crystalline superconducting materials with high critical currents.

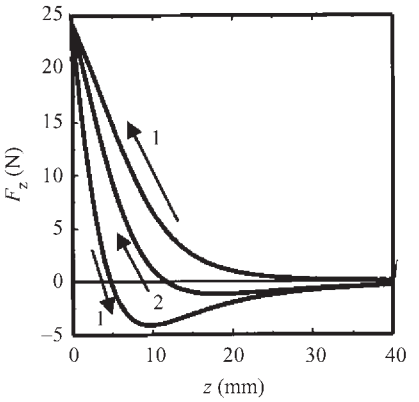

***Figure 1***
Hysteretic levitation force measured when a permanent magnet approaches a superconductor in a zero-field cooling process (1) for the first time and (2) after a whole cycle when some flux has been trapped in the superconductor.

An additional advantage of the high critical current density is the enhanced lateral and vertical stability, since magnetic stiffness is proportional to the pinning capability of the vortices penetrated within the superconductor. It must also be noted that because of the hysteretic nature of the magnetization of hard superconductors the magnetic levitation force will also be history dependent (Fig. 1). For instance, if the cooling of the superconductor is performed with the permanent magnet in close contact with the superconductor (field cooling procedure), an attractive force will be generated when retrieving it and, hence, the phenomenon of a stable magnetic suspension may also be obtained.

## *1. Superconducting Materials*

The development of practical applications based on magnetically levitating systems working at liquid nitrogen temperature requires the use of superconducting materials with high critical currents at the magnetic fields generated by high-power NdFeB or SmCo magnets ($B_r \approx 1$ T; see *Magnets: Sintered*).

Among the different high-temperature superconducting phases, that presenting the highest $J_c$ at 77 K is $YBa_2Cu_3O_7$ (Y-123), which displays an irreversibility line (the magnetic field where $J_c \approx 0$) at 77 K around 5–7 T. Also the isomorphous systems Re-123 (Re = Nd, Sm), which may have irreversibility lines as high as 10 T at 77 K, should be considered.

Also to be taken into account is the fact that the critical currents of cuprate superconductors are strongly anisotropic, the highest being those flowing within the *ab*-planes. For this reason, an optimized

material for magnetic levitation should have the *ab*-planes perpendicular to the vertical component of the magnetic field of the permanent magnet. In conclusion, the most appropriate materials for magnetic levitation are bulk quasisingle-crystalline $ReBa_2Cu_3O_7$ (Re = Y, Nd, Sm) pellets with *ab*-planes oriented parallel to the basal surface.

## 2. Processing of Bulk $ReBa_2Cu_3O_7$ (Re = Y, Nd, Sm)

The preparation of large-grain Y-123 ceramics is based on melt texturing processes. Essentially these techniques rely on a controlled crystallization from a semisolid state following the peritectic reaction $Y_2BaCuO_5(s)+3BaCuO_2(l)+2CuO(l) \rightarrow 2YBa_2Cu_3O_7$. The peritectic decomposition temperature of Y-123 occurs at $T_p \approx 1010\,^{\circ}C$, thus melt processing requires heating the samples at temperatures above $T_p$, typically 1040–1110 °C, and cooling them at a typical rate of $1\,mmh^{-1}$ in such a way that a single large grain may be grown.

The generation of single-grain Y-123 materials requires carrying out a directional solidification process where a selection of the nucleation centers is done and the conditions of a plane growth front are still maintained. Two techniques have been used successfully for this purpose: the Bridgman growth method where a temperature gradient is imposed (typically $10\,^{\circ}Ccm^{-1}$) and the top seeding growth (TSG) technique where the nucleation is generated at a crystalline seed while the homogeneous nucleation is avoided through a limitation of the degree of undercooling of the liquid.

The Bridgman technique appears to be more adapted to long ceramic shapes while the TSG technique enables one to grow large-diameter samples having the *ab*-planes oriented parallel to the basal surface. Thus, the TSG technique is the most suitable for preparing samples for magnetic levitation applications. The seeds that have been found to be chemically and structurally compatible with the high-temperature semisolid state are MgO and $ReBa_2Cu_3O_7$ (Re = Nd, Sm) single crystals. Re-123 crystals are preferred because they have a crystalline structure closer to that of the Y-123 phase. However, they have peritectic decomposition temperatures only 30–50 °C above that of Y-123 and thus they may display some solubility that has to be controlled.

Single-grain cylindrical materials with diameters up to 10 cm and the *ab*-planes oriented parallel to the basal plane have been grown based on this methodology. Levitation forces greater than 1676 N can be reached with a single SmCo permanent magnet with $B_r = 0.4\,T$, which corresponds to a magnetic pressure greater than $2.2 \times 10^{-3}\,m^2$ (Sawamura 1999).

In order to grow large domains it is essential to select a narrow temperature window where crystallization is initiated only at the seed and still providing enough driving force to the growth front. *In situ* optical observation of the growth process shows that a progressive decrease of the growth rate may occur, probably because of a change of the liquid composition (Gautier-Picard *et al.* 1997).

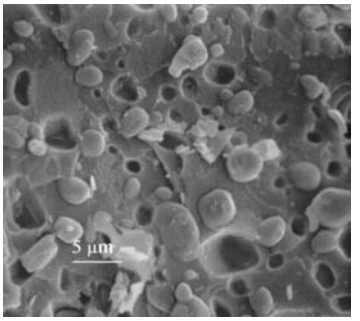

***Figure 2***
Scanning electron microscopy image of a $YBa_2Cu_3O_7/Y_2BaCuO_5$ composite where the Y-211 precipitates imbedded in the superconducting matrix can be observed.

Analysis and control of the microstructure of the single-domain material is essential, both to understand the growth process and to optimize the superconducting performance. Several additives are included in the green pellets to minimize the liquid loss and refine the final size of the Y-211 precipitates, which remain embedded in the matrix as a consequence of the sluggish character of the peritectic reaction. Platinum and $CeO_2$ particles are found to fulfill perfectly this second requirement by keeping the Y-211 particles in the submicrometer range, thus avoiding the coarsening of Y-211 particles in the semisolid state (Fig. 2).

The beneficial effects of the Y-211 precipitates are twofold: they increase the mechanical toughness and they enhance the critical currents that rise typically to $5 \times 10^4\,A\,cm^{-2}$ at 77 K and null field. A typical optimal composition of Y-123/211 ceramic tiles used for magnetic levitation would be 64% $YBa_2Cu_3O_7$ + 35% $Y_2BaCuO_5$ + 1% $CeO_2$.

Large batch processes of up to 30 samples having diameters of 40 mm have been demonstrated using quasi-isothermal furnaces with a good reproducibility of their performance. Thus there is no major limitation to scale-up of the TSG process to industrial production (Cardwell *et al.* 1998, p. 75, Ullrich *et al.* 1999).

Additionally, it is well known that the superconducting properties of the Y-123/211 composites may be strongly modified through changes of the microstructure (Sandiumenge *et al.* 1997). Postprocessing methodologies, such as oxygenation, isostatic pressing, or irradiation, show strong modification of the critical currents of Y-123/211 melt textured ceramics. For instance, an enhanced pinning capability with

$J_c \approx 10^5\,\mathrm{Acm}^{-2}$ at 77 K has been demonstrated through a cold isostatic pressing postprocessing treatment at 300 °C under 2 kbar of argon (Martinez *et al.* 1999). This process generates nanometric stacking fault loops that are very effective vortex pinning centers. Its potential relies in the enhanced levitation force that can be obtained in large-scale ceramic fabrication.

New effective flux pinning centers have also been generated in Re-123 (Re = Nd, Sm) materials displaying a large fishtail effect at 77 K. Actually, these materials form a solid solution, $Re_{1+x}Ba_{2-x}Cu_3O_{7+\delta}$, and the degree of Re substitution at the barium sites can be controlled through processing. When a small excess, in the region $x \approx 0.05$, is included there is a tendency to the formation of nanometric clusters where the local oxygen content is higher. These nanometric clusters have a decreased superconducting order parameter and consequently they become normal when a magnetic field is applied, thus becoming flux pinning centers at intermediate fields. The final concentration of neodymium excess and its pinning effectiveness is found to depend on the oxygenation pressure during the growth and postprocessing treatment (Puig *et al.* 1998).

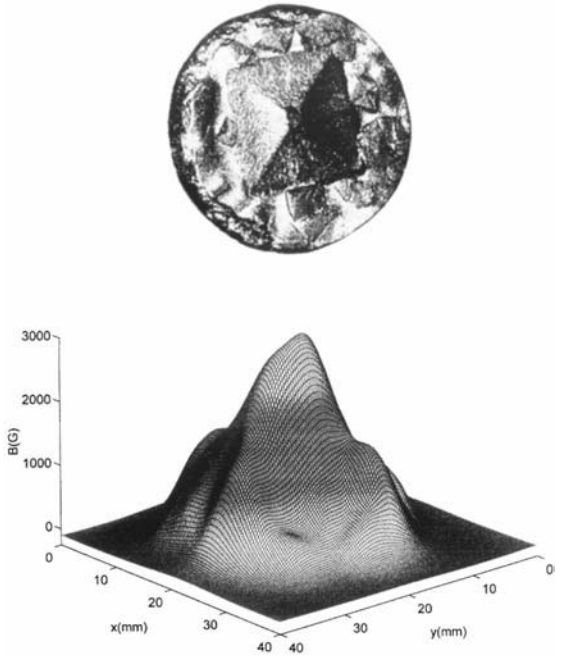

***Figure 3***
Micrograph of a $YBa_2Cu_3O_7$ pellet prepared by TSG and flux remanence profile of the superconducting cylinder after a partial penetration of magnetic flux in a zero-field cooling process. The observed asymmetries correspond to subgrain boundaries within a single domain.

The potential of Re-123 ceramic tiles for use in magnetic levitation or as trapped-field magnets appears to be very high; however, owing to the complexity of their phase diagrams the preparation process must be tightly controlled (Murakami 1998).

The most successful nondestructive testing methodologies of the final superconducting tiles are the measurement of the levitation force, which may be considered as an integral process, or the determination of the magnetic remanence flux profiles by means of Hall effect microprobes. In the latter case, it appears very easy to detect any remaining grain boundary or even subgrain boundaries and macroscopic compositional inhomogeneities (Fig. 3).

Demonstrations that bulk melt textured tiles may be integrated in real systems such as magnetic bearings, motors, flywheels, etc., continue. In this respect, the feasibility appears very promising of cutting, assembling, or even welding these materials for large-diameter rotors or the buildup of more complex shapes (Cardwell *et al.* 1998).

# Magnetic Levitation: Superconducting Bearings

Passive superconducting bearings are based on the stable levitation of a permanent magnet over a bulk superconductor. This stable levitation is due to the pinning of magnetic flux surrounding the permanent magnet on defects within the superconductor. The interest in superconducting bearings strongly increased since bulk, melt-textured $YBa_2Cu_3O_{7-x}$ (YBCO) is available, because this high-temperature superconductor exhibits large critical current densities at liquid nitrogen temperatures. Superconducting bearings can be used for rotating machines and for linear transportation systems. The main parameters of superconducting bearings as the levitation force and the magnetic stiffness will be discussed.

## 1. Levitation and Superconducting Magnetic Bearings

One of the most promising applications of bulk high-$T_c$ superconductors is the superconducting levitation which can be used in rotating superconducting magnetic bearings and in noncontact linear transportation. The advantage of superconducting magnetic bearings is that the levitation of a ferromagnetic permanent magnet over a bulk YBCO sample is completely passive. Contrary to this, no stable levitation is possible for two permanent magnets which interact via a $1/r^2$ force law the Earnshaw's theorem (Earnshaw 1842). Such an inverse square law is governed by the Laplace equation and allows only saddle-type equilibria resulting in unstable levitation. Therefore, conventional magnetic bearings composed of ferromagnetic permanent magnets require an active feedback control in order to stabilize the levitation. Inherently stable levitation can be achieved by introducing diamagnetic materials such as superconductors (Braunbeck 1939). The first superconducting bearing was developed for a small motor (Buchhold 1960) using low-temperature superconductors cooled with liquid helium. The interest in superconducting bearings strongly increased after the discovery of high-$T_c$ superconductors (HTSs), when levitation experiments could be done in open styrofoam containers filled with liquid nitrogen. Rotating HTS bearings are particularly interesting for cryogenic turbopumps, superconducting motors, high-speed centrifuges, and for flywheel energy storage systems, whereas linear HTS bearings can advantageously used for noncontact transport systems in clean rooms of microelectronic factories.

## 2. Materials Aspects: Bulk YBCO Superconductors

The material of choice for superconducting bearings is bulk YBCO. YBCO has a superconducting transition temperature of 92 K and a relatively high irreversibility field of $H_{irr} \sim 7$ T at 77 K for magnetic fields oriented parallel to the crystallographic $c$-axis. Applications are restricted to magnetic fields below $H_{irr}$, because the critical current density disappears at the irreversibility field $H_{irr} < H_{c2}$ with $H_{c2}$ as the upper critical field.

The levitation force of a superconducting bearing is proportional to the magnetization $M$ of the bulk superconductor which is given by $M = Aj_c d$, where $A$ is a constant, $j_c$ is the critical current density, and $d$ is the grain diameter. The trapped field properties and the critical current density of bulk, polycrystalline YBCO material with randomly oriented grains are strongly limited by its pronounced weak link behavior. Only very small currents are able to flow across the grain boundaries, especially if a magnetic field is applied. Weak links can be avoided by growing large grains using melt processing techniques. Several techniques have been found to be suitable for the growth of large single-domain YBCO material without high-angle grain boundaries (Murakami 1993, Krabbes *et al.* 1997).

In most cases, seed crystals (Sm-123 or MgO) are used in order to orientate the $c$-axis of the YBCO sample perpendicular to the plane surface of the sample. Large superconducting domains with a $c$-axis texture can be produced in this way. In the present state of the art, bulk, single-domain YBCO samples with diameters up to 10 cm can be produced.

## 3. Levitation Force

The most important feature of superconducting bearings is the levitation force between the superconductor and the permanent magnet. Other relevant properties of superconducting bearings are their stiffness and dynamic performance. Several reviews are available describing levitation forces and the application of superconducting bearings (Moon 1994, Hull 2000).

Stable levitation of a YBCO disk above a permanent magnet (see Fig. 1) can be achieved both from diamagnetic and flux pinning properties of the superconductor. The diamagnetic repulsive levitation is based on the flux exclusion and can be realized by cooling the superconductor below the superconducting transition temperature in a large distance from the permanent magnet. This is called zero-field cooling. In the case of YBCO, it is convenient to use liquid nitrogen as coolant. By reducing the distance between superconductor and permanent magnet, a

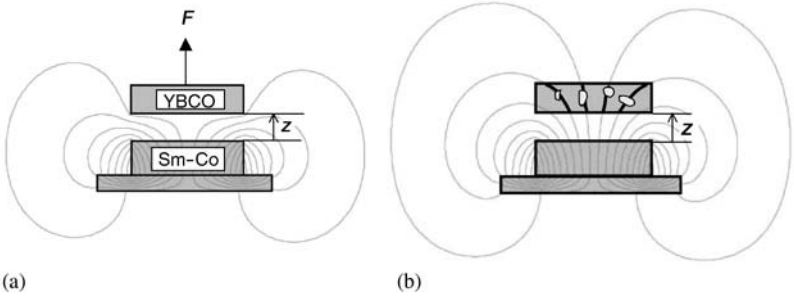

***Figure 1***
Superconducting magnetic bearing consisting of a YBCO disk and a permanent magnet. The iron plate below the permanent magnet is used to focus the magnetic flux on the superconductor. (a) Cooling of the YBCO disk in a large distance from the permanent magnet (zero-field cooling). If the distance is reduced, a repulsive force develops due to the diamagnetism of the superconductor. No magnetic flux penetrates the superconductor as shown by the magnetic field lines. (b) Cooling of the YBCO disk in a small distance from the permanent magnet (field cooling). The levitation force is based on the pinning of flux lines, i.e., by their interaction with defects within the superconductor.

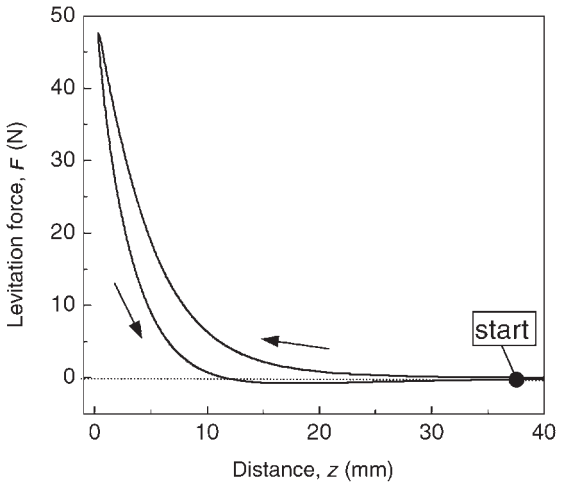

***Figure 2***
Vertical levitation force between a YBCO disk (diameter 25 mm) and an Sm–Co permanent magnet (diameter 25 mm) in dependence on the distance between superconductor and permanent magnet after zero-field cooling. The force is mainly repulsive. A very small attractive levitation force is observed only for increasing distance.

repulsive force develops. In Fig. 2, the vertical force between a YBCO disk (diameter 25 mm) and an Sm–Co permanent magnet (diameter 25 mm) is plotted against the vertical distance. The repulsive force increases as the magnet approaches the superconductor and reaches a maximum value for a small distance. The force at a given distance becomes smaller when the magnet is moved away from the superconductor. This hysteretic behavior can be explained by the penetration of magnetic flux into the superconductor. A small attractive force component develops due to flux pinning and reduces the repulsive force for increasing distance between superconductor and magnet.

The case of zero-field cooling is impractical for superconducting bearings in which superconductors and permanent magnets are assembled at 300 K. In this case, the superconductors are cooled to below $T_c$ in the presence of the magnetic field of the permanent magnets (field cooling). In type II superconductors discrete structures in the material, so-called flux lines, create paths for the magnetic flux. The motion of flux lines is prevented by their interaction with defects in the superconductor. Therefore, the field distribution of the permanent magnets is frozen within the superconductor. The pinning-assisted levitation after field cooling is generally more stable against displacements in the horizontal direction than the levitation after zero-field cooling. An example for the vertical force versus distance relation after field cooling is shown in Fig. 3. The force which is almost zero after field cooling becomes negative as the permanent magnet is moved away from the superconductor. This attractive force can be used for stable levitation via suspension, i.e., with the permanent magnet below the superconductor.

## *4. Upper Limit for the Bearing Pressure*

The levitation force of a superconducting bearing is enhanced with increasing magnetization of the superconductor, the latter being proportional to the critical current density $j_c$ and the diameter of a single-domain YBCO sample (see Sect. 2). The strong increase of the critical current density with decreasing temperature can be used to reach higher levitation

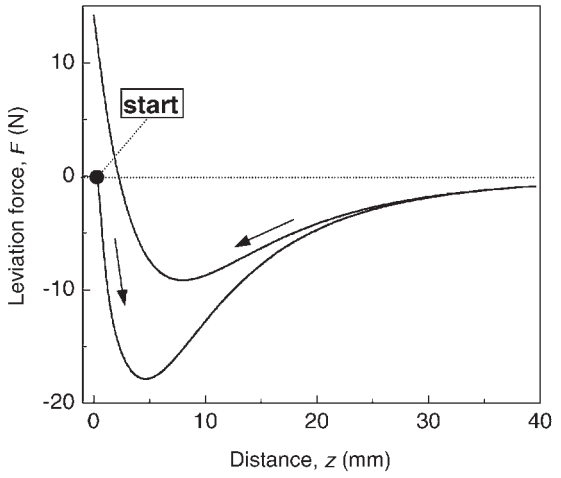

***Figure 3***
Vertical levitation force between a YBCO disk (diameter 25 mm) and an Sm–Co permanent magnet (diameter 25 mm) in dependence on the distance between superconductor and permanent magnet after field cooling. The levitation force is mainly attractive.

forces than at 77 K. However, the magnetization of the superconductor cannot exceed the magnetization value that is necessary to produce a diamagnetic image of the permanent magnet for zero-field cooling. The upper limit of the levitation force achievable for a given permanent magnet would be obtained for an ideal superconductor of infinite site and infinitely large critical current density that would perfectly shield the magnetic field of the permanent magnet. The resulting levitation force is equivalent to the interaction between the permanent magnet and its mirror magnet at zero gap and is given by (Teshima *et al.* 1996)

$$F_{\max} = AB_s^2/(2\mu_0) \tag{1}$$

where $A$ is the magnet pole face and $B_s$ is the surface field on the magnet face. By dividing this force by $A$ one obtains the bearing pressure

$$F_{\max}/A = B_s^2/(2\mu_0) \tag{2}$$

For a maximum field strength of $B_s = 0.5$ T, which is typical for good rare earth magnets, the maximum achievable bearing pressure is $F_{\max}/A = B_s^2/(2\mu_0) \approx 31\,\mathrm{N\,cm^{-2}}$. The experimental values for YBCO samples mentioned above achieve up to 70% of this upper limit. Much larger bearing pressures up to $5000\,\mathrm{N\,cm^{-2}}$ are expected if a superconducting permanent magnet with a trapped fields as high as 11 T would be used instead of a conventional permanent magnet. Such high trapped fields are available in bulk YBCO at temperatures $\sim$30 K (Gruss *et al.* 2001, Gonzales-Arrabal *et al.* 2002). The most important problem which has to be solved in order to utilize YBCO magnets for applications at temperatures lower than 77 K is to magnetize the superconductor. Pulsed magnetic fields can be used for magnetizing YBCO disks. However, large viscous forces act on the penetrating magnetic flux, especially in the case of short rise times ($\sim$1 ms) of the pulsed field. The heat generated by the rapid motion of magnetic flux strongly reduces the trapped field achievable at temperatures lower than 77 K. One possibility to overcome this problem is to increase the rise time of the pulsed field.

## 5. *Rotating HTS Bearings*

Simply designed thrust bearings (see Fig. 1) have an axial geometry, i.e., the bulk YBCO is assembled as a plane stator sandwiched by a permanent ring magnet which is connected to the rotor. However, the axial-type superconducting bearing has limitations with regard to the vertical levitation force $F_z$ and magnetic stiffness. The stiffness is defined as the change of the force for a small displacement of the permanent magnet from its initial position. In order to improve the stiffness one can replace the permanent magnet in Fig. 1 by a set of concentric permanent ring magnets. Nevertheless, especially the horizontal stiffness $\mathrm{d}F_x/\mathrm{d}x$ (for a displacement of the permanent magnet parallel to the superconductor) remains relatively small. In order to overcome these limitations, journal-type bearings have been developed (Kummeth *et al.* 2002, Schultz *et al.* 2002) in which a special arrangement of permanent magnets and iron disks leads to high magnetic gradients both in axial and radial direction. The bearing shown schematically in Fig. 4 consists of a YBCO hollow cylinder and stacks of permanent magnets and iron disks. Neighboring magnets in the YBCO hollow cylinder of the radial bearing are polarized in the opposite direction and separated by iron disks. In this way, the magnetic flux is focused on the gap between the magnets and guided in radial direction, generating a highly inhomogeneous field distribution within the superconductor. The large magnetic gradients obtained with such configurations result in high values of both radial and axial stiffness provided that the interface between the superconductor and the stack of magnets and iron disks is large enough. A radial stiffness of $160\,\mathrm{N\,mm^{-1}}$ was reported for such a bearing in which the YBCO hollow cylinder was 9 cm long and had an inner diameter of 4 cm (Schultz *et al.* 2002). The radial stiffness can be easily scaled up by increasing the radial dimension of the superconducting bearing. It is noteworthy that, independent of the bearing type, the horizontal stiffness $\mathrm{d}F_x/\mathrm{d}x$ after field-cooling is exactly half the vertical stiffness $\mathrm{d}F_z/\mathrm{d}z$.

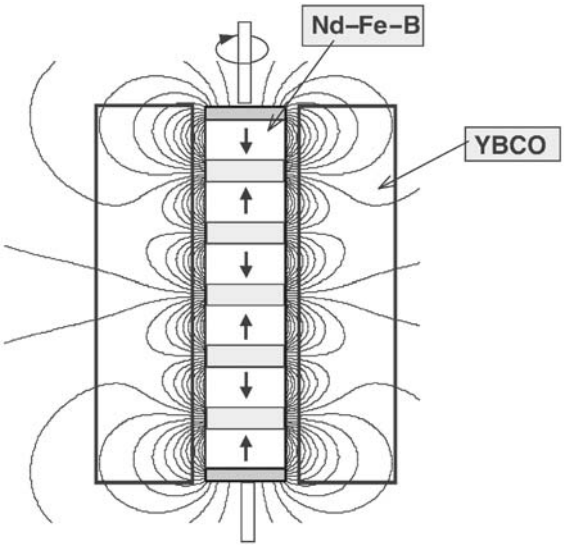

*Figure 4*
Schematic view of a superconducting magnetic bearing consisting of a YBCO hollow cylinder and a stack of Nd–Fe–B permanent magnets and iron disks (for details see text). The field distribution in the superconducting hollow cylinder after field cooling is shown. For the application in a rotating machine the YBCO hollow cylinder is held stationary, whereas the inner part with the magnets and iron disks is connected with the rotor of the machine.

## 6. Applications of HTS Bearings

Promising applications of rotating HTS bearings are cryogenic turbopumps, because in this case the cryogenic environment already exists. HTS bearings could replace the mechanical bearings of turbopumps which have very poor tribological properties at cryogenic temperatures. Of special interest are turbopumps (with HTS bearings) for liquid hydrogen which is considered as the fuel of the future. Another applications for which a cryogenic environment exists are superconducting reluctance motors in which large bulk YBCO pellets are used in the rotor in order to increase the energy density up to a factor of 2 (Oswald *et al*. 2003). High-speed centrifuges are another attractive application of HTS bearings. Prototype centrifuges designed with HTS bearings were successfully tested up to 30 000 rpm (Werfel *et al*. 2001). HTS bearings have a great potential to improve the performance of flywheels for energy storage. With HTS bearings the high-speed idling losses of flywheels can be drastically reduced to values of 0.1% per hour compared to 1% per hour for flywheels with conventional bearings. This would allow to construct flywheels with a 90% diurnal storage efficiency. In flywheels prototypes with HTS bearings, energies in the range of more than 1 kWh have already been stored (Nagaya *et al*. 2001).

Promising applications of linear HTS bearings are noncontact transport systems in clean-room environments of microelectronic factories, where the contactless motion would not create any wear debris, in track-bound individual traffic systems, or in elevators (Schultz *et al*. 2002).

## 7. Summary

The most promising application of bulk HTS is the development of HTS bearings utilizing the inherently stable levitation between the bulk HTS and permanent magnets. The main parameters of HTS bearings as the levitation forces and magnetic stiffness depend on the properties of superconductor and permanent magnet. Large melt-textured YBCO with high critical current densities are now available. As a result of the large progress in this field, the bearing pressure of modern HTS bearings, i.e., the levitation force divided by the area of the permanent magnet, is mainly limited by the surface field of the permanent magnet. HTS bearings operating at 77 K can be used in order to realize frictionless support in rotating machines (as flywheels for energy storage, superconducting motors, cryogenic pumps, high-speed centrifuges), and for frictionless linear transportation. The latter should allow transportation of extremely heavy objects which can no longer be moved by wheel systems, like concrete ports or moving bridges. Moreover, contactless transportation which does not create any wear debris can advantageously be used in clean rooms in the microelectronics industry.

## Magnetic Losses

The term magnetic losses generically refers to the various energy dissipation mechanisms taking place when a magnetic material is subject to a time-varying external field $H(t)$. As a consequence of the inherent irreversible nature of magnetization processes, part of the energy injected into the system by the external field is irrevocably transformed into heat. A case of particular interest is the one where the material is subject to a cyclic field of frequency $f$, with the field and the average magnetic induction $B$ in the material remaining colinear during the process.

Then the time integral

$$W = \int H \frac{\mathrm{d}B}{\mathrm{d}t} \mathrm{d}t \tag{1}$$

over one magnetization cycle gives the energy per unit volume transformed into heat in the cycle. This integral is usually termed *loss per cycle*, whereas the term *power loss* is used to denote the loss per unit time $P = fW$.

Simple expressions can be derived for $W$ when the equilibrium relationship between field and induction in the material is linear, $B = \mu H$, and the delayed response to time variations of the field is characterized by the single time constant $\tau$. Then, the loss per cycle under sinusoidal field can be expressed as

$$W = \frac{2\pi^2 \tau}{\mu} B^2 f \tag{2}$$

where $B$ represents the induction peak value in the cycle. Under these conditions: (i) hysteresis loops are elliptical—that is, the system response to the sinusoidal field is sinusoidal; and (ii) the loss per cycle is proportional to the frequency.

When the system is still linear but the dynamic response is controlled by multiple time constants, Eqn. (2) takes the more general form

$$W = \frac{\pi}{\mu} B^2 \mathrm{tg}\phi \tag{3}$$

where the parameter $\phi$, the so-called *loss angle*, measures the lag of the induction with respect to the field. The loss behavior is governed by the dependence of $\phi$ on frequency. In general, $\phi \to 0$ when $f \to 0$, i.e., the loss vanishes under quasi-static excitation, where the material response must reduce to the dissipationless linear law $B = \mu H$. In the particular case of Eqn. (2), $\mathrm{tg}\phi = 2\pi f \tau$.

Magnetic materials are inherently nonlinear hysteretic systems where strong deviations from the behavior described by Eqns. (2) and (3) are observed. The loss per cycle is a nonlinear function of frequency and the response to a sinusoidal excitation is usually heavily distorted. In addition, the loss depends not only on the magnetization frequency $f$ and the peak induction $B$, but also on the induction wave-shape, which means that losses under sinusoidal induction are in general different from losses under triangular induction at the same peak induction and frequency. International standards require that magnetic losses be measured under controlled sinusoidal induction rate and give detailed prescriptions about admitted methods and tolerances in the realization of the appropriate test conditions.

Various mechanisms are active during the magnetization process and can contribute to magnetic losses. Examples are the generation and decay of spin waves or acoustic waves, and, in metals, the decay by the Joule effect of the electric currents (eddy currents) induced by the induction changes in the material. These mechanisms are all activated by the motion of the domain walls separating different magnetic domains or by the large-scale instabilities accompanying the nucleation and annihilation of magnetic domains (see also *Magnets, Soft and Hard: Domains*). The chief problem in the study and application of magnetic materials is the prediction of the complex loss behavior observed in experiments in terms of these mechanisms.

Eddy current effects are dominant in metallic soft magnetic materials, where the principal magnetization process is just the eddy-current-damped motion

of magnetic domain walls. The loss figure is the fundamental quality parameter used to monitor material production and to select the materials best suited to particular applications. In the following sections, attention will be mainly focused on magnetic losses in metallic materials. Other loss aspects not discussed in this article arise in relation to magnetic after-effects (see *Magnetic Viscosity*) and resonance phenomena (see *Nuclear Magnetic Resonance Spectrometry*).

## 1. Loss Separation

The typical behavior of dynamic hysteresis loops and magnetic losses in a metallic soft magnetic material is shown in Figs. 1 and 2. The following points should be noted:

- the dynamic loops are far from elliptical, with shapes strongly dependent on frequency, peak induction, and material microstructure;
- the loop area $W$ is a nonlinear function of $f$, the nonlinearity being more pronounced at low frequency;
- the loop area $W$ tends toward a nonzero limit when the magnetization frequency is reduced toward zero: this value is referred to as (quasi)-static loss or hysteresis loss;
- the loss significantly increases above the quasi-static limit already at frequencies of a few Hz.

The physical picture underlying this complex behavior is clear in principle (Cullity 1972). A change of induction always accompanies the motion of a domain wall. Because of Faraday's law, this change gives rise to a rotational electric field **E** around the moving wall and consequently to an electric current density $\mathbf{j} = \sigma\mathbf{E}$ (eddy current), where $\sigma$ is the electrical conductivity of the material. Therefore, in any elementary volume $\Delta v$ of the material, the power $(|\mathbf{j}|^2/\sigma)\Delta v$ is dissipated through the Joule effect. The total loss is obtained by summing up these contributions over all elementary volumes. The result will depend on the space–time details of the eddy-current density $\mathbf{j}(\mathbf{r},t)$. This function will be as complicated as typical magnetic domain structures are, and a straightforward calculation of the loss by direct integration is impossible in the majority of cases.

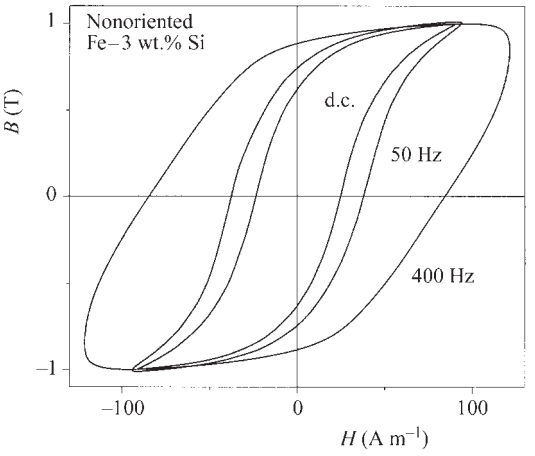

***Figure 1***
Typical dynamic hysteresis loops for a nonoriented Fe–3 wt.% Si lamination 0.35 mm thick, measured under controlled sinusoidal induction rate at a peak induction of 1 T and at different frequencies (quasi-static (d.c.), 50 Hz, 400 Hz).

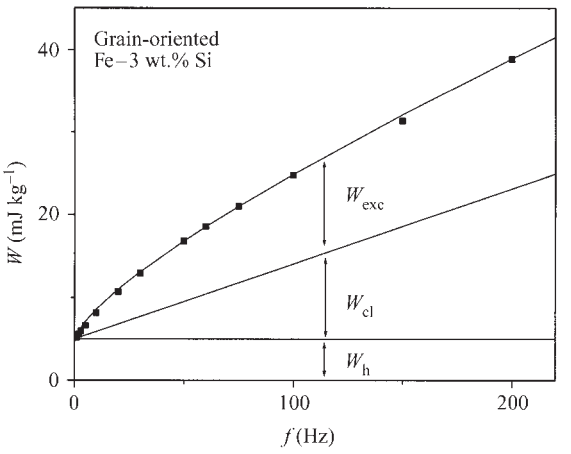

***Figure 2***
Loss per cycle and per unit mass as a function of frequency for a grain-oriented Fe–3 wt.% Si lamination 0.30 mm thick. The hysteresis ($W_h$), classical ($W_{cl}$), and excess ($W_{exc}$) loss components involved in loss separation are indicated (courtesy of Luciano Rocchino).

Given the complexity of the problem, in practice one looks for phenomenological laws summarizing in simple terms the regularities observed in experiments. Most useful in this respect is the concept of *loss separation*, according to which the total power loss $P$ at frequency $f$ is decomposed into the sum of three contributions, $P_h$, $P_{cl}$, and $P_{exc}$, termed *hysteresis loss, classical loss*, and *excess loss*, respectively (see Fig. 2), such that

$$P = P_h + P_{cl} + P_{exc} \tag{4}$$

This deconvolution reflects the existence of three scales in the magnetization process: the scale set by the specimen geometry (classical loss), the scale of domain wall-pinning mechanisms (hysteresis loss), and the scale of magnetic domains (excess loss). Given the complex, strongly nonlinear character of the magnetization process, there is no obvious reason why the superposition law expressed by Eqn. (4) should hold true under broad conditions. In fact, it is

only by applying statistical methods to the analysis of stochastic magnetization processes that one is able to show that the three scales just mentioned affect the loss in an approximately statistically independent way (Bertotti 1998).

### 1.1 Classical Loss

The classical loss is the loss calculated from Maxwell equations for a perfectly homogeneous conducting medium, that is, with no structural inhomogeneities and no magnetic domains (Bozorth 1993). The scale relevant to the classical loss is the scale set by the system geometry—for example, in a lamination, the slab thickness $d$. This scale controls the boundary conditions for Maxwell equations, which in turn determine the distribution of eddy currents in the specimen cross-section and the ensuing Joule dissipation. The classical loss acts as a sort of background loss, present under all circumstances, to which other contributions are added when structural disorder and magnetic domains play a role. By solving Maxwell equations, one finds that the classical loss takes the form

$$P_{cl} = \frac{\pi^2 \sigma d^2}{6} (Bf)^2 \quad (\mathrm{W\ m^{-3}}) \tag{5}$$

when it is calculated for a lamination of thickness $d$ and electrical conductivity $\sigma$, magnetized at the frequency $f$ and at the peak induction $B$. As mentioned before, the loss does depend on the induction waveform even when $f$ and $B$ are fixed. Equation (5) is valid under sinusoidal induction. The minimum loss is attained under triangular induction (i.e., constant $\mathrm{d}B/\mathrm{d}t$ in each magnetization half-cycle). In that case, the coefficient $\pi^2/6$ is reduced to 4/3.

Equation (5) contains no parameter describing the magnetization law of the material. All materials behave in the same way if their geometry and their electric properties are the same. This remarkable simplification derives from the fact that Eqn. (5) is actually a low-frequency limit, valid only when the induction rate $\mathrm{d}B/\mathrm{d}t$ is approximately uniform throughout the lamination thickness. With increasing frequency, this is no longer the case. The magnetic field produced by eddy currents, being opposed to the external field, tends to inhibit magnetization reversal in the interior of the lamination. This eddy-current shielding effect yields deviations from Eqn. (5) that depend on the magnetization law of the material (Mayergoyz 1998). In the case of a linear magnetization law, $B = \mu H$ and in the limit of heavy shielding, i.e., $\sigma \mu d^2 f \gg 1$, instead of Eqn. (5) one obtains

$$P_{cl} = \frac{\pi^{3/2}}{2} \sqrt{\frac{\sigma d^2}{\mu}} B^2 f^{3/2} (\mathrm{W\ m^{-3}}) \tag{6}$$

In a silicon steel lamination with $\sigma \cong 2\ 10^{-6} \Omega^{-1} \mathrm{m}^{-1}$, $\mu/\mu_0 \cong 2 \times 10^3$ ($\mu_0 = 4\pi \times 10^{-7} \mathrm{TmA}^{-1}$ is the permeability of the vacuum), and $d \cong 3 \times 10^{-4}$m, one finds that $\sigma \mu d^2 f \cong 1$ at frequencies $f \cong 2$ kHz. Conversely, whenever field amplitudes much larger than the material coercive field are involved, it may be appropriate to approximate the magnetization law of the material by a step function, jumping between opposite values of maximum induction when the field changes sign. Under these conditions, the loss takes the value

$$P_{cl} = \frac{\pi^2 \sigma d^2}{4} (Bf)^2 \quad (\mathrm{W\ m^{-3}}) \tag{7}$$

This expression is simply 3/2 times the low-frequency limit of Eqn. (5).

### 1.2 Hysteresis Loss

Hysteresis losses are the consequence of the fact that on the microscopic scale the magnetization process proceeds through sudden jumps of the magnetic domain walls that are unpinned from defects or other obstacles by the pressure of the external field (see also *Magnetic Hysteresis*). The local eddy currents induced by the induction change accompanying the wall jump dissipate a finite amount of energy through the Joule effect.

The sum over all jumps gives the hysteresis loss associated with the jump sequence. The jumps are so short (of the order of $10^{-8}$–$10^{-9}$ s) that the external field is unable to influence the internal jump dynamics. The only effect of the field is to compress or expand the time interval between subsequent jumps in inverse proportion to the field rate of change, which yields a number of jumps per unit time and an amount of energy dissipated per unit time proportional to the magnetization frequency. Therefore, for the hysteresis loss in a loop of peak induction $B$, one obtains the typical expression

$$P_h = 4 k_{hyst} B^{\alpha} f \tag{8}$$

The loss per cycle $W_h = P_h/f$ is thus independent of frequency (see Fig. 2). The parameter $k_{hyst}$ and the exponent $\alpha$ include the structural aspects affecting domain wall pinning and magnetization reversal. Their value will differ from material to material. The rule $\alpha = 1.6$ has been claimed to have some general validity and is known in the literature as Steinmetz law (Bozorth 1993).

The hysteresis loss is intimately related to the structural disorder in the material. Possible sources of domain wall pinning are interstitials, nonmagnetic or less-magnetic inclusions, voids, or dislocations. At a higher level of complexity, dislocation tangles and grain boundaries play a role. In amorphous alloys, fluctuations of local exchange and anisotropy should be taken into account, but often, in all cases where magnetostriction is not negligible, magnetoelastic coupling to randomly distributed internal stresses

dominates. Finally, in thin ribbons, surface roughness may be a substantial source of pinning effects.

### *1.3 Excess Loss*

Excess losses arise from the existence of a third relevant scale in the magnetization process, the scale of magnetic domains. The excess loss results from the smooth, large-scale motion of domain walls across the specimen cross-section, when the fine-scale jumps responsible for the hysteresis loss are disregarded. Eddy currents tend to concentrate around the moving domain walls, a fact that gives rise to losses higher than the classical ones because of the quadratic dependence of the local loss $(|\mathbf{j}|^2/\sigma)\Delta v$ on the intensity of the eddy-current density (Williams *et al*. 1950, Pry and Bean 1958).

According to the picture just described, excess losses are expected to be as ubiquitous as the presence of magnetic domains. However, the importance of excess losses in comparison with classical and hysteresis losses will substantially depend on the size and arrangement of magnetic domains. As a general rule, the finer the domain structure, the smaller the excess loss contribution. This conclusion can be given a precise quantitative measure in the case of a lamination of thickness $d$ containing longitudinal bar-like magnetic domains of random width (Bishop 1976). In this case, Maxwell equations can be exactly solved, giving the result

$$P_{exc} = \left(\frac{48}{\pi^3}\sum_{odd\ n}\frac{1}{n^3}\right)\frac{2L}{d}\,P_{cl} \cong 1.63\,\frac{2L}{d}\,P_{cl} \qquad (9)$$

where $2L$ represents the average domain width and $P_{cl}$ is given by Eqn. (5). Equation (9) identifies the ratio $2L/d$ as the relevant parameter of the problem. The excess loss is proportional to $2L/d$ and becomes negligible with respect to the classical loss when the domain width is much smaller than the lamination thickness.

This prediction is helpful in the interpretation of losses in grain-oriented silicon steels, where domain structures are often not far from the one assumed in the model. However, one should not forget that the regular arrangement of longitudinal domains assumed in the model can be far from the conditions encountered in ordinary materials. In many cases, the domain size is no longer itself the important parameter, because microstructural features introduce additional characteristic lengths (e.g., grain size, fluctuation wavelength of residual stresses, etc.) that tend to control the loss problem.

In these more complex cases, the excess loss approximately follows a law of the type (Bertotti 1998)

$$P_{exc} = k_{exc}\sqrt{\sigma}(Bf)^{3/2} \quad [\mathrm{W\ m^{-3}}] \qquad (10)$$

where the parameter $k_{exc}$ includes the effect of the various relevant microstructural factors. Equation (10) applies to grain-oriented silicon steels too, a fact that should not be interpreted as a contradiction with respect to Eqn. (9). The point is that the ratio $2L/d$ in Eqn. (9) is unknown. In particular, there is no reason why this ratio should be a constant of the material. In fact, one finds that the average magnetic domain size decreases when the magnetization frequency is increased, through the nucleation of additional domains. This domain multiplication process, together with other dynamic effects—particularly domain wall bowing (Carr 1976)—makes the dependence of losses on frequency weaker than the quadratic one of Eqn.(9) and eventually yields a loss law of the form of Eqn. (10).

### *1.4 Factors Affecting the Total Loss*

According to the previous analysis, an approximate expression for the total power loss, valid at frequencies low enough to avoid the onset of important eddy-current shielding, is

$$P \cong 4k_{hyst}B^{\alpha}f + \frac{\pi^2\sigma d^2}{6}(Bf)^2 + k_{exc}\sqrt{\sigma}(Bf)^{3/2} \quad (\mathrm{W\ m^{-3}}) \qquad (11)$$

Classical losses depend on the combination $\sigma d^2$, which shows that the losses are smaller the smaller the electrical conductivity and the lamination thickness. Magnetic cores of machines and devices are never made of bulk material for this reason. On the other hand, one of the factors that favored the introduction of silicon steels was just the fact that the addition of a few percent of silicon strongly reduces the electrical conductivity without substantially changing the other magnetic properties.

The hysteresis loss is independent of the electrical conductivity $\sigma$. The amount of energy dissipated in individual wall jumps is determined by the height of the energy barrier created by the pinning obstacle. A change in the conductivity would alter the typical velocity attained by the domain wall during the jump, but not the amount of energy eventually dissipated as heat. The hysteresis loss is also expected to be fairly independent of the lamination thickness when pinning effects are volume effects. The situation is different when the surface of the lamination also acts as a relevant pinning source. In this case, the hysteresis loss increases when the lamination thickness is reduced.

Equation (11) applies to the particular case of a material magnetized under controlled sinusoidal induction rate. However, there are several situations where magnetic materials operate under distorted flux conditions, for which a generalization of Eqn. (11) is needed. This generalization is obtained

by calculating the instantaneous power loss at individual points of the magnetization cycle and then by carrying out the time average over the particular wave-shape involved. This more general expression reads (Fiorillo and Novikov 1990)

$$P \cong P_h + \frac{\sigma d^2}{12}\overline{\left[\frac{dB}{dt}\right]^2} + k'_{exc}\sqrt{\sigma}\overline{\left|\frac{dB}{dt}\right|^{3/2}} \quad [\mathrm{W\ m^{-3}}] \qquad (12)$$

where the bars indicate time averaging over the magnetization cycle. The hysteresis loss is independent of the induction wave-shape, provided the induction is monotone in each magnetization half-cycle (no generation of inner hysteresis loops during the cycle).

## 2. Loss Behavior in Different Magnetic Materials

The dependence of losses on frequency and induction results from the combination of the three terms of Eqn. (11). The final behavior can be rather different from material to material, depending on the relative contribution of the various loss components to the total loss (Bertotti 1988) (see Fig. 3). When the objective is loss reduction, it is vital to identify the loss term giving the dominant contribution under the working conditions of interest and then to develop optimization strategies for the magnetization scale associated with that term. Metallurgical factors, structural optimization, and control of domain structures play a role in these optimization strategies.

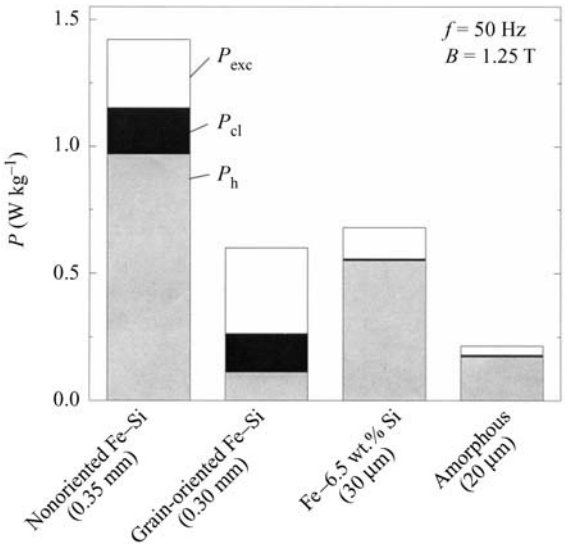

***Figure 3***
Examples of loss separation in different classes of soft magnetic materials, at 50 Hz magnetization frequency and 1.25 T peak induction.

### 2.1 Iron and Low-carbon Steels

Low-carbon steels, with a typical carbon content from 0.005 to 0.1 wt.%, are used as low-grade, low-cost materials for magnetic cores where magnetic losses are not the major concern and acceptable performance at low price is the main goal. This is reflected in the fact that these materials are usually produced as fairly thick laminations (typical thickness ranges from 0.5 to 0.85 mm) which causes substantial classical losses. The presence of carbon yields important aging effects, i.e., a progressive increase of the hysteresis loss over time. This is due to the formation of cementite precipitates, which act as additional domain wall pinning centers. Materials with improved loss properties are obtained by purification processes, which reduce the carbon, nitrogen, and sulfur content, or by the introduction of some silicon (up to 1 wt.%). When no particular purification processes are carried out and the silicon content is negligible, total losses take values of the order of $15\,\mathrm{W kg^{-1}}$ at 1.5 T and 60 Hz in laminations 0.5 mm thick. The addition of about 1 wt.% Si accompanied by better composition control can lower the loss to less than $8\,\mathrm{W kg^{-1}}$. Very clean ultra-low-carbon steels can reach loss figures as low as $4\,\mathrm{W\,kg^{-1}}$ at 1.5 T and 50 Hz in 0.5 mm laminations.

### 2.2 Silicon Steels

Silicon steels are iron-based materials where a few percent of soluble elements, like silicon or aluminum, are deliberately introduced. The addition of silicon causes a substantial increase in the electrical resistivity, with a consequent decrease in classical and excess losses. In addition, silicon alloying yields a decrease in the magnetocrystalline anisotropy constant, which results in a decrease in the hysteresis loss. The main limitation to excessive addition of silicon comes from the progressive reduction of the saturation magnetization and the increase in brittleness of the material (see also *Steels, Silicon Iron-based: Magnetic Properties*).

Silicon steels are divided into two main categories: nonoriented steels and grain-oriented steels. Nonoriented steels are characterized by an approximate isotropic grain structure. This makes them suitable for all those applications where fairly isotropic magnetic properties are needed. The silicon concentration ranges from about 1 to 3.7 wt.%. Some aluminum and manganese is also added to achieve higher electrical resistivity with no detrimental effects on the mechanical properties. The top-grade materials have about 4 wt.% Si + Al and exhibit losses of $2.1–2.3\,\mathrm{W kg^{-1}}$ at 1.5 T and 50 Hz in laminations 0.35–0.50 mm thick. Materials with improved losses are developed by a careful control of impurity content, grain size, crystallographic texture, surface state, and residual stresses. Impurities like carbon,

nitrogen, sulfur, and oxygen contribute to increasing hysteresis losses, because they form precipitates that act as pinning centers on moving domain walls. They also have an indirect detrimental effect, because they hinder grain growth and negatively affect the formation of favorable textures. Finally, the control of grain size is important. The hysteresis loss is a decreasing function of the average grain size $s$, and usually follows a law of the type $P_h \cong a + b/s$, where $a$ and $b$ are material-dependent constants. Conversely, the excess loss is an increasing function of $s$, of the type $P_{exc} \cong ks^{\beta}$, with $\beta \sim 1/2$. As a result, the total loss has a minimum for a particular grain size. Material manufacturers try to obtain materials with optimal loss performance by appropriate grain-growth treatments. The optimal grain size is of the order of 150 μm at 1.5 T and 50 Hz.

Contrary to nonoriented steels, grain-oriented steels are characterized by strongly anisotropic properties. These materials contain between 2.9 and 3.2 wt.% Si. As the result of highly sophisticated metallurgical processes of selective grain growth, a grain-oriented lamination is characterized by a particular texture, known as Goss texture, in which all the crystal grains have one of their [001] axes close to the lamination rolling direction. This fact, together with the large grain size of these materials (in the millimeter–centimeter range) and the low impurity content yields hysteresis losses about one order of magnitude lower than those typical of nonoriented steels, when the lamination is magnetized along the rolling direction. Grain-oriented steels are further subdivided into conventional grain-oriented (CGO) and high-permeability grain-oriented (HGO) materials.

The main difference is the more accurate texture control realized in HGO materials which yields better loss performance. In CGO steels, the lamination thickness ranges from 0.35 to 0.23 mm and the loss accordingly ranges from 1.4 to 1.15 $\mathrm{Wkg^{-1}}$ at 1.7 T and 50 Hz. In HGO steels, the lamination thickness ranges from 0.30 to 0.23 mm and the loss from 1.05 to 0.80 $\mathrm{Wkg^{-1}}$ at 1.7 T and 50 Hz. The more refined texture control of HGO materials is reflected in the magnetic domain structure. In fact, the nearly perfect grain orientation yields very regular structures of wide longitudinal bar-like domains, quite similar to the ones assumed in the calculation of Eqn. (9). The regularity of the domain structure and the material perfection (very low impurity content and lack of grain boundary effects because of the large grain size) give a very low hysteresis loss. However, as shown by Eqn. (9), the excess loss may attain substantial values when wide domains are present ($2L/d \gg 1$).

For this reason, methods aimed at artificially reducing the domain size without altering the hysteresis loss have been developed. Two of them are of particular interest:

- deposition of a coating on the lamination surface that exerts a tensile stress of 2–10 MPa on the material. The stress introduces a magnetoelastic energy contribution that alters the energy balance in the material and favors the formation of smaller magnetic domains;
- scribing of the lamination surface by one among many possible techniques (mechanical scratching, laser irradiation, plasma jet scribing, or etch pitting). Scribing alters the magnetoelastic and magnetostatic energy content of the lamination in a way that again favors the formation of smaller domains.

The power loss at 1.7 T and 50 Hz is as low as 0.80 $\mathrm{Wkg^{-1}}$ in coated, scribed laminations of 0.23 mm thickness.

### 2.3 *Rapidly Solidified Materials*

Soft magnetic materials can be prepared as very thin ribbons by means of rapid solidification methods, in particular by planar-flow-casting. The resulting ribbons have variable width (up to 20 cm and more) and a thickness of 10–100 μm. The reduced thickness inhibits classical losses (see Fig. 3) and makes these materials suited to high-frequency applications, where classical losses play the most detrimental role. On the other hand, rapid solidification permits the preparation of materials in a variety of quenched metastable states not present in the equilibrium phase diagram, which display a broad range of interesting magnetic and mechanical properties.

Amorphous ribbons, lacking long-range atomic order, are prepared by rapid solidification of alloys containing around 80 at.% transition metals and 20 at.% metalloids (B, Si, P, C). The lack of atomic order yields electrical resistivities two to three times larger than the corresponding crystalline alloy (typical values are in the range 120–140 $10^{-8}\,\Omega$m), with important benefits for losses. At the same time, atomic disorder leads to a random distribution of local magnetic anisotropy, which is averaged to zero over the typical distances involved in magnetization processes, a fact that yields magnetic softness and low hysteresis loss. Magnetic softness is further enhanced in materials with vanishing magnetostriction, because the absence of magnetoelastic coupling eliminates the pinning action of internal stresses. In $Fe_{78}B_{13}Si_9$ amorphous ribbons 25 μm thick, power losses attain values around 0.25 $\mathrm{Wkg^{-1}}$ at 1.4 T and 50 Hz. Of this, the main contribution comes from the hysteresis component (compare Fig. 3). A similar behavior is exhibited by nanocrystalline materials (grain dimension of the order of 10 nm) obtained by suitable annealing of amorphous materials of appropriate composition ($Fe_{73.5}Cu_1Nb_3Si_{13.5}B_9$ in so-called Finemet materials) (see also *Amorphous and Nanocrystalline Materials*).

Rapidly solidified Fe–6.5 wt.% Si materials exhibit a favorable combination of high resistivity, low magnetocrystalline anisotropy, and vanishing magnetostriction, which contribute to lowering losses. Materials

with this composition cannot be prepared by rolling techniques because of material brittleness. This drawback is circumvented by rapid solidification. Ribbons with thicknesses between 30 and 100 μm can be prepared. Power losses are lower than 15 $Wkg^{-1}$ at 1 T and 1 kHz, which compares favorably with other materials for medium-frequency applications.

### 2.4 Nickel–Iron Alloys

Nickel–iron alloys are of particular interest because a broad variety of qualitatively different magnetic properties can be obtained by adjusting the composition and the preparation process. There are no restraints to rolling so it is possible to obtain good laminations with thickness down to 10–20 μm, with great benefits for classical losses. Both the crystal anisotropy and the magnetostriction cross the zero value for compositions around 80 wt.% Ni. Treatments on materials with approximately this composition (and the deliberate introduction of other elements like Mo, Cu, and Cr) yield materials with extremely low hysteresis losses (coercive field less than 1 $Am^{-1}$), and a variety of hysteresis loop shapes controlled by induced anisotropy. The combination of low hysteresis losses and low classical losses makes these materials most suited to applications at high frequencies.

### 2.5 Soft Ferrites for High-frequency Applications

Most applications at high frequency, up to the 100 MHz region, make use of soft ferrites, because their nonmetallic nature precludes eddy current dissipation. In most applications, mixed Mn–Zn or Ni–Zn ferrites are employed, in which it is possible to tailor the material properties to specific applications by tuning the concentration of the component atoms. The electrical resistivity is of the order of $10^7$ Ωm in Ni–Zn ferrites and $10^{-2}$–10 Ωm in Mn–Zn ferrites. The initial susceptibility is constant and the loss angle (see Eqn. (3)) is negligible up to frequencies of some MHz for Mn–Zn ferrites and 100 MHz for Ni–Zn ferrites (see also *Ferrites*).

## 3. Conclusions

In metallic materials, magnetic losses exhibit a remarkably complex phenomenology. Although the physical loss mechanism is in principle clear (Joule effect associated with the eddy currents induced by domain wall motion), the details depend on the space–time eddy current distribution $\mathbf{j}(\mathbf{r}, t)$, which is as complicated as typical magnetic domain structures are in ordinary materials. Of central importance to the treatment of the loss behavior is the concept of loss separation, according to which the total loss is broken down into the sum of three distinct contributions: classical, hysteresis, and excess loss. Each of these contributions is related to processes occurring in different spatial scales and has a distinct dependence on magnetization frequency, peak induction, and microstructure. Therefore, the crucial step in any loss optimization strategy is to clarify which of the three loss terms gives the dominant contribution and modify appropriately the microstructural or geometrical conditions affecting the magnetization process on that particular scale.

# Magnetic Materials: Domestic Applications

Hard magnetic materials or permanent magnets, and soft magnetic materials are fundamental to the technological success of many devices and products, in particular electric machines and related devices (see Fig. 1). In modern industrialized western economies

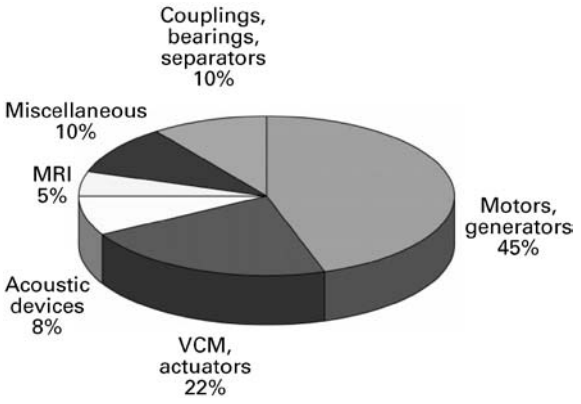

*Figure 1*
Expected application of $Nd_2Fe_{14}B$ in Europe for 1995 (Krebs 1995).

the electric motor is ubiquitous and consumes 40–45% of all electrical energy generated. Most of this energy is consumed by large industrial electric drives, but nonetheless an increasing proportion is consumed by small electric motors used in domestic appliances, for example, in refrigerators which operate continuously. Regardless of the motor application there is pressure to improve electric motor efficiency as people and governments become more aware of the consequences of global warming, due to the emission of the greenhouse gas, $CO_2$, from large coal-fired power stations.

Electric motors are present in many household products (for the purposes of this section "domestic" is defined as any product that is found in the home). Products containing electric motors can be grouped according to their domestic application area and a list, by no means exhaustive, includes: laundry—washing machine and clothes dryer; kitchen–dishwasher, microwave oven, fan-forced convection oven, refrigerator, food blender, electric knife, garbage disposal unit, mixmaster, etc; bathroom—hairdryer, electric tooth brush, hair clippers, electric shaver, etc; entertainment—videorecorder, CD player, hi-fi system, camcorder, walkman, camera, etc; home study—personal computer, printer, photocopier, facsimile machine, etc; general household—vacuum cleaner, exhaust fans, ceiling fans, swimming pool and spa pumps, air-conditioner, fans in gas and electric heating systems, etc; and garage—electric drills, saws, routers and grinders, electric screwdriver, electric lawn mower, edge clipper, garden shears, garage door/gate opener, etc.

Some products or appliances may contain as many as four or five individual motors, for example, a camcorder, and where there is a motor there is likely to be power and control electronics, for example, a switch-mode power supply that incorporates magnetic components. Not included in domestic appliances is the family automobile, which may contain up to 40 or even more electric motors. The use of magnetic materials is not just confined to motors, as they are used in speakers in televisions and hi-fi systems, holding devices, water-meters, watt-hour meters and fluorescent lighting ballasts.

## 1. Motor Technology

A conventional brushed d.c. electric motor can be viewed as having three key components: a field system, which usually consists of a winding around teeth on a stator yoke; an armature, consisting of a series of coils wound in slots on a rotor; and a commutator, for making the electrical connection to the armature coils (Hamdi 1994). The stator and armature laminations are made from a soft magnetic material, usually low-loss silicon steel laminations, and are part of the magnetic circuit which carries and guides the magnetic flux in the machine. In a permanent magnet machine the field system uses permanent magnets rather than producing the field by passing current through coils.

The replacement of the wound field system by permanent magnets results in a significant improvement in motor efficiency, as no electrical energy is used in field production. The motor can then be turned inside-out with the field magnets being attached to the rotor, a multiphase armature winding on the stator, and the commutator replaced by electronic switching devices which switch the current through the stator windings (see Fig. 2). This configuration has the advantage of improved thermal performance, as improved cooling is obtained by having the high-current stator winding in good thermal contact with the motor case. Motors of this type are known as permanent magnet brushless d.c. motors or just brushless d.c. motors (Hughes 1993, Gieras and Wing 1997).

Modern permanent magnet brushless d.c. motors have the advantages of high torque or power per unit volume, improved efficiency, better dynamic response (due to the low inertia of the rotor), reduced volume, reduced weight, mechanical simplicity and reliability (as there are no brushes or commutator), and quiet operation (Hanitsch 1989). These improvements did not happen overnight, but are the result of advances in materials science over the past 30 years, particularly the development of rare-earth permanent magnets ($Sm_2Co_{17}$ and $Nd_2Fe_{14}B$) (see *Rare Earth Magnets: Materials*), and new soft magnetic materials, such as amorphous or glassy metals (see *Amorphous and Nanocrystalline Materials*). In parallel with these developments in materials science there have been major advances in magnetic circuit design, using computational methods based on finite-element techniques, and a revolution in semiconductors, resulting in low-cost microprocessors and digital signal

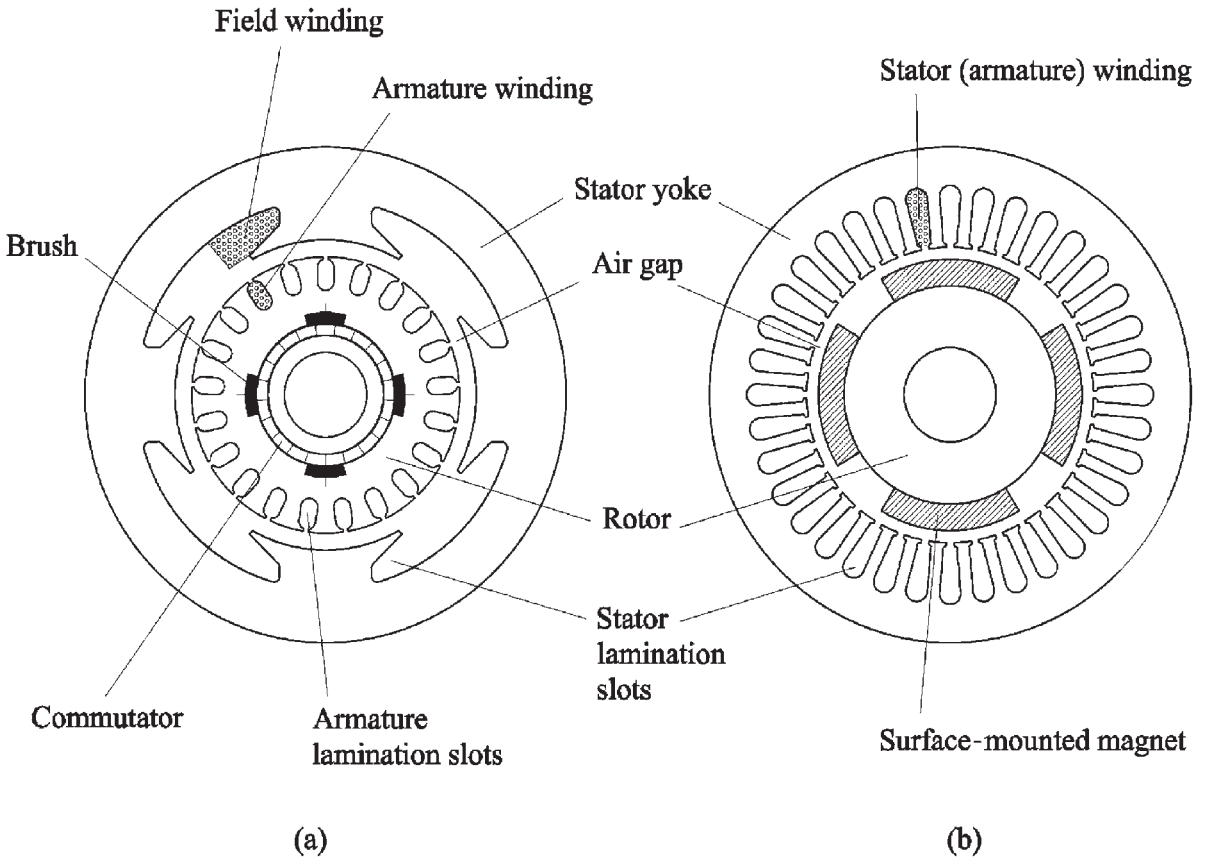

***Figure 2***
Schematic showing (a) a wound field brushed DC motor and (b) a brushless permanent magnet motor.

processors for motor control, and high-power switching devices.

Losses in electric motors have three main sources:

- copper losses or $I^2R$ losses, which are due to the finite electrical resistance of the copper wire used in the windings (in a brushed machine this also includes losses from brush contact resistance);
- magnetic or iron losses from both magnetic hysteresis losses in the soft magnetic components and eddy currents; and
- friction and windage losses from bearing friction, brushes, if present, and the rotor peripheral speed (Hamdi 1994).

The design of a high-efficiency motor requires minimization of the losses, and may be achieved by the use of novel motor topologies, good magnetic circuit design, and judicious choice of materials, for example, low-loss electrical steels. Innovative motor designs may not use any iron at all; an example is an axial flux in-wheel motor developed for a solar powered car that has an efficiency of 98% (Ramsden 1998).

Motors used in domestic applications range in power from a fraction of a watt, or a few watts, to about 2 kW, have an output torque in the range from a few mNm to about 10 Nm, an efficiency of 60 to 70%, and an operational speed from a few rpm to 25 000 or 30 000 rpm. No one motor type satisfies all these power, torque, and speed requirements. A variety of motor types is used, each with performance characteristics to match the application. For example, a vacuum cleaner motor is required to operate at high speed, and may be only used for an hour per week.

With this intermittent operation there is no great need for high reliability or high efficiency; rather, manufacturers aim for a motor of minimum cost. The situation is somewhat different with a washing machine. Here the motor has two extremes of operation; it is required to operate at low speed with high torque for the wash cycle and high speed with low torque

during the spin cycle, to remove water from the clothes. On the other hand, for a refrigerator that operates continuously or a battery-powered hand-held drill there is an advantage in having a motor of high efficiency as this will minimize energy consumption, and for the drill it will give a longer period of use between battery charges.

Generally most domestic appliances are low-cost items, and the motor is usually chosen with this in mind. A common motor type used in intermittently operated hand-held appliances is the brushed universal motor (it has the same configuration as a brushed d.c. motor). Universal motors are made in a variety of sizes, are very low cost, and have the advantage of a simple controller for variable speed operation, though they are noisy at high speeds. Universal motors are used in hair-dryers, food blenders, vacuum cleaners, electric drills, saws and routers, mixmasters, etc. Induction motors tend to be favored in constant-speed continuous operation situations, for low noise and for their low-cost: for example, in fans, compressors in air-conditioners and refrigerators, clothes dryers, pool and spa pumps, etc.

Permanent magnet motors may use either hard-ferrite or rare-earth permanent magnets (very rarely AlNiCo), with the former often used in small pumps in washing machines and dishwashers, and in compact low-noise fans and the latter where the features of high efficiency and high power/torque per unit volume are required, e.g., video-recorders, computer disk drives, CD players, camcorders, cameras, facsimile machines, battery-powered screw drivers, and drills. The situation with washing machines is interesting and reflects market diversity. In Europe frontloading washing machines dominate and tend to use brushed universal motors, while in the USA front-loaders may use a switched reluctance motor. For toploading machines, which are popular in the USA and Australia, both induction motors and direct-drive ferrite permanent magnet motors are used.

In domestic applications hard ferrite magnets dominate, with only limited use of rare-earth permanent magnet motors. More widespread use of rare-earth permanent magnet motors will occur when some, or all, of their advantages of compactness, high efficiency, high torque/power per unit volume, and improved dynamic response are required by the particular product. Domestic applications are highly cost-sensitive, and manufacturers are constantly seeking the lowest cost solution, which inhibits the take-up of motors using rare-earth permanent magnets as they are often of higher cost compared with competing motor types. This is changing as rare-earth magnet prices decrease, motor numbers increase, and the technical advantages of rare-earth permanent motors in particular applications become more apparent.

## 2. *Soft Magnetic Materials*

In an electrical machine, the magnetic losses or core losses are due to the soft magnetic material operating in a time-varying magnetic field. Core losses (see *Magnetic Losses*) are made up of eddy current losses that arise from circulating electrical currents induced in conducting materials (the electrical steel used in the stator and copper used in the motor windings) and magnetic hysteresis losses which are proportional to the enclosed area of the B–H loop of the particular material. The characteristics required of the soft magnetic material are:

- high saturation induction to minimize weight and volume of the iron parts;
- high permeability for design of a low reluctance magnetic circuit;
- low coercivity to minimize hysteresis losses; and
- high resistivity to minimize eddy current losses (minimization of eddy currents is also achieved by using thin laminations that are covered by a thin insulating layer to provide interlaminar insulation).

These desirable magnetic properties are not found in one material, as there are many factors that affect the magnetic properties. The magnetic properties of a material may be tailored by the addition of chemical elements, mechanical working of the material, and heat treatment. The characteristics of a range of soft magnetic materials are shown in Fig. 3 and Table 1 (for reference data see Warlimont 1990 and Clegg *et al*. 1993).

### 2.1 *Silicon–Iron Electrical Steels*

The most common soft magnetic material used in electrical machines is silicon–iron electrical steel (see *Steels, Silicon Iron-based: Magnetic Properties*) in the form of thin laminations. The addition of silicon to soft iron results in a significant decrease in coercivity,

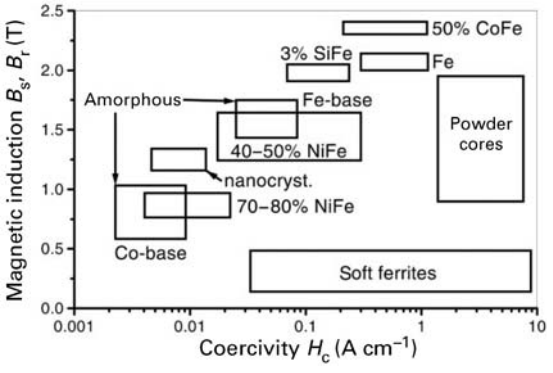

***Figure 3***
Typical property ranges of soft magnetic materials.

***Table 1***
Properties of some common soft magnetic materials.

| Grade | Thickness (mm) | Nominal silicon content (%) | Resistivity (μΩ m) | Core loss at 1.5 T and 50 Hz ($Wkg^{-1}$) |
|---|---|---|---|---|
| *Low-loss Si–Fe steel, nonoriented* | | | | |
| Transil 300-35-A5 | 0.35 | 2.9 | 0.48 | 2.95 |
| Losil 400-50-A5 | 0.50 | 2.4 | 0.44 | 3.60 |
| Losil 800-65-A5 | 0.65 | 1.3 | 0.29 | 6.5 |
| *Low-loss Si–Fe steel, oriented* | | | | |
| Unisil 35M6 | 0.35 | 3.1 | 0.48 | 1.00 |
| Permendur 49 (Co49/Fe49/V2) | 0.35 | NA | 0.40 | 3.0 |
| METGLAS 2605SA1 | 0.025 | NA | 1.3 | 0.16[a] |
| SMC (iron powder) | NA | NA | NA | 10 |

a Measured at 1.4 T.

a slight decrease in saturation magnetization, and an increase in resistivity. There are two distinct categories of electrical steels: nonoriented isotropic products with silicon contents in the range 1–3.5%, and grain-oriented anisotropic products which contain 2.9–3.15% Si (+Al). Silicon levels above 3.5% result in the steel becoming very brittle and hard to work. Oriented steels have the lowest core loss (see Table 1) and are used in transformers, whereas nonoriented steel is used in electrical machines as there are varying flux directions.

Domestic appliances are dominated by low-cost universal and induction motors, with efficiencies of 60–70%. The quest for low cost results in motors that use lower-quality nonoriented electrical steels and thicker laminations (typically 0.65 mm), the latter resulting in a reduction in the number of stamping operations necessary to produce the stator lamination stack.

### 2.2 Iron–Cobalt Alloys

Iron–cobalt alloys (such as Permendur 49, 49Co–49Fe–2 V) have the highest saturation magnetization of all the soft magnetic materials (see Fig. 3). They have the disadvantage of a much higher cost than silicon–iron steels, but are used in applications where it is advantageous to reduce size and weight. Iron–cobalt alloys are used in aircraft generators, some 400 Hz motors, and active magnetic bearings.

### 2.3 Amorphous or Glassy Metals

Amorphous metals (see *Amorphous and Nanocrystalline Materials*) are made from alloys whose constituents may include Fe, Ni, and Co and a metalloid or glass former such as silicon, boron, or carbon. A typical amorphous metal, offered for sale by Allied-Signal Inc, USA, is METGLAS 2826, which has the composition $Fe_{40}Ni_{40}P_{14}B_6$. Amorphous metals are very thin, of the order of 0.025 to 0.04 mm. They have the lowest coercivity of all the soft magnetic materials and a higher resistivity than electrical steels, resulting in a material with the lowest core loss (see Table 1).

There is a number of issues regarding the use of amorphous metals in electrical machines. The very desirable feature of low coercivity is counterbalanced by the lower saturation magnetization, $\approx$1.5 T compared with $\approx$2 T in silicon–iron steels. The cutting and forming of amorphous metal laminations is expensive due to increased tool wear from their hardness (over C-80 Rockwell), and being very thin there is a greater number of stamping operations, and the material does not stack as well. Amorphous metals have been used in electrical motors where high efficiency is all-important (>94%), but it is in distribution transformers where the material is proving most beneficial (DeCristofaro 1998).

### 2.4 Soft Magnetic Composites

Soft magnetic composite (SMC) materials are made from bonded iron powders. The iron powder is coated with an insulating layer and pressed into a solid material using a die before final heat treatment to cure the bond. It is not a powder metallurgy process where sintering is used. SMC materials are rather new and have a number of advantages. The material is isotropic, enabling the design of magnetic circuits that have three-dimensional flux paths, and since there is an insulating layer between the iron powder particles, losses due to eddy currents are minimized.

The material can be used at frequencies up to 100 kHz, and the cross-over point for core loss for it and 3% silicon steel (0.5 mm thick) is about 400 Hz, where at 1.5 T the loss for both materials is about 90 W $kg^{-1}$. The main advantage of the material may

be in low-cost manufacture, as parts can be made to net shape, using highly-automated mass production methods. The main disadvantage of the material is its high core loss at 50 Hz when compared with silicon–iron electrical steels. Nonetheless, a number of prototype transverse flux and claw-pole electrical machines have been made using SMCs (Jack 1998).

### 2.5 *Soft Ferrites*

The magnetically soft ferrites (see *Ferrites*) have the general chemical formula $MeFe_2O_4$, where Me is most commonly MnZn (MnZn ferrite) or NiZn (NiZn ferrite), and have the cubic structure of the mineral spinel. The properties of the soft ferrite may be further adjusted by additions of Mg, Cu, or Co, or a mixture of these. The soft ferrites have the general characteristics of low coercivity, high permeability, and high resistivity.

The high resistivity results in negligible losses due to eddy currents, enabling the material to be used at high frequencies ($\gg 1$ MHz). Generally the NiZn ferrites have a higher resistivity than the MnZn ferrites, but a lower saturation induction. The soft ferrites are manufactured in a range of core shapes, rings, pots, and E and C cores, for use in inductors and transformers. Their use is primarily in compact electronic power supplies and telecommunication components. Their relatively low saturation induction makes them unsuitable for use in power or high-flux transformers.

Another class of soft ferrites, the iron garnets with the general formula $R_3Fe_5O_{12}$, where R is a rare-earth, usually yttrium, is used in specialized microwave devices.

## 3. *Hard Magnetic Materials*

The role of hard magnetic materials, in particular high-energy permanent magnets, in electric motors is replacement of the field winding. In any application, including motors, there is a multitude of factors that require consideration to ensure that the optimum magnet material is selected (Coey 1996a, Kirchmayr 1996). Of importance are:

- magnetic parameters: remanence, intrinsic coercivity, and magnetic energy product, $BH_{max}$;
- temperature stability of the magnetic parameters;
- ease of magnetizing the material;
- ease of forming the magnet into the desired shape;
- environmental factors, such as resistance to corrosion; and
- cost (cost can be treated in a variety of ways, and includes material cost, cost per unit of magnetic energy product, and the cost of forming the material into the desired shape and its magnetization).

Selection of the permanent magnet material impacts on the motor design; for example, a motor using a hard ferrite has narrow stator teeth, compared to the wider teeth in a machine using rare-earth permanent magnets, where the magnetic flux density is much higher. It is also desirable for motors that the magnet material has a linear $B$–$H$ curve in the second, or demagnetizing, quadrant of the hysteresis loop. Both hard ferrite and rare-earth magnets have this characteristic, whereas AlNiCo differs by exhibiting a highly nonlinear demagnetization behavior.

For the motor designer rare-earth permanent magnets offer the advantages of a high $BH_{max}$, which reduces the amount of magnet material required, and high-intrinsic coercivity, which is important if the motor is to withstand high armature currents, which could lead to demagnetization of the magnets. Typical properties for a range of permanent magnet materials are given in Tables 2 and 3. For detailed information on magnet types see McCaig and Clegg (1987) and Coey (1996b); see also Hard Magnetic Materials, Basic Principles of).

The use of any permanent magnet material in a particular application is not only governed by the

***Table 2***
Typical properties of some common permanent magnet materials.

| Material | Remanence (T) | Intrinsic coercivity ($kAm^{-1}$) | Energy product ($kJm^{-3}$) |
|---|---|---|---|
| Sintered $Nd_2Fe_{14}B$ | 1–1.4 | 3200–1000 | 190–380 |
| Sintered $Sm_2Co_{17}$ | 1.04–1.12 | 2070–800 | 200–240 |

magnetic, physical, and chemical parameters, but also by the cost of the material. Applications and products are driven by markets, and the success or failure of a product in a particular market is driven by cost. The world market for various magnet types is given in Table 4 (Ormerod and Constantinides 1997), and it shows that the market is dominated by the low-cost hard ferrites. Included in Table 4 is the price per kilogram for various magnet materials. These prices are at best estimates, and are based on information from a variety of sources, including Abraham (1995) and material presented at the 1999 Gorham/Intertech NdFeB '99 Meeting (Gorham/Intertech Consulting, Portland, ME, USA). It is difficult to give accurate pricing, as this information is often kept confidential by manufacturers, can be very dependent on quantity and complexity of the magnet shape, and subject to market volatility. For example, the advent of low-cost $Nd_2Fe_{14}B$ from the Far-East has had a considerable impact. Nonetheless, Table 4 does give a guide to the relative prices. In terms of cost per unit of energy, both sintered hard ferrite and sintered $Nd_2Fe_{14}B$ are approaching parity (hard ferrite of 27 kJm$^{-3}$, \$2.50–3.00 kg$^{-1}$, $\approx$\$0.10 (kJm$^{-3}$)$^{-1}$ and $Nd_2Fe_{14}B$ of 250 kJm$^{-3}$, \$30 kg$^{-1}$, $\approx$\$0.12 (kJm$^{-3}$)$^{-1}$). In recent years, both sintered and bonded $Nd_2Fe_{14}B$ have decreased in price, and it appears this trend will continue as market share increases and $Nd_2Fe_{14}B$ becomes cost-effective in new applications and replaces existing magnet materials in current applications.

### *3.1 Rare-earth Cobalt Magnets*

Sintered and polymer-bonded magnets based on both the $SmCo_5$ and $Sm_2Co_{17}$ alloy composition are available from a variety of manufacturers. The main advantage of Sm–Co-based magnets is their high Curie temperature, making them suitable for use in applications at elevated temperatures, but they suffer from the disadvantage of high cost. The sintered material tends to be somewhat harder and more brittle than $Nd_2Fe_{14}B$, but it has excellent corrosion resistance. Sintered Sm–Co magnets are used in applications where arduous conditions apply, for example, in motors that are used in oil-wells, high-temperature automotive sensors, and microwave switches in telecommunication satellites.

### *3.2 Neodymium–Iron–Boron ($Nd_2Fe_{14}B$) Magnets*

$Nd_2Fe_{14}B$ magnets are commercially available in a number of forms—anisotropic sintered and anisotropic

and isotropic powders for polymer bonded magnets. Isotropic powders are prepared using a rapid solidification method and anisotropic powders by the HDDR (hydrogenation, desorption, disproportionation, recombination) process (Kirchmayr 1996). Projections suggest a cost of \$30 $kg^{-1}$ for isotropic powder by 2001. Polymer-bonded magnets are formed by either compression or injection molding, and binders include nylon 6/6. The great advantage of polymer-bonded magnets is that complicated shapes and geometries can be prepared to near-net or net shape using very low-cost production processes.

For applications requiring magnets of the highest possible energy product, sintered $Nd_2Fe_{14}B$ is the magnet of choice (see Magnets: Sintered). The thermal stability of sintered $Nd_2Fe_{14}B$ magnets has improved, with operating temperatures of 200 °C now attainable. Similar advances have been made in corrosion resistance with the addition of cobalt and other alloying components. Sintered magnets find uses in applications that require the best possible performance, for example, servomotors in machine tools.

Polymer-bonded magnets are the most rapidly growing section of the permanent magnet market. The reason for this rapid expansion is the demand for magnets for computer disk drives. Currently more than 50% of rare-earth magnets produced in Japan are used in computer disk drives, and the world market for computer disk drives is expected to exceed 250 million units by 2002. There is also considerable demand for polymer-bonded magnets for small motors in video recorders, camcorders, printers, facsimile machines, office automation, automotive, and portable drills (Ormerod and Constantinides 1997).

### 3.3 *Aluminum–Nickel–Cobalt (AlNiCo) Magnets*

AlNiCo magnets are manufactured by a powder metallurgy process or by casting, and are available in both isotropic and anisotropic forms. They tend to be expensive due to the cost of the raw materials, but they have good corrosion resistance and a very respectable remanence, 1.26 T, when compared with the value of 1–1.4 T for $Nd_2Fe_{14}B$. The major disadvantage of AlNiCo is its low coercivity, which creates problems in handling and its use in electric motors. For example, removal of AlNiCo magnets from the magnetic circuit in a small electric motor often results in their partial, or complete, self-demagnetization. A consequence of this is that it is usually necessary to magnetize AlNiCo magnets *in situ*.

The advantage that AlNiCo has compared with other commonly used permanent magnets is its excellent temperature stability. It has a reversible temperature coefficient of remanence of $-0.01$ to $-0.02\%K^{-1}$, compared with $-0.13\%K^{-1}$ for $Nd_2Fe_{14}B$. The excellent temperature stability of AlNiCo makes it the magnet of choice for watt-hour meters, ammeters, and voltmeters. Additionally, AlNiCo magnets are frequently used in small servomotors in aircraft and military hardware (see also *Alnicos and Hexaferrites*).

### 3.4 *Hard Ferrite Magnets*

In terms of the global permanent magnet market hard ferrite magnets still dominate. Ferrite magnets have the stoichiometry $BaFe_{12}O_{19}$ or $SrFe_{12}O_{19}$, the latter being increasingly used due to its higher coercivity. They are very cheap, as the raw materials from which they are made are abundant. A further advantage is their resistance to many chemicals, and being an oxide they are ideal for use in damp or wet environments. Isotropic and anisotropic sintered magnets, and polymer-bonded magnets formed from the milled powder, are widely available and used extensively.

The temperature coefficient of the intrinsic coercivity is positive for the hard ferrites, in contrast to rare-earth permanent magnets, and consequently there is a risk of demagnetization if the hard ferrite magnet is exposed to too low a temperature. Hard ferrite magnets are found in applications ranging from door seals in refrigerators to small electric motors used in dishwashers and washing machines (see also *Alnicos and Hexaferrites*).

## 4. *Selected Applications*

### 4.1 *Computer Disk Drives*

Computer disk drives are a prime example of where performance enhancements are traceable to improvements in permanent magnets. In a fixed disk drive permanent magnets are used in the spindle motor, in the actuator that drives the read/write heads (generally termed the voice coil motor (VCM)), and the latch assembly (see Fig. 4). Disk drives nowadays have a 2.5, 3, or 3.5 inch form factor, as emphasis has switched from miniaturization to making the storage capacity of the drive as large as possible.

The availability of high-remanence rare-earth magnets has enabled the disk drive designer to reduce dramatically the size of the VCM, as only a small volume of magnet material is required, and to decrease access times. Disk drives of $>1$–2 GB capacity use a high-grade sintered $Nd_2Fe_{14}B$, showing typically a remanence of 1.4 T, an intrinsic coercivity of 1,190 $kAm^{-1}$, and an energy product of 360 $kJm^{-3}$. One or two magnets may be employed, with a total weight of 15.5 g, and return poles are made of low-carbon steel. Spindle motors may use sintered or polymer-bonded material, with the latter often favored as it can be easily molded to shape. Spindle motor speed is important as the higher the speed the shorter the seek time. High-capacity drives found in file-servers

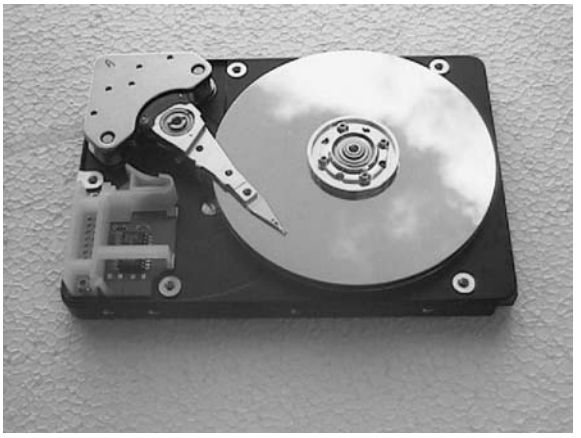

*Figure 4*
Hard disk drive unit; the VCM actuator can be seen in the top left hand corner.

have a spindle speed of 10 000 rpm, while drives used in desktops and notebooks have speeds of 7200 rpm and 5400 rpm, respectively. Removable cartridge drives of 100 to 250 MB capacity use linear motors and polymer-bonded $Nd_2Fe_{14}B$, to keep their cost down. On the horizon are compact disk drives for use in digital cameras. IBM is building a 1-inch 340 MB hard drive for that application that uses $Nd_2Fe_{14}B$ magnets.

### 4.2 White Goods

The domestic appliances most often associated with motors are refrigerators, washing machines, and dish washers. On the whole these products appear to have changed little over the years, but there is increasing pressure to improve their energy efficiency. In the USA the Department of Energy mandated a 30% reduction in energy use for refrigerators manufactured after July 2001. An energy-efficient refrigerator has been developed in the USA that uses $1.16\,kWhd^{-1}$, and part of this efficiency improvement comes from the use of DC brushless motors (Braham 1997).

A permanent magnet brushless motor of innovative design is used in a top-loading washing machine made by Fisher & Paykel, New Zealand, and is shown in Fig. 5. The motor is of an axially compact design, approximately 270 mm diameter and 65 mm long, and uses an outer rotor with hard ferrite permanent magnets. The agitator is coupled directly to the motor. This simplifies the design of the washing machine, as the gearbox or belt-drive reduction is eliminated. Fisher & Paykel also make a low-profile pump motor for use in dishwashers (Fig. 6). Again, this is a hard ferrite brushless permanent magnet

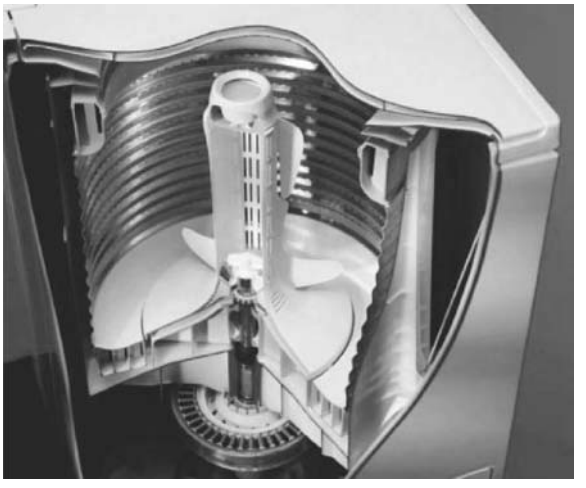

*Figure 5*

motor. The magnets are located on the rotor, and the rotor runs in contact with the water detergent mix of the dishwasher. This is possible due to the excellent resistance of ferrite to chemical attack.

## 5. The Future

Hard and soft magnetic materials will continue to be fundamental to many domestic applications, and as improvements are made in their physical, chemical, and magnetic properties there will be corresponding product improvements. In the future one can foresee

the ''plastic'' motor which will be constructed from an injection or compression-molded soft magnetic composite stator and polymer-bonded magnets, bonded directly on the rotor. The great attraction of such a motor will be its excellent performance and low cost, as its key components can be manufactured using low-cost plastic molding methods.

# Magnetic Materials: Hard

The prerequisite for permanent magnet materials that owe their hard magnetic properties to the presence of magnetocrystalline anisotropy is a crystal structure of less than cubic symmetry. The tetragonal structure of the AuCu type ($L1_0$) is a well-known example able to generate uniaxial magnetic anisotropy in compounds in which the magnetic moments are carried by cobalt, iron, or manganese atoms. As illustrated in the left-hand (or right-hand) part of Fig. 1, the unit cell of this structure can be obtained by atomic ordering of the two components (filled and open circles), an atomic ordering that leads to a small contraction of the *c*-axis. As discussed below, the attainment of this tetragonal structure for CoPt and FePt alloys is metallurgically different from that for MnAl alloys. The permanent magnets based on compounds of this tetragonal crystal structure are rather expensive for CoPt and FePt owing to the high price of platinum metal. The application of the latter magnets is therefore a restricted one. The MnAl magnets are low-cost, low-performance magnets, but their widespread application suffers from the competition of hard ferrite magnets (see *Alnicos and Hexaferrites*).

### 1. Permanent Magnets based on Noble Metal Compounds

At high temperatures the platinum–cobalt phase diagram is characterized by a range of complete solid solubility. The crystal structure is a disordered f.c.c. structure over the whole solid solubility range, in which cobalt and platinum atoms statistically occupy the crystallographic sites. This high-temperature phase is practically useless for permanent magnet applications because it does not show a sufficiently high magnetic anisotropy. Structural transformations take place, however, when the rapidly cooled solid solution $Co_{1-x}Pt_x$ alloys are annealed at lower temperatures. The f.c.c. phase gives rise to a disorder–order transformation for comparatively high platinum concentrations ($x > 0.75$) whereas for

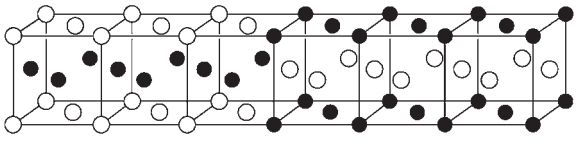

***Figure 1***
Schematic representation of an array of unit cells of the tetragonal AuCu structure type in which one component occupies the basal plane positions and the other component the equatorial plane positions. Switching of positions can lead to an antiphase boundary visible in the central part.

relatively low platinum concentrations ($x < 0.23$) it transforms into a h.c.p. structure. The applicability of $Co_{1-x}Pt_x$ alloys as permanent magnet materials is based on the transformation of the disordered f.c.c. phase to an ordered face-centered tetragonal (f.c.t.) phase occurring for alloys in the intermediate concentration range ($40 < x < 75$). Only the latter phase has a sufficiently high uniaxial magnetic anisotropy, the easy magnetization direction being along the tetragonal *c*-axis.

The origin of the magnetic anisotropy and the role played by the orbital moment in transition metal compounds in CoPt has been explained by means of first principles band structure calculations using the local spin density approximation. For a more detailed discussion of this topic the reader is referred to the review by Buschow (1997). The Curie temperature of these materials is around 500 °C for the equiatomic composition and slightly decreases with platinum concentration.

The maximum of the magnetic anisotropy energy $E_A = K_1 + 2K_2$ is found at the equiatomic composition, although the maximum of the anisotropy field $H_A = (2K_1 + 4K_2)/M_s$ is located at slightly higher $x$ values because of the fairly strong decrease of the saturation magnetization, $M_s$, with $x$. For obtaining optimum values for the coercivity slightly higher platinum concentrations than the equiatomic composition are desirable because it is the anisotropy field rather than the anisotropy energy that determines the coercivity (see *Coercivity Mechanisms*). However, the energy product depends very strongly on the magnetization. For this reason, concentrations close to the equiatomic composition are generally chosen for practical applications in permanent magnets.

As described in detail elsewhere (see *Coercivity Mechanisms*) high coercivities are usually obtained in magnet bodies composed of an assembly of sufficiently fine particles. CoPt alloys are known to have outstanding mechanical strength and for this reason the powder metallurgical route commonly used for the attainment of high coercivities in many other permanent magnet materials (see *Magnets: Sintered*) is not applicable here. In these alloys one may profit, however, from particulars of the phase diagram because the presence of the f.c.c.-to-f.c.t. phase transition provides ample means of obtaining sufficiently small f.c.t. particles. This is the reason that the generation of coercivity in CoPt alloys is a matter of controlling the nucleation and growth of f.c.t. particles during the phase transformation. This process involves heat treatments of the ingots under carefully selected conditions.

Kaneko *et al*. (1968) have shown that the coercivity passes through a maximum when CoPt alloys are heat treated for variable aging times at temperatures sufficiently below the f.c.c.–f.c.t. transformation temperature, the optimum annealing temperature being around 680 °C. Furthermore, it has been found that even better results are obtained when the first aging step is followed by a second aging step, provided the first aging step is kept sufficiently short to prevent overaging. The first annealing step is regarded as leading to the formation of a fine precipitate of the f.c.t. phase in the f.c.c. matrix, whereas the second step is held responsible for an increase of the magnetocrystalline anisotropy of the f.c.t. phase. This increase is probably associated with a more perfect atomic ordering of the cobalt and platinum atoms in the f.c.t. grains. By applying this two-step annealing process, coercivities can be obtained of greater than $700\,kAm^{-1}$ for alloys annealed first at 680 °C and subsequently at 600 °C for variable times. The corresponding energy products of the ingot magnets can reach values around $100\,kJm^{-3}$.

The origin of the coercivity in f.c.t. CoPt alloys has been studied (Zhang and Soffa 1994) by means of Lorentz microscopy. It has been shown that the occurrence of antiphase boundaries (APB) is essential for the understanding of the coercivity in these materials. It is mentioned above that the f.c.t. phase precipitates from a disordered f.c.c. matrix phase on annealing. This phase transformation proceeds by means of a nucleation and growth mechanism, starting at a multitude of different locations in the alloy. The coalescence of the ordered regions during the growth process invariably leads to the occurrence of a large number of APBs. The atomic arrangement at APBs is shown schematically in Fig. 1. Zhang and Soffa (1994) showed by means of electron microscopy that the microstructure of fully ordered alloys can be characterized by profuse micro- and macrotwinning, leading to a dense net of APBs within the micro- and macrotwins. It is assumed that the coercivity is controlled by domain wall pinning at APBs and stacking faults.

Behavior fairly similar to that described above for $Co_{1-x}Pt_x$ alloys is found also for $Fe_{1-x}Pt_x$ alloys. High coercivities for $Fe_{1-x}Pt_x$ alloys are obtained when alloys around the equiatomic composition are first homogenized at high temperatures and subsequently annealed at temperatures below the order–disorder transition temperature. Tanaka *et al*. (1997) made a fairly detailed investigation of the microstructures of heat-treated $Fe_{1-x}Pt_x$ alloys and the resulting coercivities. It was shown that composition control is essential for the attainment of high coercivities. In as-quenched alloys optimum coercivities are reached for 39.5 at.% platinum because the disordered f.c.c. phase disappears during quenching and can no longer act as nucleation centers for domain walls. Tanaka *et al*. (1997) further showed that alloys with optimum coercivities are reached after heat treatments in which the local stress associated with the cubic-to-tetragonal transformation is not yet released by twin formation, and the f.c.t. phase is still present in the form of nanoscale antiphase domains. The antiphase domain boundaries between the single-domain particles act as

pinning sites for domain wall motion and in this way generate high coercivities. An overlong aging treatment leads to particle growth so that these are no longer single-domain particles. Consequently, the coercivity is reduced.

Investigations by Watanabe (1991) have made it clear that permanent magnets with hard magnetic properties even superior to those of CoPt alloys can be obtained for FePt alloys to which a small amount of niobium is added. The corresponding ingots are first homogenized at 1325 °C and then quenched in water. The desired high coercivity is obtained after a subsequent isothermal annealing treatment performed in a temperature range of 600–700 °C. The iron moments are somewhat higher than the cobalt moments in the iron alloys. This implies also that the remanences in the iron alloys are higher than in the cobalt alloys. This, in turn, leads to larger maximum energy products with $(BH)_{max}$ values higher than $160\,kJm^{-3}$.

The platinum-based magnets are extremely expensive owing to the fact that they consist of roughly 75 wt.% platinum. Advantages of these magnets are that they can be produced as ingot magnets, avoiding the complicated powder metallurgical manufacturing route. The magnets are of high mechanical strength and of unequalled corrosion resistance. Because of price considerations they are produced only in small quantities and are mainly used for medical implants. Investigations (Liu *et al.* 1998) have shown that PtFe-type permanent magnets can also be obtained in the form of thin films by combining Fe/Pt multilayering and rapid thermal processing. Energy products as high as $318\,kJm^{-3}$ (40 MGOe) have been reached and attributed to the presence of exchange coupling between the hard magnetic f.c.t. phase and soft magnetic f.c.c. phase. A detailed description of the exchange coupling mechanism and the concomitant remanence enhancement in nanostructured microstructures can be found in *Magnets: Remanence-enhanced.*

When comparing the manufacturing routes of Alnico magnets (see *Alnicos and Hexaferrites*) and platinum alloy magnets one may notice that there is a striking similarity. In both cases the manufacturing benefits from the fact that an extended range of solid solubility exists at high temperatures and that on cooling this solid solution becomes supersaturated and leads to the precipitation of new phases. In both cases the decomposition of the supersaturated solid solution has to be performed at sufficiently low temperatures so that the resulting microstructure consists of fine grains and exhibits magnetic hardness.

Interestingly, neither of the two parent solid solutions has a magnetic anisotropy of any significance. In the case of the platinum alloys the required magnetic anisotropy is obtained by the formation at low temperatures of a phase of lower symmetry (f.c.t.) than the parent phase (f.c.c.). In contrast to the latter, the former phase exhibits a fairly strong magnetocrystalline anisotropy. Both phases have the same composition and the particle size is not very critical for the generation of anisotropy. Roughly speaking it can be said, therefore, that the main goal of finding optimum annealing treatments is to generate microstructures with grain sizes sufficiently small for generating coercivity. By contrast, the main goal of finding optimum annealing treatments in the case of Alnico alloys is to produce microstructures where not only the size but also the shape of the precipitated particles is at a premium, because not only coercivity but also shape anisotropy has to be generated owing to the absence of magnetocrystalline anisotropy.

## 2. *MnAl Permanent Magnets*

Permanent magnets based on MnAl alloys owe their hard magnetic properties to the so-called $\tau$-phase. This is an intermetallic compound with an f.c.t. structure (CuAu-type superstructure). It occurs in the composition range 51–58 at.% (67—73 wt.%) manganese. The manganese atoms are located predominantly at the 1a and 1c positions at (0, 0, 0) and $(\frac{1}{2}, \frac{1}{2}, 0)$, respectively. The aluminum atoms occupy mainly the 2e positions at $(0, \frac{1}{2}, \frac{1}{2})$ in this crystal structure. Owing to the fact that the composition is richer in manganese than the equiatomic composition, not all the manganese atoms can occupy the former two sites. This has as a consequence in that the excess manganese atoms must be accommodated at the $(0, \frac{1}{2}, \frac{1}{2})$ positions, which they share with the aluminium atoms. Neutron diffraction results indicate that deviations from the ideal site occupancy in this type of MnAl alloy can lead to antiferromagnetic coupling between the manganese moments. This unfavorable feature has important consequences for the saturation magnetization and for the hard magnetic properties of permanent magnets based on MnAl alloys.

A second difficulty associated with MnAl alloys is the metastable nature of the $\tau$-phase. In fact, this phase is not found in the Mn–Al phase diagram (see Fig. 2). It can be obtained by starting from the high-temperature equilibrium $\varepsilon$-phase occurring in this concentration range, which has an h.c.p. structure. However, the preparation of the f.c.t. $\tau$-phase from the h.c.p. $\varepsilon$-phase is not easy. Formerly it was believed that the $\tau$-phase forms from the $\varepsilon$-phase via an intermediate phase, $\varepsilon'$, of orthorhombic structure (B19) by means of the reaction scheme

$$\text{h.c.p.}(\varepsilon) \rightarrow \text{B19}(\varepsilon') \rightarrow \text{f.c.t.}(\tau)$$

where the h.c.p. structure ($\varepsilon$) transforms first into the orthorhombic $\varepsilon'$-phase by an atomic ordering reaction. Subsequently, the metastable f.c.t. ferromagnetic $\tau$-phase is formed by way of shear transformation. However, this reaction scheme is rather unlikely in

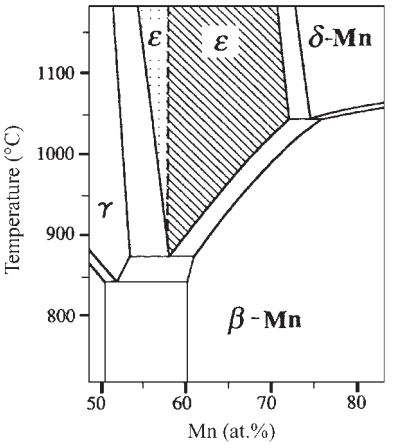

*Figure 2*
Central portion of the Mn–Al phase diagram as reported by Liu *et al.* (1996). The shaded area of the homogeneity region of the $\beta$-phase corresponds to alloys that transform into $\beta$-Mn on quenching.

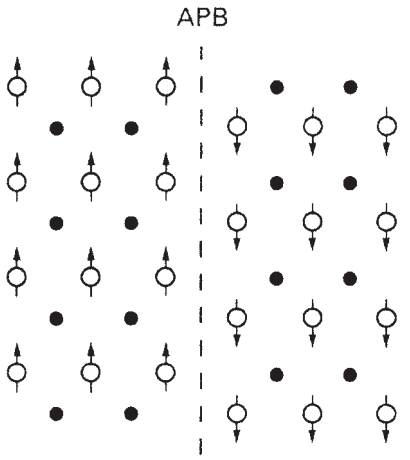

*Figure 3*
Schematic representation of an antiphase boundary and the corresponding reversal in magnetization direction across the boundary.

view of the observation by electron microscopy that precipitates of the $\varepsilon'$-phase in undercooled $\varepsilon$ do not act as nucleation centers for $\tau$.

The occurrence of a massive transformation has been proposed by Hoydick *et al.* (1997). It is furthermore important to realize that the metastable $\tau$-phase, after an annealing time that depends on alloy composition and the annealing temperature, tends to decompose into the two stable phases with $\beta$-Mn ($\beta$) and $Cr_5Al_8$ type structure ($\gamma_2$). For this reason, the annealing time has to be chosen carefully.

Various heat treatments have been proposed to obtain and preserve the $\tau$-phase, as discussed in more detail in the review of Müller *et al.* (1996). In several investigations (Otani *et al.* 1977, Pareti *et al.* 1986) it has been shown that doping with carbon can lead to significant improvements in the kinetics associated with the formation and decomposition of the $\tau$-phase. In the carbon-doped alloys, an incubation period is involved with the formation of the $\tau$-phase. The equilibrium phases $\beta$ and $\gamma_2$ do not form simultaneously with the $\tau$-phase, but form subsequently. The upshot is that the retardation of the formation allows for better process control because it also delays the formation of the undesirable $\beta$- and $\gamma_2$-phases. Carbon doping has, furthermore, a beneficial effect on the saturation magnetization, although there is a substantial decrease in Curie temperature.

The partial occupation of aluminum sites by manganese atoms at $(0, \frac{1}{2}, \frac{1}{2})$ implies that many antiphase domain boundaries occur in the crystal lattice of the $\tau$-phase. As shown in Fig. 3, these antiphase domain boundaries can act as nucleation sites for Bloch walls, which leads to a relatively easy magnetization reversal and hence to low values of the coercivity and remanence.

The magnetic properties of the $\tau$-phase in the concentration range 67–73 wt.% manganese have been investigated by Pareti *et al.* (1986). It has been shown that an increasing manganese concentration in the homogeneity range of the $\tau$-phase leads to an increase in the Curie temperature but it lowers the saturation magnetization. The increase of $T_C$ is the result of a general increase of the exchange interaction when magnetic manganese replaces nonmagnetic aluminum. The decrease of the saturation magnetization originates from the excess manganese atoms occupying former aluminum sites. These manganese moments, when coupled antiparallel to those of the main lattice, can cause a reduction in the net saturation moment. The anisotropy field shows a slight increase with manganese content. According to Pareti *et al.* (1986) this increase in $H_A$ is not a real increase in anisotropy but merely reflects the fact that the anisotropy constant, $K_1 = M_s H_A/2$, remains approximately constant since $M_s$ decreases with manganese concentration. The effect of carbon addition and aluminum concentration on the anisotropy field is shown in Fig. 4.

An important improvement in the magnet manufacturing is due to Otani *et al.* (1977). They have shown that the hard magnetic properties can be significantly enhanced when using a high-temperature extrusion process. In this process microstructures are realized consisting of very fine grains while also the number of antiphase boundaries is strongly reduced. The manufacturing route involves the following steps. The alloys (typically 70.0 wt.% Mn, 29.5 wt.% Al,

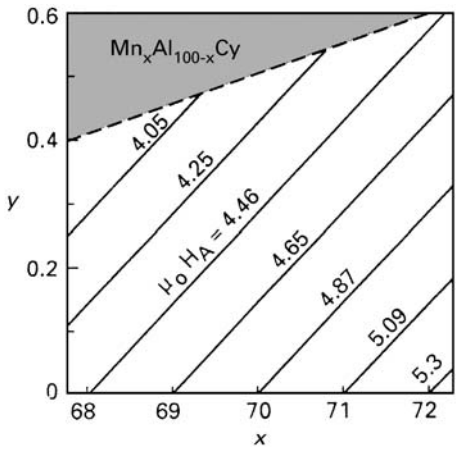

***Figure 4***
Dependence of the room temperature anisotropy field, $H_A$, on carbon and manganese content in $Mn_xAl_{100-x}C_y$ with $68 < x < 72$wt.% and $0 < y < 0.6$ wt.%. Constant anisotropy field values are represented by solid lines. The shaded area corresponds to alloys above the carbon solubility limit (after Pareti *et al*. 1986).

0.5 wt.% C) are given a homogenizing treatment at 1100 °C for 1 h. After quenching the ingots to 500 °C they are annealed at 600 °C for 30 min. The hot extrusion is performed at 700 °C with a pressure of 80 kgmm$^{-2}$. Finally, the extruded material is aged at 700 °C for 10 min. The energy product can reach values close to 56 kJm$^{-3}$ (7 MGOe). Compared with the energy products reached in rare earth-based magnets (see *Rare Earth Magnets: Materials*) these values are very low. However, one has to take into consideration that the raw materials costs are much lower. Moreover, the production cost is much lower because the whole processing route can be performed in air.

## Magnetic Materials: Transmission Electron Microscopy

The application potential of many advanced magnetic materials depends on a combination of the intrinsic and extrinsic properties of the materials in question. Hence a detailed knowledge of both the physical and magnetic microstructure is essential if the structure–property relation is to be understood and materials with optimized properties produced. Most of the materials of interest today are markedly inhomogeneous with features requiring resolution on a sub-50 nm scale for their detailed investigation. Transmission electron microscopy (TEM) has two primary attractions. It offers very high spatial resolution and, because of the large number of interactions that take place when a beam of fast electrons hits a thin solid specimen, detailed insight into compositional, electronic, as well as structural and magnetic, properties. The resolution that is achievable depends largely on the information sought and may well be limited by the specimen itself. Typical resolutions achievable for structural imaging are 0.2–1.0 nm, for extraction of compositional information 0.5–3.0 nm, and for magnetic imaging 2–20 nm.

Although TEM is used extensively for both microstructural and micromagnetic studies it is only the latter that are considered in this chapter. It begins with a description of the basic interaction, which allows magnetic domains to be revealed. Thereafter a

brief description is given of the most widely used imaging modes together with the performance expectation of each. Studies can be made of specimens in their as-prepared states, in remanent states and in the presence of applied fields. From these can be derived basic micromagnetic information, the nature of domain walls, where nucleation occurs, and the importance or otherwise of domain wall pinning and many other related phenomena. It is only recently that extensive *in situ* magnetizing experiments have been undertaken and there is a short discussion of the various ways of implementing them. In the final section, examples of the application of TEM to magnetic materials are given. As TEM is essentially restricted to viewing material sections $<200\,\text{nm}$ thick, it is ideally suited to the study of thin films. Illustrative examples for both hard and soft films are presented. However, useful information on bulk magnetic material can also be determined and the use of TEM in this area is discussed briefly.

## 1. Imaging Magnetic Structures by TEM

The principal difficulty encountered when using a TEM to study magnetic materials is that the lenses are essentially electromagnets and the specimen is usually immersed in the high magnetic field (typically $>0.6\,\text{T}$) of the objective lens. This is sufficient to completely eradicate or severely distort most domain structures of interest. A number of strategies have been devised to overcome the problem of the high field in the specimen region (McFadyen and Chapman 1992). These include (i) simply switching off the standard objective lens, (ii) changing the position of the specimen so that it is no longer immersed in the objective lens field, (iii) retaining the specimen in its standard position but changing the pole-pieces, once again to provide a non-immersion environment, or (iv) adding super mini-lenses in addition to the standard objective lens which is once again switched off. The last named is the preferred option as it offers both high performance and minimum disruption to the other microscope functions.

Magnetic structures are most commonly revealed in the TEM using one of the modes of Lorentz microscopy. This generic name is used to describe all imaging modes in which contrast is generated as a result of the deflection experienced by electrons as they pass through a region of magnetic induction (Hale *et al*. 1959). The Lorentz deflection angle $\boldsymbol{\beta}_{\mathrm{L}}$ is given by

$$\boldsymbol{\beta}_{\mathrm{L}} = e\lambda t(\mathbf{B}\cdot\mathbf{n})/h \qquad (1)$$

where $\mathbf{B}$ is the induction averaged along an electron trajectory, $\mathbf{n}$ is a unit vector parallel to the incident beam, $t$ is the specimen thickness, and $\lambda$ is the electron wavelength. Substituting typical values into Eqn. (1) shows that $\beta_{\mathrm{L}}$ rarely exceeds $100\,\mu\text{rad}$. Given the small magnitude of $\beta_{\mathrm{L}}$ there is no danger of confusing magnetic scattering with the more familiar Bragg scattering where angles are typically in the range 1–10 mrad.

The description given so far is classical and much of Lorentz imaging can be understood in these terms. However, for certain imaging modes and, more generally if a full quantitative description of the spatial variation of induction is sought, a quantum mechanical description of the beam-specimen interaction must be sought (Aharanov and Bohm 1959). Using this approach the magnetic film should be considered as a phase modulator of the incident electron wave, the phase gradient $\nabla\varphi$ of the specimen transmittance being given by

$$\nabla\varphi = 2\pi et(\mathbf{B}\cdot\mathbf{n})/h \qquad (2)$$

where $e$ and $h$ are the electronic charge and Planck's constant respectively. Substituting typical numerical values shows that magnetic films should normally be regarded as strong, albeit slowly varying, phase objects. For example, the phase change involved in crossing a domain wall usually exceeds $\pi$ rad.

## 2. Imaging Modes in Lorentz Microscopy

Magnetic imaging can be performed in either fixed-beam or conventional (C)TEMs or in scanning (S)TEMs. Examples of each along with their associated advantages and drawbacks are given below. Fuller details on the techniques can be found in Reimer (1984), Jakubovics (1994), Chapman (1984), and Chapman and Scheinfein (1999).

### 2.1 Fresnel and Foucault Imaging

The most commonly used techniques for revealing magnetic domain structures are the Fresnel (or defocus) and Foucault imaging modes. Both are normally practiced in a CTEM. Schematics of how magnetic contrast is generated are shown in Fig. 1. For the purpose of illustration, a simple specimen comprising three domains separated by two 180° domain walls is assumed. In Fresnel microscopy the imaging lens is simply defocused so that the object plane is no longer coincident with the specimen. Narrow dark and bright bands, delineating the positions of the domain walls, can then be seen in an otherwise contrast-free image. For Foucault microscopy, a contrast-forming aperture must be present in the plane of the diffraction pattern and this is used to obstruct one of the two components into which the central diffraction spot is split due to the deflections suffered as the electrons pass through the specimen. Note that in general, the splitting of the central spot is more complex than for the simple case considered here. As a result of the partial obstruction of the diffraction

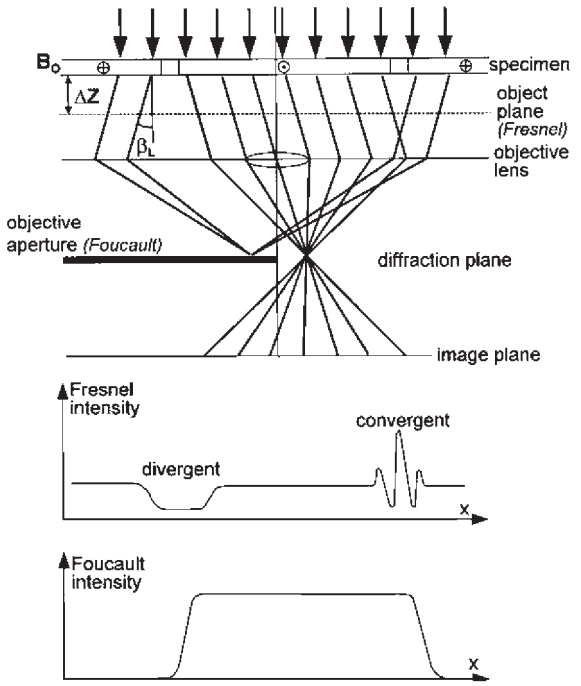

***Figure 1***
Schematic of magnetic contrast generation in the Fresnel and Foucault imaging modes.

spot, domain contrast can be seen in the image. Bright areas correspond to domains where the magnetization orientation is such that electrons are deflected through the aperture and dark areas to those where the orientation of magnetization is oppositely directed.

The principal advantages of Fresnel and Foucault microscopy together are that they are fairly simple to implement and they provide a clear picture of the overall domain geometry and a useful indication of the directions of magnetization in (at least) the larger domains. Such attributes make them the preferred techniques for *in situ* experimentation (see Sect. 3). However, a significant drawback of the Fresnel mode is that no information is directly available about the direction of magnetization within any single domain, whilst reproducible positioning of the contrast-forming aperture in the Foucault mode is difficult. Moreover, both imaging modes suffer from the disadvantage that the relation between image contrast and the spatial variation of magnetic induction is usually nonlinear. Thus extraction of reliable quantitative data, especially from regions where the induction varies rapidly, is problematic.

Part solutions to these problems have very recently been provided. Whilst the statements made above stand if a single Fresnel image is considered, a novel development (proposed by Paganin and Nugent (1998)) is to make use of two images of exactly the same area recorded with the same values of under- and over-focus. By combining the images in different ways maps of the two orthogonal components of magnetic induction perpendicular to the direction of electron travel can be obtained. Initial results look very promising but it remains to be seen down to what level reliable information can be extracted. A variant on standard Foucault microscopy—coherent Foucault imaging—has been introduced by Johnston and Chapman (1995). Here the standard objective aperture is replaced by a thin film aperture, which instead of obscuring part of the central diffraction spot simply phase shifts those parts passing through the film. Provided there is a region of free space close to the magnetic specimen and the thin film aperture is positioned to cut the (undeflected) diffraction spot arising from the free space area, the image takes the form of a magnetic interferogram corresponding to the lines of flux running through the magnetic specimen. Similar interferograms are generated using electron holography and further discussion is delayed until Sect. 2.4.

### *2.2 Low Angle Diffraction*

An alternative approach towards determining quantitative data from the TEM is by directly observing the form of the split central diffraction spot. The main requirement for low angle diffraction (LAD) is that the magnification of the intermediate and projector lenses of the microscope is sufficient to render visible the small Lorentz deflections. Camera constants (defined as the ratio of the displacement of the beam in the observation plane to the deflection angle itself) in the range 30–100 m are typically required. Furthermore, high spatial coherence in the illumination system is essential if the detailed form of the low angle diffraction pattern is not to be obscured. In practice this necessitates the angle subtended by the illuminating radiation at the specimen to be considerably smaller than the Lorentz angle of interest. The latter condition is particularly easy to fulfil in a TEM equipped with a field emission gun (FEG). Thus whilst LAD moves some way to supplementing the deficiencies of standard Fresnel and Foucault imaging, the fact that it provides global information from the whole of the illuminated specimen area rather than local information means that alternative imaging techniques are still desirable.

### *2.3 Differential Phase Contrast Imaging*

Differential phase contrast (DPC) microscopy (Dekkers and de Lang 1974, Chapman *et al.* 1990) overcomes many of the deficiencies of the imaging modes discussed above. Its normal implementation

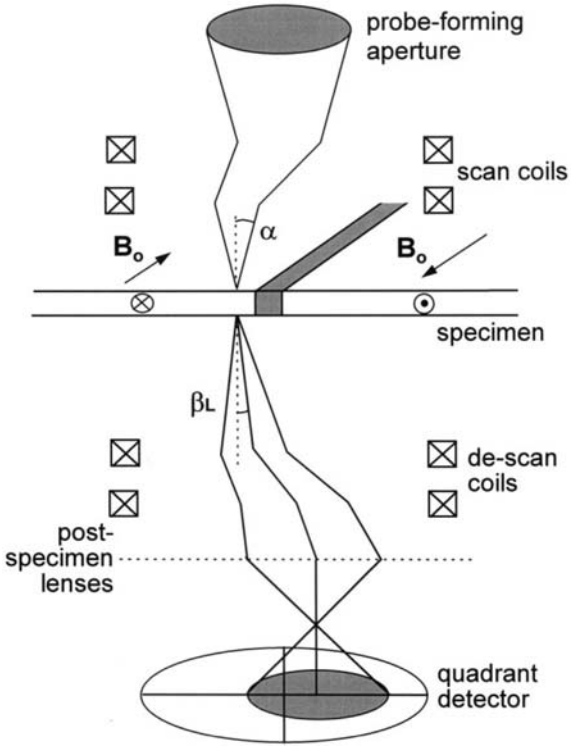

***Figure 2***
Schematic of magnetic contrast generation in the DPC imaging mode.

requires a STEM. It can usefully be thought of as a local area LAD technique using a focused probe; Fig. 2 shows a schematic of how contrast is generated. In DPC imaging the local Lorentz deflection at the position about which the probe is centered is determined using a segmented detector sited in the far field. Of specific interest are the difference signals from opposite segments of a quadrant detector as these provide a direct measure of the two components of $\beta_L$. By monitoring the difference signals as the probe is scanned in a regular raster across the specimen, directly quantifiable images with a resolution approximately equal to the electron probe size are obtained. Providing a FEG microscope is used, probe sizes $<10$ nm can be achieved with the specimen located in field-free space. A full wave-optical analysis of the image formation process confirms the validity of the simple geometric optics argument outlined above for experimentally realizable conditions. The main disadvantage against which this must be set is the undoubted increase in instrumental complexity and operational difficulty compared with the fixed-beam imaging modes.

The two difference-signal images are collected simultaneously and are therefore in perfect registration. From them a map of the component of magnetic induction perpendicular to the electron beam can be constructed. In addition a third image formed by the total signal falling on the detector can be formed. Such an image contains no magnetic information (the latter being dependent only on variations in the position of the bright field diffraction disk in the detector plane) but is a standard incoherent bright field image as would be obtained using an undivided spot detector. Thus a perfectly registered structural image can be built up at the same time as the two magnetic images, a further distinct advantage of DPC imaging. However, at this point it is important to recognize one of the primary difficulties encountered in all Lorentz microscopy modes. The simple analyses given above have assumed that image contrast arises solely as a result of the magnetic induction/electron beam interaction whereas, in reality, contrast arising from the physical microstructure is present virtually always as well. Moreover, it is frequently stronger than that of magnetic origin with the result that the resolution at which useful magnetic information is extracted is often limited by the specimen rather than the inherent instrumental capability.

Although the presence of unwanted contrast of structural origin is serious, its effect can be ameliorated to some extent by suitable choice of operating conditions or modification of the techniques themselves. It is frequently (but not always!) the case that the physical microstructure is on a significantly smaller scale than its magnetic counterpart. If this is so, the influence of high spatial frequency components in the image can be reduced by substitution of the solid quadrant detector by its annular counterpart (Chapman *et al.* 1990). Indeed, in the latter case, not only is the unwanted signal component suppressed considerably but the signal-to-noise ratio in the magnetic component is significantly enhanced.

### *2.4 Electron Holography*

Whilst DPC imaging can provide high spatial resolution induction maps and direct information on domain wall structures, difficulties still remain when absolute values of $\beta_L$, rather than relative variations, are sought. A final class of techniques, involving electron holography, go some way to overcoming this problem. Here the electron wave, phase-shifted after passing through the specimen in accordance with Eqn. (2), is mixed with a reference wave and the resulting interference pattern is analyzed to yield a full quantitative description of the averaged induction perpendicular to the electron trajectory. Several distinct strategies exist for mixing the specimen and reference waves and for realizing an interpretable image. In off-axis holographic techniques, a charged wire acts as a biprism, which is located before the specimen in scanning TEMs (Mankos *et al.* 1994) and after it in fixed-beam instruments (Tonomura 1987,

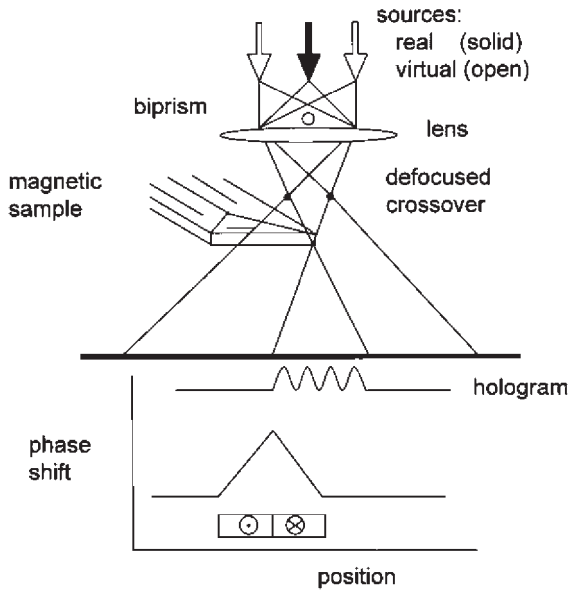

*Figure 3*
Schematic of how electron holography is implemented in a scanning instrument.

Dunin-Borkowski *et al.* 1998). Figure 3 shows a schematic relating to the former case. Images generated by holography are frequently in the form of magnetic interferograms which can be produced directly or by computer- or optical-processing of recorded holograms. The flux enclosed between adjacent fringes in the interferograms is h/e and so absolute values of the induction integrated along an electron trajectory can be determined. Difficulties with holographic techniques are the high level of instrumental sophistication (a FEG is essential and other instrumental modifications are usually mandatory), the difficulty of imaging away from specimen edges where suitable reference beams are inaccessible, the rapid deterioration in performance with increasing inelastic scattering (severely restricting maximum specimen thicknesses accessible) and excessive fringe separations when very thin specimens are under investigation. Thus, whilst a very powerful addition to the available techniques of Lorentz microscopy, holography brings with it its own associated problems and limitations.

## 3. *In Situ Studies of Magnetization Reversal by TEM*

One of the major attributes of TEM is the ability to change the magnetic state of the specimen *in situ*. To observe how magnetic structures evolve as a function of temperature is particularly straightforward, and simply involves mounting the specimen in a variable temperature holder. The use of a small furnace built into a holder allows temperatures to be raised from room temperature to temperatures in excess of 1200 K, which is beyond the Curie temperature of essentially all magnetic materials of interest. Alternatively, cooling holders can be used in which case the temperatures attained depend on whether liquid nitrogen or helium is the coolant employed. In these cases, the minimum temperatures at the points of observation are usually significantly greater than the liquefaction temperatures of the coolants involved. Realistic temperatures achievable at the center of a thin film specimen are 110 K and 20 K for liquid nitrogen and liquid helium respectively. Lower temperatures are difficult to achieve mainly as a result of poor thermal paths rather than because of significant heating in the electron beam itself. The energy deposited, and hence the consequent temperature rise, is generally very small in a thin film sample.

For magnetic specimens, *in situ* observations of the magnetization reversal process itself are crucial if, for example, hysteresis is to be understood at a microscopic level. There are two different approaches to subjecting the specimen to varying magnetic fields in a TEM. In the first a magnetizing stage is used which generates a horizontal field in the plane of the specimen. Two variants are possible. A magnetizing stage can be built into the specimen mounting rod (Hefferman *et al.* 1990) or, if spare ports are available at appropriate positions in the microscope column, one can be introduced as a separate entity. As the maximum available field relates strongly to the volume of the exciting coils and the nature of the magnetic circuit, greater fields can usually be generated using an independent stage. However, irrespective of which variation is adopted, the presence of a horizontal field over a vertical distance many times greater than the specimen thickness results in the electron beam being deflected through an angle orders of magnitude greater than typical Lorentz angles. Under these conditions the illumination normally disappears from the field of view and can only be restored using compensating coils. This introduces an additional element of complexity and the inevitable result is that in such experiments there is limited opportunity to observe changes as they occur; rather the changes that took place due to a change of field are normally observed some time after the event.

An alternative approach, which can be used in instruments where super mini-lenses are present as well as the standard objective lens, is to use the latter as a source of magnetic field given that the specimen remains located somewhere close to its center (Chapman *et al.* 1995, McVitie *et al.* 1995). The objective lens now acts as a source of vertical field whose excitation is under the control of the experimenter. Variation in the excitation of the mini-lenses compensates for the additional focusing effect

introduced. As the field of the objective lens is parallel to the optic axis, it is clearly suitable for studying magnetization processes in perpendicular magnetic materials. However, by tilting the specimen, a component of field in the plane of the specimen can also be introduced. Furthermore, given that demagnetizing effects perpendicular to the plane of a thin film are very large, the presence of even moderately large perpendicular fields can often be ignored and it is the smaller fields in the plane of the specimen that are of interest. When this is the case the objective is set to an appropriate fixed excitation giving a constant vertical field and the sample is simply tilted from a positive angle to a negative one and back again to take it through a magnetization cycle. The principal attraction of the second approach is that the electron optical conditions do not vary during the experiment. Hence, the specimen can be observed throughout and the experimenter can devote full attention to the changing magnetization distribution. It is this approach, which has been used primarily to obtain the results described in the following section.

## *4. Illustrative Examples of the Use of TEM to Study Soft and Hard Magnetic Materials*

In this section the use of TEM is illustrated with reference to some materials systems of current magnetic interest. Soft and hard magnetic films, as well as displaying many fascinating scientific properties are also of major technological importance. Soft magnetic films are used extensively as sensors whilst hard magnetic films are the material of choice for storing information in hard disks and other recording systems. As an example of the former, some magnetic images from spin-valves are presented (Sect. 4.1) whilst domain studies in thin CoPt films serve to show the kind of small-scale domain structure found in magnetically hard films (Sect. 4.2). TEM is also used to study bulk materials such as hard magnetic alloys used in permanent magnets. However, unlike the case with thin films where specimen preparation is at most restricted to the removal of an underlying substrate, here the magnetic material itself must be thinned. Once thinning is undertaken, particularly to the extent required for TEM, the macroscopic magnetic properties themselves change markedly. Thus, taking sintered NdFeB as an example, the grain size is likely to be in the range of 5–10 μm so that the domain structure existing in such a grain situated in the bulk of the material will be quite different from that in a 100 nm thick section of the material as typically used in TEM. This arises primarily as a consequence of the increased importance of the magnetostatic contribution to the total energy in the latter case. Hence extreme care must be taken in making deductions from TEM domain images. Despite this, useful information can be extracted on, for example, magnetic coupling across grain boundaries. Typical results are presented in Sect. 4.3.

### *4.1 Domain Structures in Spin-valves*

Reduced to its simplest form a spin-valve comprises four thin layers (Dieny 1994, Kools 1996). Two are ferromagnetic films, frequently permalloy, which are separated by a thin non-magnetic spacer, usually copper. On top of one of the ferromagnetic layers is deposited an antiferromagnetic film, which serves to "pin" the magnetization of that layer. Changes in resistance occur when the magnetization orientation of the other magnetic layer—the so-called "free" layer—changes under the influence of a small magnetic field. In the absence of any applied field the orientation of the free layer magnetization is generally parallel to that in the pinned layer due to weak magnetostatic coupling between the layers. A magnetic field of 5–30 Oe is often all that is required to completely reverse the magnetization in the free layer. Under such small fields there is no change in the orientation of the pinned layer magnetization. To overcome the exchange-biasing between the pinned layer and the antiferromagnet and so effect a reversal of the magnetization here, fields well in excess of 100 Oe are the norm. For optimized sensor performance it is important to know the mechanism by which each of the two layers reverses and it is here that Lorentz microscopy has a very important role to play.

Figure 4 shows Fresnel images of a spin-valve taken under different applied fields. Initially both layers are uniformly magnetized and no contrast is seen (Fig. 4(a)). As the field increases, magnetization ripple becomes apparent (Fig. 4(b)) after which a number of domain walls appear (Figs. 4(c, d)) and it is clear that reversal is by domain propagation. The walls are not particularly straight nor are they as mobile as in a single isolated ferromagnetic permalloy layer (Gillies *et al*. 1995). Another feature to notice is that black-white walls form and these can be identified as 360° structures (Figs. 4(e, f)); these have an enhanced stability and do not disappear at the same field as the other walls. Once they have been annihilated the reversal of the free layer is complete and no further contrast changes are seen until much higher fields are applied. If information on the nature of the walls themselves is required, the DPC mode is appropriate. Figure 5 shows an image pair, sensitive to orthogonal in-plane induction components, from some 360° walls formed during the reversal of the free layer. These images, recorded at much higher magnification give direct information of the profile of this complex domain structure.

At higher fields magnetic contrast again appears as the reversal of the pinned layer commences. Figure 6 shows examples of the kind of domain structure that occurs in pinned or exchange-biased layers. The most

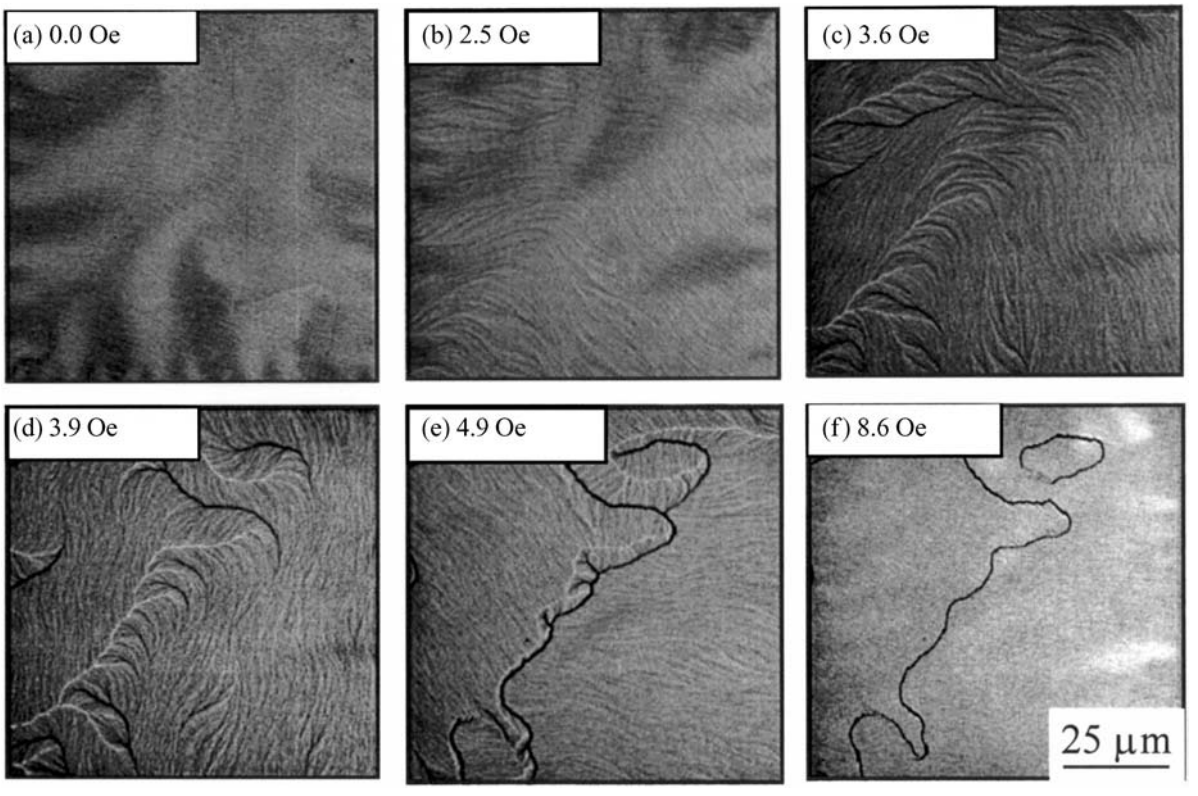

***Figure 4***

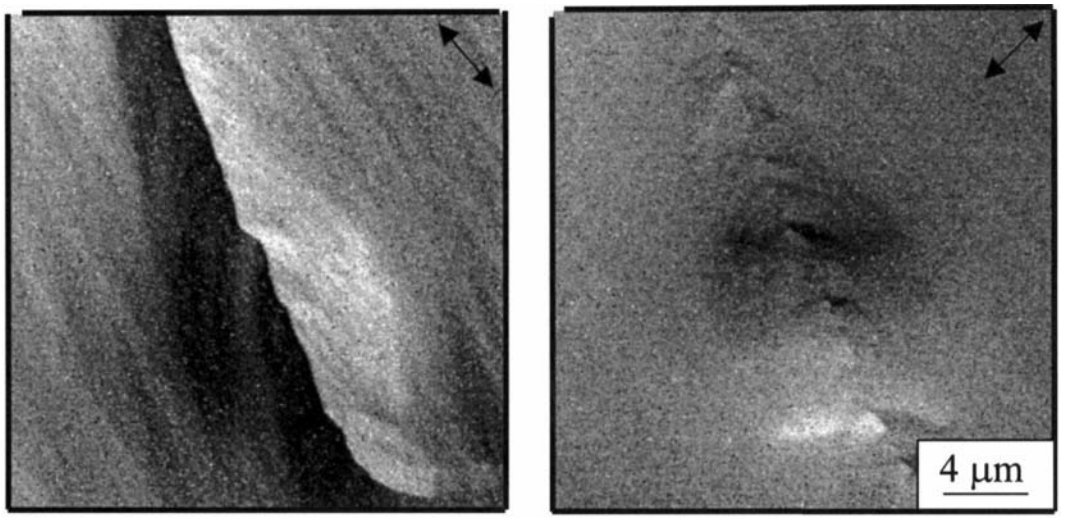

***Figure 5***
DPC images of a 360° wall segment in the free layer of a spin-valve. The arrows denote the direction of induction mapped in each image.

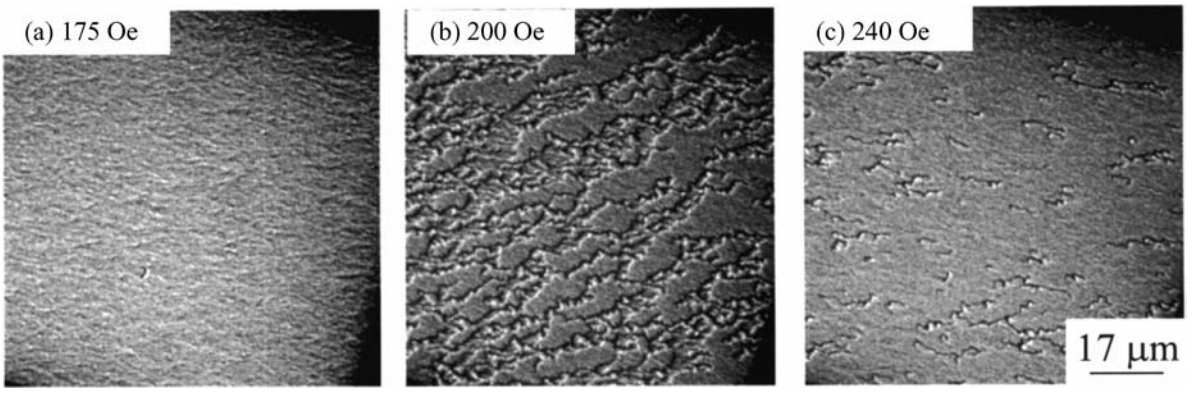

***Figure 6***
(a)–(c) Fresnel image sequence showing magnetization reversal of an exchange-biased layer. Fields at which each image was recorded are shown in the insets.

important point to note is that whilst reversal is again primarily by domain processes, the geometry and scale of the resulting domains are completely different from those observed in the free layer.

### *4.2 Domain Structures in CoPt Films with in-plane Magnetization*

The storage layer in a hard disk is almost universally a thin film with a granular structure (Richter 1999). Most usually the main constituent is cobalt but up to four additional elements can be present in commercial hard disk media, the most important additions being chromium and/or platinum. The films themselves are generally produced by sputtering and have a mean grain size in the 10–15 nm range. The roles of the additional elements are to achieve very small grains with a tight size distribution and to reduce substantially the exchange coupling between individual grains. The latter is of the utmost importance if the medium is to support small domains and this, in turn, is necessary if information is to be stored at high density. If the medium does not support small domains, or if the stability of these domains is low, then the bit pattern, written by the recording head, changes with consequent loss of information. To avoid accidental erasure and to minimize the effect of thermal demagnetization, the coercivity of the cobalt alloys must be high. Hence, if Lorentz microscopy is to be used effectively to study domain processes in hard cobalt alloy films it is necessary to be able to subject the specimen to changing fields in the range 1–3 kOe. Whilst observation in these fields may also be desirable, it is frequently not necessary as it is irreversible changes in the magnetization distribution that are of the greatest interest here. Hence observations can be made, for example, of a remanence as opposed to a hysteresis cycle. Figure 7 shows Foucault images and their associated LAD patterns at different stages in a remanence cycle. Fresnel imaging is not appropriate here as the wall contrast simply does not stand out against the relatively high crystallographic contrast present. From the Foucault images, it is clear that the film does support small domains (linear dimensions of the smallest domains $\leqslant 100$ nm); from the LAD patterns, the overall dispersion of the magnetization in the corresponding states can be assessed from the variation in circumferential intensity around the arcs.

### *4.3 Domain Structures in Thin Sections of NdFeB-type Alloys*

As noted in the introduction to this section, the information obtainable from bulk specimens using Lorentz microscopy is more limited than that from magnetic thin films. Nonetheless much useful information can be gleaned and this is illustrated by reference to studies on NdFeB-type alloys. These alloys are used extensively as high-energy product permanent magnets and derive their attractive properties from a combination of intrinsic and extrinsic properties, the latter depending on the processing to which the materials are subjected (Gutfleisch and Harris 1996, Buschow 1998). TEM is thus needed to characterise both the physical and magnetic microstructures although it is only the latter, which is of interest here. At comparatively low magnifications and in an unmagnetized specimen, Foucault imaging reveals the domain geometry and allows the orientation of the magnetization in the domains to be determined. Mismatches between orientations in nearby grains relate to the overall anisotropy or lack of it in the sample. Furthermore, in some instances estimates can be made of the domain wall energy from studies of wall spacings in grains whose

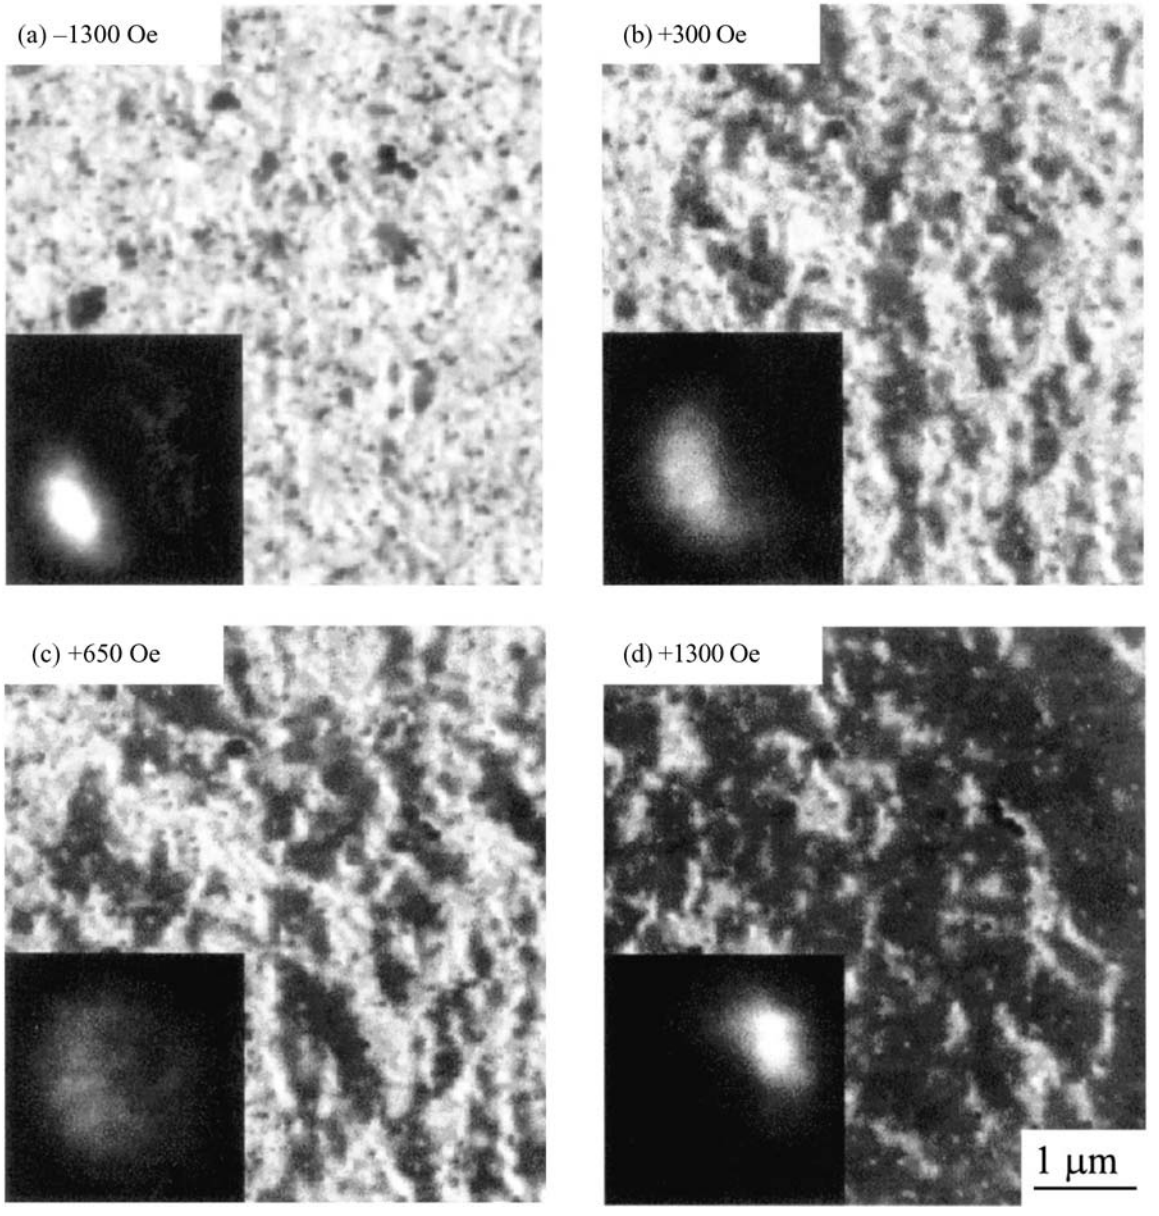

***Figure 7***
(a)–(d) Foucault images and accompanying LAD patterns from a CoPt film in different remanence states following application of the fields shown in the insets.

physical size is much larger than the mean wall separation (Young and Chapman 1993). At higher magnification attention shifts to the boundaries between adjacent grains, as shown in Fig. 8. The Foucault image here shows how the domain structures distort as walls approach the boundaries. Continuity or otherwise across a boundary then provides important information as to whether there is exchange coupling across boundaries or if interactions between grains are primarily magnetostatic in nature.

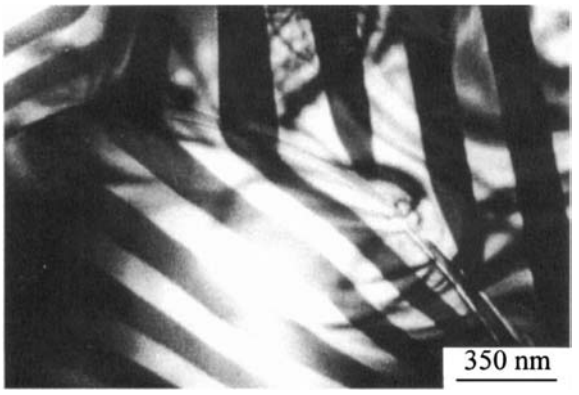

***Figure 8***
Foucault image of the boundary regions between grains in a thinned section of a NdFeB-type alloy.

### *5. Conclusions*

The techniques of Lorentz microscopy provide a powerful and direct means of obtaining experimental micromagnetic information from magnetic films and, to a slightly lesser extent, from thinned sections of bulk magnetic materials. Many of the techniques possess complementary advantages. The experimenter can choose between an imaging mode that is easy to implement and which is suitable for rapid specimen assessment and real-time studies, or one which yields a detailed quantitative description of the distribution of induction at very high spatial resolution. It is noteworthy that the phenomenon of magnetization reversal varies markedly in different material systems. Hence, the ability to observe directly how reversal proceeds, and to study the nature of domain walls involved, provides invaluable insight into the overall magnetic behavior.

## Magnetic Measurements: Pulsed Field

Pulsed high field systems are important for studying physical properties in high magnetic fields. A large variety of experiments is possible here. Therefore, generation and permanent increase of the available

fields is an important topic. The production of high magnetic fields dates back to 1924 where fields up to 200 kOe were produced by discharging a large number of accumulators (Kapitza 1924). Later, as a most common technique, the discharge of large condenser batteries was used in order to achieve fields up to 1 MOe (100 T), but for a short time period, typically several microseconds (Foner and Fisher 1967).

Static fields are nowadays generated using superconducting solenoids. With this technology, fields up to 21 T are available (Brown *et al*. 1996, Kiyoshi *et al*. 1996). Higher static fields can be produced using resistive magnets with a huge power supply of about 10 MW in a polyhelix (Schneider-Muntau 1989) and with 13.5 MW in a combined system using a bitter magnet with a polybitter-type helix, which allows static fields up to 27 T (Bird *et al*. 1996). Hybrid systems combining a superconducting magnet with a resistive magnet generate static fields up to about 40 T. Such machines were constructed at the High Magnetic Field Laboratory (HMFL) in Grenoble, at the National High Magnetic Field Laboratory (NHMFL) in Tallahassee, and also in Japan (Sendai and Tsukuba); for a review see Herlach and Perenboom (1995). Beyond 40 T, transient fields are used. One can differentiate between reproducibly—non destructive—methods and single-shot experiments.

Using a condenser battery in connection with a reinforced and well-optimized wire wound magnet, pulsed fields between 53.6 T (Asano *et al*. 1995) and 72.6 T are reproducibly achieved (Herlach 1994). The typical pulse duration is of the order of 5–10 ms, the amplitude of the produced field is limited by the mechanical properties of the conductors, such as Cu–Ag, Cu–SS (SS: stainless steel), Cu–Nb, etc. (Dupouy *et al*. 1995, Frings and van Bockstal 1995, Foner *et al*. 1988). Fields up to 200 T are produced in single-turn coils (von Ortenberg *et al*. 1996) and up to 550 T by flux compression (Miura *et al*. 1996). These are single-shot experiments with a typical pulse duration of 10 μs. A pulse duration below 1 ms is, for metallic samples, generally too short to obtain reliable results. A survey of the magnet laboratories worldwide using nondestructive pulsed fields is given by Herlach and Perenboom (1995).

The disadvantages of short pulsed fields are eddy currents, which limit the experimental studies of metallic samples. In order to overcome this problem, in several laboratories, systems with quasi-static field pulses (100 ms to 1 s) were built. Examples of such high field facilities are located at the University of Amsterdam (Roeland *et al*. 1989, Gersdorf *et al*. 1965), the new installation at the Technical University of Vienna (Grössinger *et al*. 1999), and the CNRS in Toulouse (Askenazy *et al*. 1989). In these systems quasi-static fields between 40 T and 60 T are achieved. The systems of Amsterdam and Vienna use a regulated current supply, which is directly connected to the line delivering 5.4 MW and 10 MW respectively, at times up to 1 s. In Toulouse a huge condenser battery of 1 MJ is in operation. A larger battery of 12 MJ is just under installation. A new high quasi-static field center is under construction in Dresden. A condenser battery of 1 MJ is used to produce fields up to 50 T in a wire-wound magnet. Additionally, a larger installation with a condenser battery of 30 MJ is expected to allow fields up to 100 T.

## 1. *Applications of High Magnetic Fields to Magnetism*

Experiments that need high magnetic fields cover areas from semiconductor physics (e.g., quantum dots) and superconductivity (organic superconductors, high-$T_c$ super-conductors) to magnetism (phase diagram of rare earth 3d compounds, study of actinide compounds, organic ferromagnets, etc.). A comprehensive survey of applications of high magnetic fields has been compiled (*MRS Bulletin* 1993). In the area of magnetism and magnetic materials, there are many publications with open questions, owing to the necessity for experiments with magnetic fields higher than those available. Some examples are: field-induced magnetism, e.g., in $YCo_2$ and similar compounds (Misawa 1995, Yamada 1995); field-induced changes of the spin structure, e.g., in the $R_2Co_{17}$ and $R_2Fe_{17}$ based materials (Sinnema *et al*. 1986); and also topics related to the application of hard magnetic materials such as the study of the magnetocrystalline anisotropy covering a broad temperature range, e.g., the $Sm_2Co_{17}$ based permanent magnets (Tellez-Blanco *et al*. 1996), $R_2Fe_{14}B$ (Grössinger *et al*. 1985), $R(Fe,Ti)_{12}$ (Kou *et al*. 1993, Grössinger *et al*. 1994) and other materials with high anisotropy.

## 2. *Set-up for a High Field System*

### 2.1 *Block Diagram*

Figure 1 shows the block diagram of a high field system based on a condenser discharge. It consists of a charging unit, a condenser battery, a discharge switch (e.g., thyristors + diode), a pulse magnet, a measuring system and some measuring electronics. The stored energy (units J or Ws) is given by $C \cdot U^2/2$. In other words, the power (W) can be varied by changing the pulse time. The pulse duration is determined by the design of the magnet, which also determines the volume where the field is available and the maximum achievable field. The pulsed field technique can be used for measurements of magneto-resistance, magnetization, magnetostriction and also for more sophisticated techniques such as de Haas–van Alphen or Schubnikov–de Haas effect but also for the determination of elastic constants in high magnetic fields using an ultrasonic method.

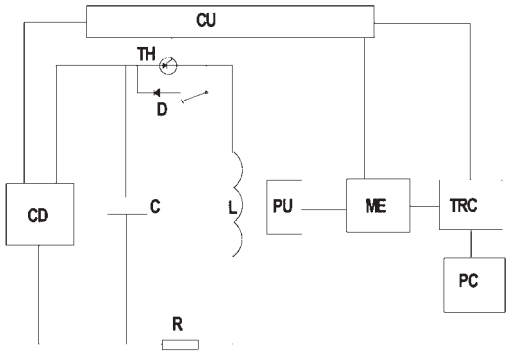

*Figure 1*
Block diagram of a high pulsed field system (CD, charge device; CU, control unit; PU, pick-up system; ME, measuring electronics including amplifier, integrator, differentiator and input protector; TRC, transient recorder; PC, personal computer; R, resistance from wire; C, condenser battery; L, field generating coil "Magnet"; D, diode, TH, thyristor).

### 2.2 The Magnet

High field magnets need high current densities. They are limited mainly by two factors: the heating of the magnet and stresses in the magnet windings.

The adiabatic heating can be calculated from:

$$\int j^2(t)\mathrm{d}t = \int_{T_1}^{T_2} \frac{D \cdot c(T)}{\rho(T)}\,\mathrm{d}T = \Gamma \qquad (1)$$

where $j(t)$ is the current density, $D$ is the density of the conductor, $c(T)$ is the specific heat and $\rho(T)$ is the specific resistivity of the conductor. The temperature rise of a pulse magnet can be calculated assuming that thermal conductivity within the short time of the high-field experiment can be neglected (adiabatic condition). The right-hand side of Eqn. (1) shows that the heating of the magnet is determined only by material parameters of the conductor such as $D$, $c(T)$ and $\rho(T)$. This expression is called the current carrying capability function ("action integral") $\Gamma$ (van Bockstal 1994). The magnet is generally cooled with liquid nitrogen (77 K) in order to reduce the Joule losses.

However, the more serious limiting factor is the stress in the magnet, which is caused by the Lorentz forces. The stress equilibrium condition of the magnet is given by the derivative of the stress in the radial direction:

$$\frac{\partial \sigma_r}{\partial r} = \frac{\sigma_\theta - \sigma_r}{r} - \lambda \cdot F_r \approx \frac{\sigma_C}{r} - \lambda \cdot j \cdot B_z(r) \qquad (2)$$

where $\sigma_r$, $\sigma_\theta$, and $\sigma_z$ are the stress components in cylindrical coordinates, $\sigma_C$ is the yield strength of the wire material, $\lambda$ is the filling factor, $r$ is the distance from the axis, and $F_r = j \cdot B_z$ is the radial body force. Solving this differential equation including boundary conditions (reinforcement, etc.) leads to stress in the $z = 0$ plane, which allows a decision about the mechanical stability of the magnets to be made. Additionally, for stability of the magnets the plastic deformation of the wire material as well as the reinforcement must be considered (Gersdorf and Frings 1995, Liang and Herlach 1995).

The maximum achievable field using a certain conductor material is determined, therefore, by considering both the stresses and the "action integral" $\Gamma$ (Bockstal 1994). So far, the maximum field that can be achieved using standard copper conductors is 40 T. However, it is possible to obtain higher fields when a conductor with a higher yield strength, and/or a stress-adjusted reinforcement of each layer (Askenazy 1995) and/or a variation of the current densities in each layer (Askenazy 1996, Gersdorf and Frings 1995) are realized.

## 3. Magnetization Measurements

For magnetization measurements three main methods exist which can be used in high pulsed fields:

(i) Measurement of the force acting on a magnetic dipole

(ii) Magnetization measurement using the law of induction

(iii) Magneto-optical methods

The first two methods are focused on here.

### 3.1 Force Method

A magnetic dipole recognizes a force in an inhomogeneous field. For static magnetization measurements this method is commonly known as the Faraday balance. In fast-pulsed high magnetic fields, the measurement of magnetic forces is technically difficult, owing to the occurrence of mechanic resonances. However, for long pulsed fields a so-called cantilever method has been developed (Naugthon *et al*. 1998). A small sample is mounted on a semiconducting cantilever, which bends owing to the magnetic force. The bending of this cantilever is proportional to the force on the magnetic dipole. The bending is determined using integrated sensor electronics. In the case of a high magnetic field system, the signal is relatively large, owing to the amplification factor of high fields.

### 3.2 Induction Method

Generally, magnetization is measured using a compensated pick-up coil system, in order to measure the magnetization $M$ instead of the inductance $B$. For this purpose different arrangements of pick-up coils are used. The general idea is always to get a signal which is proportional to $\mathrm{d}M/\mathrm{d}t$. Such systems consist at least of two coils.

The induction voltage in such coils can be given by:

$$u_1(t) = -\mu_0 N_1 K_1 \pi R_1^2 \left(\frac{\mathrm{d}H}{\mathrm{d}t} + \frac{\mathrm{d}M}{\mathrm{d}t}\right)$$
$$u_2(t) = \mu_0 N_2 K_2 \pi r_2^2 \left(\frac{\mathrm{d}H}{\mathrm{d}t}\right)$$
$$u_s(t) = u_1(t) + u_2(t) \qquad (3)$$

where $\mathrm{d}H/\mathrm{d}t$ is the applied field rate, $u_i$, $N_i$, $K_i$, $r_i$ ($i = 1, 2$) are induction voltage, number of windings, coupling factor or radius of the outer ($i = 1$) and inner ($i = 2$) pick up coil, respectively. The addition of $u_1(t)$ and $u_2(t)$ shall be performed in such a way that $u_s(t)$ is proportional to $\mathrm{d}M/\mathrm{d}t$. One can get this condition in the following cases:

(i) An axial two-coils system *N–N*: two identical coils are wound on the same diameter, then we may have $N_1 = N_2$; $r_1 = r_2$ and $K_1 = K_2$ (see Fig. 2). This system is sensitive to the local position and therefore sensitive to vibrations.

(ii) An axial three-coils system $\frac{N}{2}/N/\frac{N}{2}$: compensating coils, $u_2(t)$, are formed by two $N/2$ coils. In this case we have: $N_1 = N$; $N_2 = N/2$; $r_1 = r_2$; and $K_1 = K_2$ (see Fig. 2(b)). This system needs a long homogeneous field.

(iii) A coaxial system where $N_1 \neq N_2$; $r_1 \neq r_2$; $K_1 \approx K_2$ (see Fig. 2(c)). The coaxial systems, which are based on Maxwell coils (a centric spherical coil system) are best suited (Gersdorf *et al*. 1967). The requirement of a larger volume is one of the disadvantages of this system. In the compensated system, from Eqn. (3), we can get:

$$N_1 r_1^2 = N_2 r_2^2 \qquad (4)$$

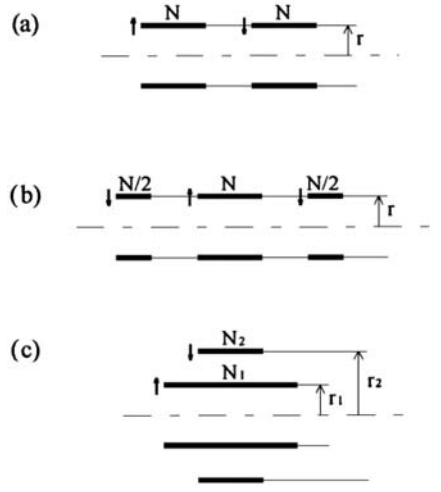

***Figure 2***
Scheme of the different types of pick-up systems for magnetization measurements. See text for details.

In order to achieve an optimum pick-up geometry (length) for a given experiment, also cancelling of the quadrupolar contribution, the homogeneity field range according to the size of the sample and the inductivity of the two coils has to be considered. Finally, a good degree of compensation of the field, which also holds for higher frequency components, should be achieved. However, the compensation is very sensitive to deviations of the radii or lengths of the induction coils. Therefore, all dimensions of the pick-up coil have to be of the highest possible accuracy ($\approx 0.001$ mm). The sensitivity of measuring magnetization is limited by the remaining unbalance of the pick-up system. It is worth noting that for measuring paramagnetic substances a compensation of $1 \times 10^6$ is desired! The dynamic behavior of such systems is described by the transfer function. Especially in this case, possible resonance peaks have to be avoided.

It should be mentioned that the degree of compensation changes with temperature, owing to the thermal expansion of the supporting materials. Therefore, in this case, the use of supporting materials with a very low thermal expansion (as, e.g., quartz glass, ceramics) or additional position coils which allow a readjustment of the system at each temperature, is suggested. Below 20 K, the magnetoresistance effect of the wire, which may change the calibration constant of the pick-up coils, must be considered.

The magnetization of the magnetic materials is obtained by integrating $\mathrm{d}M/\mathrm{d}t$. Generally, in quasi-static systems, owing to the low frequency integration, this method presents a bad signal-to-noise ratio, resulting in low sensitivity. To improve the signal-to-noise ratio, two different methods for measuring the magnetization are proposed: modulation and vibration techniques. In the first method, the field pulse $H(t)$ will be modulated by a small a.c. field of the type $H_{\mathrm{ac}} = H_0 \sin \omega t$ (with $H_0 \ll H$ and $T \ll \tau$; where $T$ is the period of a.c. field and $\tau$ is the pulse duration). The disadvantage of this method is that the technique of modulating a high field pulse is very complicated. In the second method, the sample can be mounted on a vibrating piezoelectric actuator. The frequency is chosen according to the characteristics of the quasi-static pulse field system. For example, 100 kHz is sufficient for a 100 ms to 1 s quasi-static system. However, generally the amplitude of a piezoelectric system decreases with increasing frequency.

In both cases a periodic induction voltage is produced in pick-up coils, allowing use of a lock-in technique which combines a high Q band pass with a phase-locking method, improving the signal-to-noise ratio drastically. However, for fast a.c. field measurements of a metallic sample in a short pulse magnetic field, the skin effect (penetration of the magnetic field into the material) has to be considered.

***Table 1***
Skin depth of conducting materials.

| Frequency | $\delta_{Cu}$ (mm) | $\delta_{Nd\text{-}Fe\text{-}B}$ (mm) |
|---|---|---|
| 100 Hz | 11 | 69 |
| 100 kHz | 0.35 | 2.2 |

The skin depth, $\delta$, is given by:

$$\delta = \sqrt{\frac{2}{\omega \cdot \mu_r \cdot \mu_0 \cdot \sigma}} \qquad (5)$$

where $\mu_r$ is the relative permeability, $\mu_0$ is the vacuum permeability and $\sigma$ is the conductivity of the material. To compare the skin depth values between good and bad conductors (Cu: $1/\sigma = 5 \times 10^{-8}\,\Omega$m; Nd–Fe–B: $1/\sigma = 200 \times 10^{-8}\,\Omega$m) Table 1 shows $\delta$ values obtained for a pulse duration of 10 ms and for a modulating frequency of 100 Hz and 100 kHz.

Two factors are extremely important for an accurate magnetization measurement in a pulsed high-field magnetometer, namely: (a) field and magnetization calibration of the magnetometer and (b) eddy current effect in conducting magnetic materials.

*(a) Calibration of pulsed field magnetometer*

In a magnetometer the field and the magnetization have to be calibrated. For pulsed magnetic high-field calibration, the "calibration sample" method is often used. For low temperature magnetization measurements, samples with well known critical fields at which a magnetic transition occurs are chosen for the field calibration. One example is the anti-ferromagnetic $MnF_2$ where at a field of 9.2 T a spin-flop transition occurs at 4.2 K. For high temperatures, the field is usually calibrated to the internal anisotropy field, $H_A$, of barium ferrite ($H_A = 1.65$ T, at room temperature). This material is chosen because $H_A$ changes only slightly around room temperature (Kojima 1982). The magnetization $M$ is usually calibrated using the $M(H)$ of pure nickel or iron.

The reliability of pulsed field measurements was tested by comparison with static measurements performed at the CNRS in Grenoble. Figure 3 shows hysteresis loops measured on an isotropic barium ferrite sample obtained in the static system of Grenoble and that measured in a well-calibrated pulsed field system (TU Vienna). The use of barium ferrite has the advantage that there are no eddy currents, because this material is insulating. The difference is within the line thickness.

*(b) Eddy current effect*

The effect of eddy currents in the sample depends on the sample geometrical dimensions and the pulse

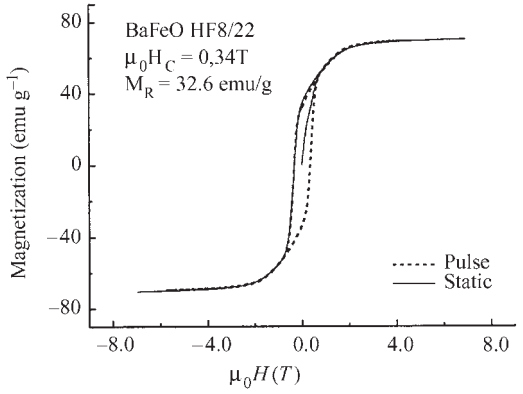

***Figure 3***
Hysteresis loop measured on the isotropic BaFeO HF 8/22 spherical sample.

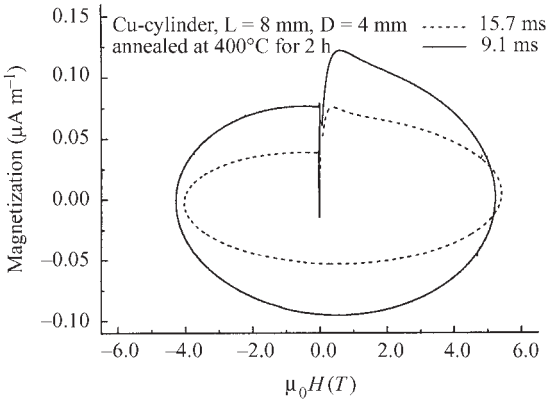

***Figure 4***
Hysteresis loops measured on a cylindrical copper sample with $\mu_0 H_{max} = \pm 5.7$ T and two different pulse durations of 9.1 ms and 15.7 ms.

time. For a cylinder of nickel of about 4 mm in diameter and a pulse time of about 15 ms the eddy current effect in the magnetization is about 2%. Theoretically, for a well defined sample geometry, it is possible to correct the eddy current effect to the magnetization, but use of a nonconducting soft magnetic calibration is preferred (Grössinger *et al.* 1999). For this type of calibration, material such as $Fe_3O_4$ is proposed.

In pulsed field measurements, the effect of eddy currents that occur in a metallic sample is shown by measuring the mean magnetization that is generated by these currents. Figure 4 shows, as an example, the magnetization curve measured on a cylindrical copper sample at room temperature applying a field pulse with $\mu_0 H_{max} = \pm 5.7$ T at two different pulse

durations, namely 9.1 ms and 15.7 ms. The increase of the eddy current moment with decreasing pulse duration is clearly visible. The phase shift between magnetization and field is approximately 90°. The experimentally determined eddy currents agree well with a Finite Element calculation. It was shown that plotting the eddy current magnetization versus $dH/dt$ delivers a linear relation which can also be explained theoretically (Grössinger *et al*. 1999).

## 4. The SPD method

A very important magnetic property of hard magnetic materials is the magneto-crystalline anisotropy (see *Magnetic Anisotropy*). Generally, to investigate this anisotropy a direction-dependent study of single crystals is needed. In many cases such single crystals of technically relevant materials are not available. Often, hard magnetic materials cannot be aligned, owing to special preparation methods. In this case the so-called SPD method (Asti and Rinaldi 1974) is a unique technique for determining the anisotropy.

The SPD method is based on the idea that in higher derivatives of the magnetization with respect to the field, $d^nM/dH^n$, a singularity appears just at that field where $H_{ext} = H_A$. In the case of a uniaxial material the second derivative of the magnetization is already sufficient. The amplitude of the singularity is proportional to the ratio of anisotropy constants $K_2/K_1$ and also proportional to the distribution function of the crystallites. Additionally, the amplitude is determined by $\omega^2(H_{max}^2 - H_A^2)$. This means that a maximum external field sufficiently higher than the anisotropy field is necessary. Moreover, the pulse time $\tau$ ($\omega \approx 2\pi/\tau$) should be as short as possible taking into account that the scaling is proportional to $\omega^2$ and that the noise is reduced with increasing frequency. An example of the use of the SPD method is shown in Fig. 5. It shows singularities obtained by measurement (a) and by calculation (b) for the polycrystalline $Sm_2Co_{17}$ at room temperature. Although the theoretical peak is sharper than that obtained by experiment, an excellent agreement in the peak position is observed.

The SPD method delivers the physically real anisotropy field, $H_A$, from which, knowing the saturation magnetization, the technically relevant anisotropy energy can be obtained.

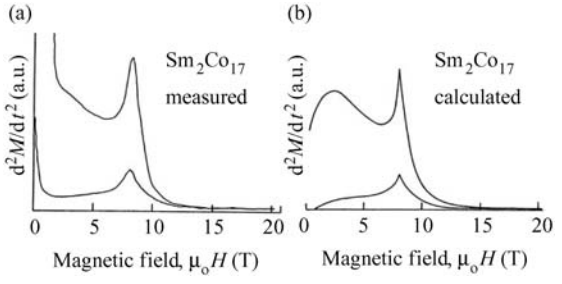

***Figure 5***
Measured (a) and theoretically calculated (b) singularity of polycrystalline $Sm_2Co_{17}$ at $T = 300$ K.

## Magnetic Measurements: Quasistatic and ac

It is of great importance to develop and to improve measurement systems for groups of magnetically ordered materials, which have special demands with respect to typical sample shapes and also to the field range. A magnetically ordered material is characterized by its critical temperature, the Curie temperature $T_C$, which is proportional to the exchange energy. In rare earth–3*d* based materials at low temperatures a spin reorientation may occur due to the interplay between the different sub-lattice magnetization or because of the crystal electric field (see, e.g., Kou *et al.* 1993, 1995a, 1998, Grössinger *et al.* 1996). One of the usual methods determining these critical temperatures is the measurement of a.c. susceptibility in low fields as a function of temperature.

The most important technique to characterize magnetic materials is the measurement of their hysteresis loop (see *Magnetic Viscosity*). Figure 1 shows a typical hysteresis loop of a ferromagnetic material with all the significant parts and points of the loop. A loop like this is obtained by applying a cycle of magnetic field $H$ to a magnetic material and by recording the change of the magnetization $M$ or of the magnetic induction $B$ along the field direction. Hysteresis loops may take many different shapes and are important for obtaining parameters that give a first characterization of loop properties such as the coercive field $H_c$, and the remanence $M_r$. The technically relevant materials differ only in the special properties of the loop (see Table 1). For hard magnetic materials the coercive field lies between 80 and 1600 $kAm^{-1}$, whereas for soft magnetic materials the coercive field is below 100 $Am^{-1}$.

An additional parameter of basic importance in the characterization of soft magnetic materials is the power loss, which is proportional to the area of the hysteresis loop. The most important parameter characterizing the strength of a hard magnetic material is the maximum energy product, which gives a measure of the energy density available in the magnet for external work. The coercive fields of magnetic recording materials lie somewhere between those of hard and soft materials. In both cases the saturation magnetization, $M_s$, should be as high as possible. Generally,

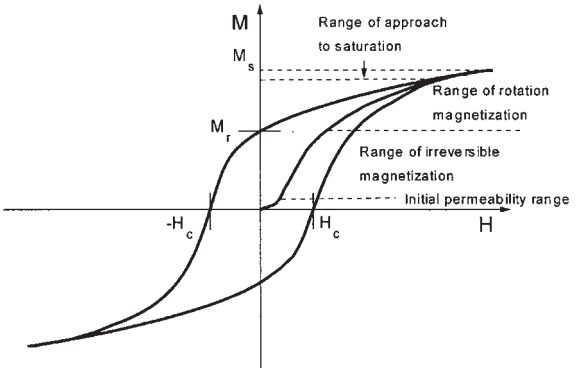

***Figure 1***
Hysteresis curve of a ferromagnetic material.

***Table 1***
Comparison of important magnetic properties between soft and hard magnetic materials.

| | Soft magnetic material | Hard magnetic material |
|---|---|---|
| Saturation magnetization | As high as possible (0.8–2 T) | As high as possible (0.2–1.5 T) |
| Coercive force | As low as possible ($<100\,\mathrm{Am}^{-1}$) | As high as possible ($80–400\,\mathrm{kAm}^{-1}$) |
| Permeability | As high as possible 10 000–200 000 | Not important |
| Losses | As low as possible, frequency-dependent | Area of loop $\cong$ stored energy as high as possible |
| Shape of loop | Important because it determines application | Important and should be rectangular |
| Remanence | Not important | As high as possible |
| Conductivity | Determines a.c. losses | Important for magnetizing procedure |

for obtaining the "true" saturation magnetization the law of approach to saturation extrapolating for $H \to \infty$ or fitting the $M(H)$ curve (Akulov 1931, Gans 1932, Grössinger 1981) may be applied.

In addition, the loop itself as well as parts of the hysteresis (initial curve, minor loops, recoil curves) is used for modeling, and this yields an understanding of the magnetization process (Mayergoyz 1991, Bertotti 1996, Hauser 1994).

A hysteresis loop can be created in terms of $B(H)$ or of $M(H)$, where $\mathbf{B} = \mu_0(\mathbf{H} + \mathbf{M})$. For technical applications $B(H)$ is more important whereas for scientific investigations $M(H)$ is generally used. In contrast to hard materials where $H$ and $M$ have comparable orders of magnitude, in a soft material (for low $H$) plotting $B(H)$ or $M(H)$ makes no difference due to a very good approximation, $\mathbf{B} \cong \mu_0\mathbf{M}$. In hard magnetic materials ${}_{\mathrm{I}}H_{\mathrm{C}} > {}_{\mathrm{B}}H_{\mathrm{C}}$, whereas in soft magnetic materials both coercivities are equal (${}_{\mathrm{I}}H_{\mathrm{C}}$ is coercivity where $\mathrm{I} = \mu_0\mathbf{M} = 0$, ${}_{\mathrm{B}}H_{\mathrm{C}}$ is coercivity where $\mathbf{B} = 0$). Therefore a hysteresigraph for soft magnetic materials is technically different from that of a system suited for hard magnetic materials or for recording materials.

Consequently, within this contribution two groups of measurements will be proposed which are important for characterizing hard and soft magnetic materials:

A.c. susceptibility. The temperature dependence of the susceptibility yields the Curie temperature, spin reorientation temperature, freezing temperature for spin glasses, magnetic relaxation, etc. and also domain parameters such as the Rayleigh constant and the pinning field;

Magnetization and hysteresis loop. This delivers the coercive force, remanence, saturation magnetization, and energy losses (or stored energy) and also gives information about the magnetization process. A special type of instrument used here is a torque magnetometer which allows determination of the anisotropy constants.

## *1. Susceptibility Measurements*

### *1.1 Theoretical Considerations*

Starting from a demagnetized state of the hysteresis loop, the inclination of the initial curve is called the initial susceptibility $\chi_{\mathrm{i}}$ (if one considers $M = \chi_{\mathrm{i}}H$) or the initial permeability $\mu_{\mathrm{i}}$ (if one considers $B = \mu_{\mathrm{i}}H$). For a soft magnetic material the initial susceptibility is very high and $\mu_{\mathrm{i}} \approx \chi_{\mathrm{i}}$.

In randomly oriented particle systems, polycrystalline bulk materials where due to the presence of differently oriented crystal grains a random variation of anisotropies exists, or in magnetically soft materials where a fluctuating internal stress couples magnetoelastically to the magnetization, the response to small fields is mainly controlled by the local anisotropy fields. In this simple case the initial susceptibility can be written as:

$$\chi_{\mathrm{i}} = \frac{\mu_0 M^2{}_{\mathrm{s}}}{cK} \tag{1}$$

where $K$ stands for all kinds of anisotropy energies including the magnetoelastic energy and $c$ is a dimensionless factor dependent on the specific distribution of the anisotropy axes of anisotropy constants. Very often an additional contribution comes from the actual microstructure. However, this is very difficult to estimate.

With increasing fields the first irreversible losses have to be considered. If local inhomogeneities (local stress centers, etc.) occur a well-defined pinning field can be observed as will be discussed below. The different field dependencies of the permeability are shown in Fig. 2. The hysteresis loop of low fields, where the maximum fields involved are much smaller than the coercive field, can be described by the Rayleigh law (Fig. 2(a); see, e.g., Jordan 1922 or Chikazumi 1964). Within the Rayleigh law, under small but finite fields, the permeability consists of two contributions: the reversible magnetization is

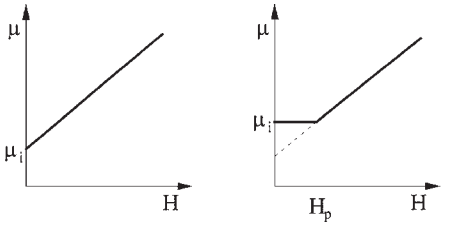

***Figure 2***
Field dependence of the permeability: (a) assuming the Rayleigh law; (b) showing an initial range below $H_p$.

described by the first term (initial permeability $\mu_i$) and the irreversible part that depends on the square of the field:

$$B = \mu_i H + \nu H^2 \tag{2}$$

where ν is the Rayleigh constant. This law is important in principle as a description of the initial steps of irreversibility.

If a magnetic material is magnetized by an a.c. field $H = H_0 e^{i\omega t}$, the magnetic flux density $B$ is delayed by the phase angle $\delta$ because of the presence of losses and is then expressed as $B = B_0 e^{i(\omega t - \delta)}$. The permeability is given by:

$$\mu_r = \frac{B}{\mu_0 H} = \frac{B_0 e^{i(\omega t-\delta)}}{\mu_0 H_0 e^{i\omega t}} = \frac{B_0}{\mu_0 H_0} e^{-i\delta} = \mu' - i\mu'' \tag{3}$$

where the real part is $\mu' = (B_0/\mu_0 H_0)\cos\delta$ and the imaginary part $\mu' = (B_0/\mu_0)\sin\delta$. The imaginary part is related to the losses. Another important loss contribution for ferromagnetic metals and alloys is the eddy current loss. Since a power loss of this type increases proportionally to the square of the frequency, it plays an important role in the high-frequency range.

Generally in soft magnetic materials due to the existence of well-defined local pinning centers a critical field, the pinning field $H_p$, is often observed (see Fig. 2(b)). Up to $H_p$ the permeability is constant and for an applied field higher than $H_p$ the permeability increases. If a linear behavior is observed the permeability can be described by a modified Rayleigh law:

$$\mu = \frac{B}{H} = \mu_i + \nu(H - H_p) \tag{4}$$

If one considers now the magnetization curves in more ordinary materials where the presence of structural defects or disorder plays a dominant role under most circumstances, the measurement of the a.c. susceptibility is one of the techniques to characterize these materials. In hard magnetic materials the shape of the virgin magnetization curve as well as the shape of the loop with increasing external field is used to determine roughly the different types of magnetization processes (nucleation or pinning controlled) (Becker 1976).

### *1.2 Experimental Determination of the a.c. Susceptibility*

As shown above the measurement of the initial susceptibility (in a field which should be small compared with the coercivity) as a function of temperature is important. Because the susceptibility is roughly proportional to $1/K$ (Eqn. (1)) it shows a dramatic change at any spin reorientation temperature, crystallization temperature, or the Curie temperature, because the anisotropy goes much faster to zero than $M_s$. For this purpose a small a.c. field is applied to a sample which is surrounded by a pick-up coil. In principle the a.c. susceptibility can be measured in most hysteresigraph systems (using an air coil), where one has just to drive the magnet with a low a.c. field. The pick-up coil system is then connected to a lock-in amplifier which can measure the real and imaginary parts of the susceptibility simultaneously. A block diagram suitable for soft magnetic ribbons is shown in Fig. 3. In this device an external stress can also be applied to the sample which additionally causes an effect on the domain configuration (Holzer 1998). In the case of a hard magnetic material the ribbon is replaced by a (spherical) sample inside a compensated pick-up system.

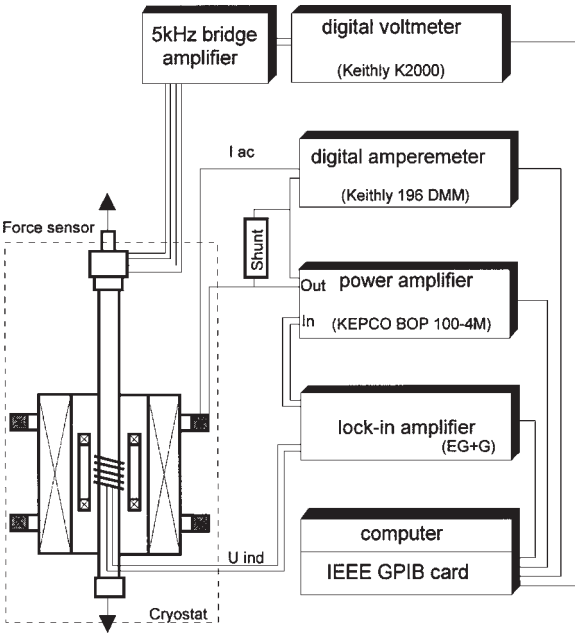

***Figure 3***
Setup for a.c. susceptibility measurements (after Holzer 1998).

The temperature of the sample can be varied by using either a furnace or a cryostat. The susceptibility deduced for a lock-in amplifier ($U_{ac}$ = RMS value of the signal) is given by:

$$\chi = \frac{U_{ac}}{N_{pick}\mu_0 2\pi f k I_{ac} X} = \mu - 1 \qquad (5)$$

where $N_{pick}$ is the number of turns of the pick-up coil, $f$ is the frequency of the a.c. current, and $k$ is the calibration factor of the field coil. For a ribbon $X = A_{rib}$ (cross-section of the sample) because the ribbon is much longer than the pick-up coils. For a small sample, $X$ takes the value of the area of the cross-section of the pick-up coil (e.g., a hard magnetic spherical specimen). The voltage $U_{ac}$ is in any case proportional to the mass of the sample—the calibration factor has to be determined experimentally.

For an absolute value of the measured susceptibility, the following points have to be considered. In the case of thin long samples such as amorphous ribbons one can measure on toroid and open ribbons:

*Toroid ribbon*: this is a magnetically closed circuit, which means the demagnetizing factor is zero. The disadvantage is that in the case of a soft magnetic thin ribbon this is not a stress-free state. Also stress-dependent measurements are not possible on a toroid. It should be mentioned that the domain structure of soft magnetic materials is strongly stress-dependent (Badurek *et al*. 1988, Veider *et al*. 1986);

*Straight ribbon*: this is not a closed magnetic circuit. Therefore, the measurements in low fields are very sensitive to external fluctuating fields. Either a very effective shielding or an accurate earth field compensation is essential for soft magnetic materials. Additionally the demagnetizing factor $N$ may be considered. The effective susceptibility with the internal field $H_{int}$ can be described as:

$$\chi = \frac{M}{H_{int}} = \frac{M}{H - NM} = \frac{\chi_{meas}}{1 - N\chi_{meas}} = \frac{1}{(1/\chi_{meas}) - N} \qquad (6)$$

For a soft magnetic material $\chi$ is large which means that the measured $\chi$ is proportional to $1/N$. Therefore the samples should be very long compared with the cross-section in order to reduce $N$. For hard magnetic materials $\chi$ is small and proportional to $1/K$.

## 2. Magnetization Measurements

There are many techniques for measuring hysteresis loops and magnetization. The majority of them is based on the law of induction. Besides this, devices exist where the magnetization is measured via the force of a dipole in an inhomogeneous field (Faraday balance) or even magneto-optically by measuring the Faraday rotation due to the magnetization. The latter method is, of course, important for recording materials. Figure 4 shows a sketch of the Faraday method. The field can be produced using a solenoid which can be also superconducting or have an iron-yoke. In the case of an electromagnet the specially shaped pole pieces generate a field gradient in the air gap. The force can be measured by all kinds of force sensors such as strain gauges or piezoelectric sensors. Also torque magnetometers, in which a single crystalline sample feels a torque $\mathbf{L} = \mathbf{m} \times \mathbf{H}$ in a magnetic field, are based on similar principles. These systems are very important for studying magnetocrystalline anisotropy.

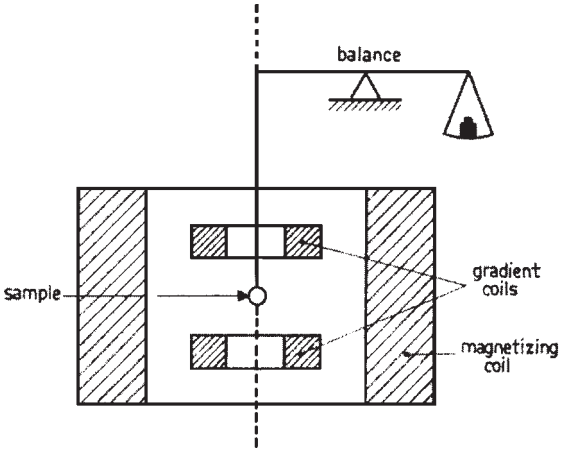

***Figure 4***
Sketch of a Faraday balance arranged in a solenoid.

One can consider two main possibilities for induction-based methods.

The first is that one can integrate the induction voltage which is proportional to $dB/dt$ and consequently to $dM/dt$ during the variation of the field. Generally this method is a d.c. technique because the variation of the field, which is produced by an electromagnet or by a superconducting magnet, is performed slowly. This technique needs a very stable integrator. The sensitivity is limited principally by the thermal drift of the system as well as by the $1/f$ noise.

The second method uses a type of modulating method either by vibrating the sample or by slowly modulating the varying field. This technique overcomes the drift problem. In this case the induced voltage $u$ is a periodic signal which is proportional to $dM/dt \sin(\omega t + \delta)$. Normally in this technique a lock-in amplifier is used which provides a drastically enhanced signal-to-noise ratio due to reduction of the bandwidth of the system. In metallic samples the frequency is chosen such that eddy current effects can be avoided. Consequently the frequency is rather low ($< 82$ Hz), so drift problems can be overcome but the $1/f$ noise problem cannot be solved completely.

### *2.1 Vibrating Sample Magnetometer*

A vibrating sample magnetometer (VSM) is a state-of-the-art device for magnetization measurements. There exist several commercial VSMs which operate from very low temperatures up to about 1000 K. In a VSM the sample is driven by a mechanically vibrating system and the signal is measured by a pick-up system. The first working model of a VSM was assembled by Foner (1956) using a reduced-amplitude 60 Hz line excitation of a loudspeaker. The sample vibrates perpendicularly to the applied field. Small permanent magnets were used to generate a reference signal in order to stabilize the movement of the loudspeaker. Field modulation combined with lock-in amplification was used for signal processing and a lock-in amplifier was used to enhance the signal-to-noise ratio. Later, Foner (1959) described a more standard version of a VSM in a comprehensive paper. In the first system electromagnets generated the external field. With the development of high-field superconductors, superconducting solenoids were introduced into the VSM, producing fields up to about 20 T. These systems are commercially available for measurements from low temperatures up to furnace systems. The principal setup of a VSM is shown in Fig. 5.

### *2.2 SQUID Magnetometer*

SQUID (superconducting quantum interference device) magnetometers are generally used to measure the magnetization of very small samples (e.g., thin films) or systems that are just on the limit of magnetic order. Therefore, SQUID magnetometers are mainly applied to scientific investigations. Measuring materials with a high magnetization requires the use of an attenuator, but due to their very great sensitivity geological, biological, and medical applications are increasing. The operation of a SQUID magnetometer is based on two effects: flux quantization and the Josephson effect.

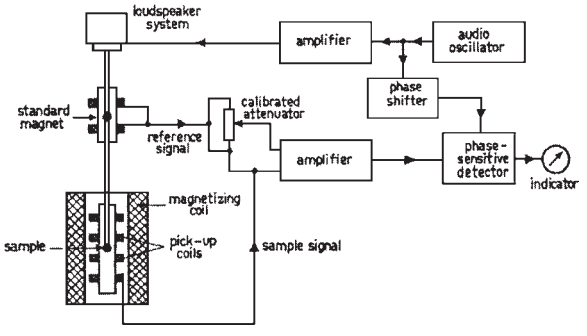

***Figure 5***
Principal setup of a VSM.

The classical Josephson junction consists of an insulating barrier between two superconductors thin enough to couple "weakly." This allows an electron pair tunneling via the barrier. The flux $\Phi_0$ in the superconducting state is quantized in steps of $\Phi_0 = h/2e = 2.07 \times 10^{-15}$ Wb, where $h$ is Planck's constant and $e$ is the electron charge. Due to the different types of electronic readout, a SQUID consists basically of a superconducting ring interrupted at one or two positions by a Josephson junction. SQUIDs with one junction are RF-SQUIDs (radio-frequency) and those with two junctions are d.c.-SQUIDs (see *SQUIDs: The Instrument*).

Figure 6 shows the basic electronic circuit of a RF-SQUID. The peak value of the voltage drop $V_{rf}$ across the tank circuit is measured by a RF amplifier together with a detector. This signal has to be set in relation to the RF signal at a power $P_{rf}$ applied to the tank circuit. The value of $V_{rf}$ depends on the low-frequency input signal, i.e., the flux $\Phi_{ext}$ is applied to the SQUID ring via the inductively coupled input coil. The advantage of a RF-SQUID is that the use of a high-frequency a.c. signal allows the application of a.c. techniques which improve the signal-to-noise ratio. Unlike the inductive detector VSM, whose output is proportional to frequency, the output of the SQUID detector is independent of frequency.

The SQUID generally operates at 4.2 K since the critical temperature of superconductors is low. High-$T_C$ superconductors allow systems to operate at temperatures up to 77 K. Since the SQUID is an extremely sensitive flux detector it must be carefully

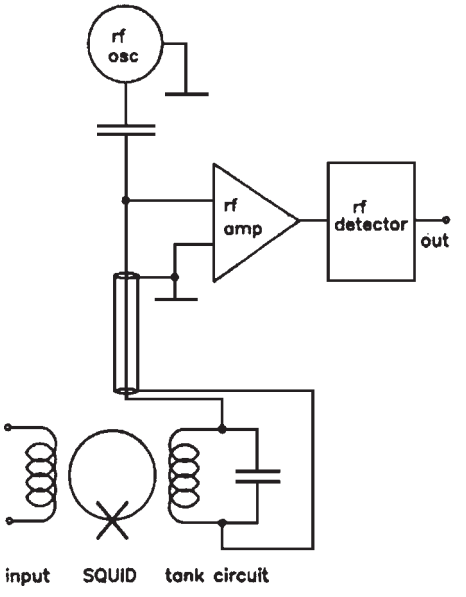

***Figure 6***
Block diagram of a RF-SQUID.

shielded. But the high sensitivity means it can be used to measure very small fields. There are SQUID magnetometers which operate in external fields up to 6 T. They can also be used for medical applications such as measuring brain currents. A good survey of this field is given by Koch (1991).

### 2.3 Pulsed Field Magnetometer

Generally, pulsed field systems are used for measurements in high external fields which are above those which are available as static fields. This means that such magnetometers are used in fields up to 100 T (Herlach 1994) and higher. However, there are also technical applications which are interesting because here the easy-to-handle factor and fast measurement becomes important. Modern high-quality permanent magnets, such as Sm–Co- or Nd–Fe–B-based materials, need rather high magnetic fields in order to measure the hysteresis loop. Static fields such as those available with Fe-yokes (up to about 2 T) are not sufficient here. Additionally, static hysteresis measurements take too much time for an industrial production control. Using pulsed field magnetometry full hysteresis loops $M(H)$ of a hard magnetic material can be measured very quickly and with an accuracy of 1% at room temperature (for details see *Magnetic Measurements: Pulsed Field*).

## 3. Characterization of Soft Magnetic Materials

Soft magnetic materials (see *Magnets, Soft and Hard: Magnetic Domains*), such as Fe–Si strips, amorphous ribbons, or nanocrystalline materials, exhibit a special geometry. Because of its technical importance Fe–Si needs a very accurate and standardized determination of the hysteresis properties. For measuring the losses as well as the permeability in fields that are not too high the so-called Epstein frame (Epstein 1900) is well established (see *Magnetic Hysteresis*).

New kinds of soft magnetic materials such as amorphous ribbons based on a 3*d* metal (Fe, Co)–metalloid (B, Si, C) compound (see, e.g., Luborsky 1983) are thin ribbons (typical thickness 20–50 μm, width 1–15 mm) produced by rapid quenching through melt spinning. Some of them can be transformed after special heat treatment into the nanocrystalline state and they also exhibit excellent soft magnetic properties (Yoshizawa *et al*. 1988, Herzer 1990) (see also *Amorphous and Nanocrystalline Materials*). The ribbon-like geometry requires special equipment. Due to their very low coercive field (typically between 1 and 20 $Am^{-1}$) standard magnetometers using either an electromagnet or a superconducting solenoid cannot be used, since the lowest achievable field is determined by the remanence of the system which is in the order of 10 $kAm^{-1}$.

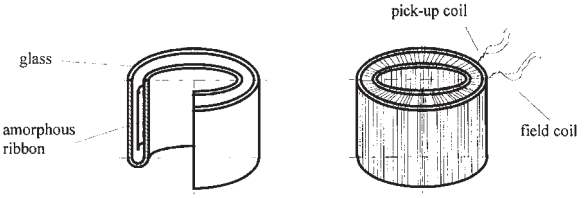

***Figure 7***
Example of a toroidal measurement facility suited for use in a furnace: glass toroid, sample, and coils.

Additionally, at very low fields, the electromagnetic noise of the surroundings is a limiting factor. As examples, two systems suitable for scientific applications are described which allow measurements at both low and elevated temperatures.

The magnetic properties of soft ferromagnetic ribbons (hysteresis loop, susceptibility) can be measured either on toroidal samples or on single strips. The toroidal sample (see Fig. 7) has the advantage that, to the first order, the demagnetizing field can be neglected, which is important especially for permeability and loss measurements such as in an Epstein frame. However, for determining the saturation magnetization, this shape is no more advantageous due to the increase in the stray field of the system with the increase of the applied field, which causes an undefined error.

### 3.1 Low-temperature Hysteresis Loops

Low-temperature measurements are generally important in order to test the validity of theoretical predictions such as the Bloch law (Bloch 1930) or the $l(l+1)$ power law for the anisotropy and magnetostriction (Callen and Callen 1966). For the system that will be described here (see Fig. 8) the temperature dependence of the hysteresis loops can be measured on wires, single ribbons, or thin sheets. Due to the special geometry of the setup, an external stress can also be applied which is very useful for studying the effect of the magnetoelastic energy on the hysteresis. This effect is especially important for sensor applications.

Figure 8 shows a system that measures hysteresis loops between 4.2 K and room temperature. The facilities necessary for measuring the hysteresis loop are field coils (cylindrical coil + Helmholtz coil), a compensated pick-up coil, a current source, an amperemeter, and an integrator (fluxmeter). The devices can be connected and controlled by a data acquisition and control unit forming a fully automatic hysteresis loop system. The external stress is measured by a strain gauge bridge. To avoid the influence of eddy currents and magnetic relaxation effects measurements are performed quasi-statically (0.05–0.03 Hz).

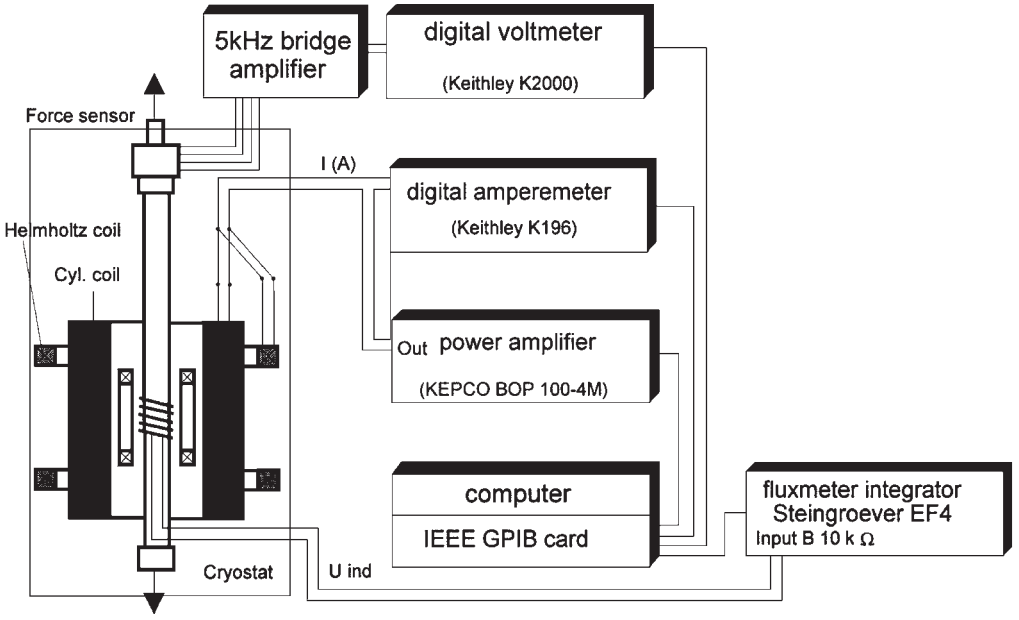

***Figure 8***
Hysteresigraph for quasi-static hysteresis measurements and device for force measurements (Polak 1992, Holzer 1998).

In this case the measurement of one hysteresis loop takes 20–30 s. The magnetic field is deduced from the current measured by the amperemeter and the induction from the magnetic flux is measured by the integrator. Since the change of the induction voltage is slow, a very stable industrial integrator (e.g., Fluxmeter Steingroever EF4) is required. Effectively it is a d.c. method where the drift is a limiting factor.

When a time-dependent magnetic field is applied, the induction signal in the pick-up coil is:

$$u_{\text{pick-up}} = -N_{\text{pick}}\frac{\mathrm{d}\Phi_{\text{pick-up}}}{\mathrm{d}t} = -N_{\text{pick}}\mu_0\left(A_{\text{rib}}\frac{\mathrm{d}M}{\mathrm{d}t} + A_{\text{pick}}\frac{\mathrm{d}H}{\mathrm{d}t}\right) \quad (7)$$

and the induction signal in the compensation coil is:

$$u_{\text{comp}} = -N_{\text{comp}}\frac{\mathrm{d}\Phi_{\text{comp}}}{\mathrm{d}t} = -N_{\text{comp}}\mu_0 A_{\text{comp}}\frac{\mathrm{d}H}{\mathrm{d}t} \quad (8)$$

Then in the compensated system the signal is:

$$u_{\text{ind}} = u_{\text{pick-up}} - u_{\text{comp}} = -N_{\text{pick}}\mu_0 A_{\text{rib}}\frac{\mathrm{d}M}{\mathrm{d}t} \quad (9)$$

For this measurement system there are three important points.

The resistance of the pick-up system is temperature-dependent for low-temperature measurements. The resistance of a pick-up system with many windings can be several hundreds of Ohms at room temperature, which can change by a factor of 7 to 10 when it is cooled down to 4.2 K. Generally, the input resistance of a fluxmeter is not very high (typically 10 kΩ); therefore, this has to be taken into consideration in the calibration procedure.

A zero-signal must be subtracted. This is necessary because the compensation changes with temperature.

Equation (9) contains also the cross-section $A_{\text{rib}}$ of the ribbon. Therefore, it is very difficult to obtain an accurate value of $A_{\text{rib}}$ of amorphous or nanocrystalline ribbons due to fluctuations in thickness as well as in the width. This often limits the accuracy of the determined magnetization values.

### *3.2 High-temperature Hysteresis Loops*

For the study of magnetic properties at high temperature, generally three aspects are considered: (i) the temperature range up to 100 °C is technically relevant for many applications; (ii) investigations up to $T_{\text{C}}$ are important to study the break-down of the ordering process or phase transition; and (iii) higher temperature ranges are necessary to determine the susceptibility above $T_{\text{C}}$ from which the effective paramagnetic moment can be deduced. They are also used for the study of metastable materials. As examples, investigations of relaxation effects in the amorphous state (Grössinger *et al.* 1996) or of the

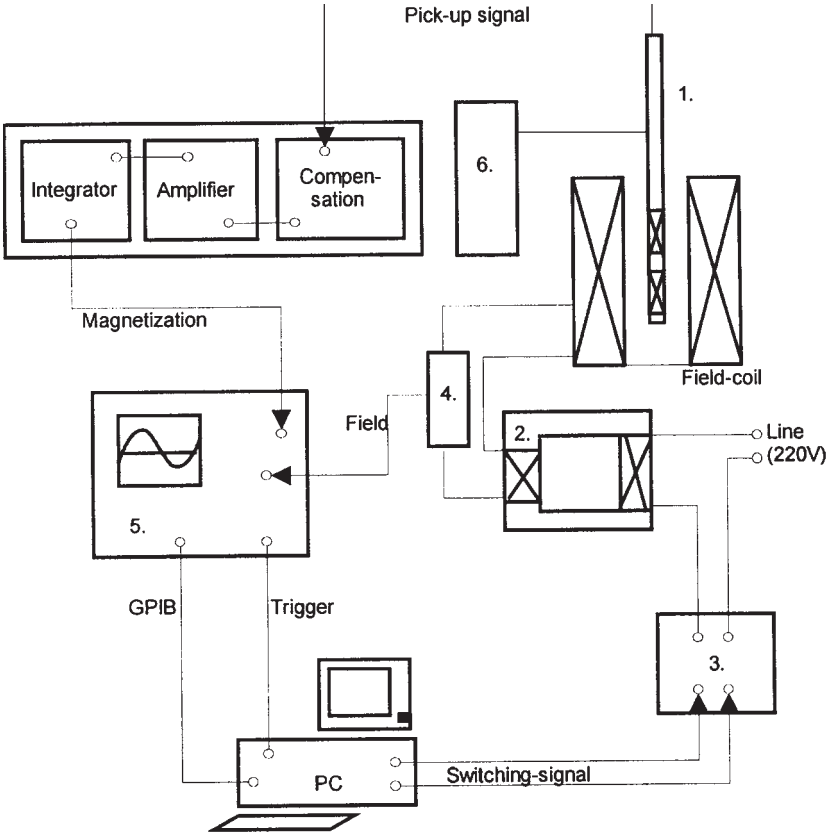
onset of crystallization *in situ* to obtain nanocrystalline materials (Grössinger *et al.* 1995, Schwetz *et al.* 1998) can be cited. Additionally, the thermal stability investigation in metastable hard magnetic materials such as $Sm_2Fe_{17}N$ (Kou *et al.* 1995b) should be mentioned here. However, a complete experimental curve of $M_S(T)$ is of great importance because, by analyzing this curve, important magnetic parameters such as the exchange constant or critical exponents can be obtained.

The setup for high-temperature hysteresis loop measurements is similar to that of Fig. 8 when the cryostat is replaced by a furnace. One of the technical difficulties of the construction of high-temperature systems is to obtain a sensitive and well compensated pick-up system that survives higher temperatures.

One other very useful high-temperature hysteresigraph is the system described in Fig. 9, which uses the technically relevant line frequency of 50 Hz (Schwetz *et al.* 1998). The basic idea of this system is the use of one or two periods of the main line to generate a reasonable high field in an air coil. The apparatus consists of:

A field-generating coil with a high-power transformer which is connected on the primary side to the line as power supply;

A pick-up system which is placed inside the inner diameter of the field generating coil;



1. ...Pick-up coil
2. ...Transformer (220V prim.-33V sec.)
3. ...Relais ( HRS 240 D45)
4. ...Shunts (Arcol, 5 x 100 W, 0.1 Ohm )
5. ...Storage Oscilloscope
6. ...Heating- (Powersupply 60W) and Cooling Device

***Figure 9***
High-temperature hysteresis measurement system.

A switching unit with a solid-state, high-current switch;

Electronic devices to compensate, amplify, and integrate the signal induced in the pick-up system;

A storage oscilloscope and a personal computer (PC);

A heating system employing a bifilar wound heater in order to avoid a field due to the heating current.

For producing the field a current (several cycles of 50 Hz) is applied to the field-generating coil which will induce a signal in the pick-up system. This signal is compensated, amplified, integrated, and then saved in the memory of a storage oscilloscope. The field-producing current is measured by shunts and stored also in the oscilloscope. Afterwards the measured data are transferred to the PC. The switching and heating procedures, the oscilloscope, and the electronic devices are controlled by a PC.

This a.c. method system is very easy to realize. However, very close to application, due to possible 50 Hz noise, the accuracy is rather limited. With this system many interesting *in situ* high-temperature studies can be performed (Schwetz *et al*. 1998). Due to the high intensity of the applied field (maximum field of $300\,\mathrm{kAm^{-1}}$), this system can be used to investigate the semihard magnetic materials.

These are only two examples of high-temperature systems. There are many other possibilities to realize a high-temperature magnetometer that works in the gap of an electromagnet or in the temperature-isolated hole of a superconducting solenoid. Here, various methods such as the integration of the induction voltage in a pick-up system or the detection of an a.c. voltage (of a VSM) can be used.

## 4. Characterization of Hard Magnetic Materials

The magnetic methods characterizing hard magnetic materials (see *Hard Magnetic Materials, Basic Principles of*) differ slightly from those of soft magnetic materials. In hard magnetic materials the shape of the initial curve, minor loops as well as recoil curves, is important for studying the magnetization process.

Hard magnetic materials have a high coercive field (typically between $240\mathrm{kAm^{-1}}$ and $1600\,\mathrm{kAm^{-1}}$) where the origin is a high magnetocrystalline anisotropy. Therefore, high external fields are necessary for studying these types of materials. A standard tool for studying permanent magnet materials is an electromagnet as shown in Fig. 10. The field is generated by the electromagnet and the sample is in the air gap of pole pieces. In the case of room-temperature measurements the sample should have polished and plane surfaces in order to avoid undefined air gaps which cause stray field errors. The magnetization can be measured by pick-up coils and the actual field by a magnetic potentiometer or by Hall probes. The signal is then integrated using a fluxmeter. Such a system is well suited for measuring minor loops and recoil curves; however, for determining the full loop or the saturation magnetization, the achievable external field, which is about $800\,\mathrm{kAm^{-1}}$, is not sufficient. Additionally, a determination of $H_c$ for high coercive field materials is also limited by the insufficiently low external field. Because an electromagnet has a high induction the change of field with time is slow. Therefore, the measurement usually takes seconds and the sensitivity of the system is limited by drift problems as well as by noise.

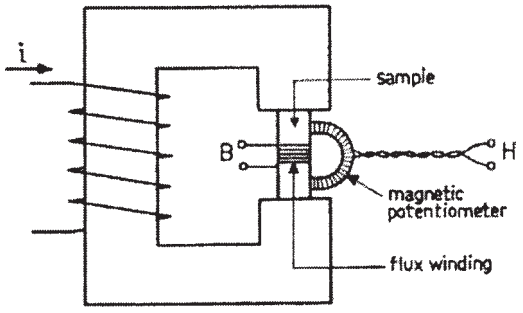


***Figure 10***
Sketch of magnetic measurement in an electromagnet.

If measurements at variable temperatures are to be performed this system loses its advantage (magnetically closed system) because the use of a furnace or a cryostat causes an air gap, which means that the demagnetizing field of the sample has to be considered. Generally, the available field in the air gap of an electromagnet is too low ($800–1200\,\mathrm{kAm^{-1}}$) for modern hard magnetic materials. This situation can be improved using a superconducting solenoid which allows the field range to be extended such that fields up to about 20 T become available.

## 5. Conclusions

The main techniques to characterize hard magnetic materials besides the a.c. susceptibility measurements are magnetometers as described in Sect. 2. In short, the advantage of a VSM is that it gives good accuracy in reasonablly high fields covering a wide field and temperature range. A SQUID is an extremely sensitive device where a magnetic field resolution in the order of femtoteslas can be achieved.

## Magnetic Micro-actuators (MAGMAS)

Magnetic micro-actuators and systems (MAGMAS; also called "MAG-MEMS," (micro-electromechanical systems)) present outstanding performance for powerful integrated conversion from electrical to mechanical energy. MAGMAS, due to available forces and energies, belong to the recently appearing "Power-MEMS" family. Besides, the diversity of structures and the range of possible applications, including distance and remote-controlled actuation, explains the many recent publications and the large scope of research in this field. The topics addressed range from power energy microsources, to micromotors, microactuators, microswitches, levitation and remote-controlled magnetic micro-objects. The corresponding devices comprise optical, electrical, radiofrequency (RF), biomedical, and fluid dynamics applications.

MEMS are presently diversifying towards different principles of actuation, either electrostatic, magnetic, piezoelectric, or thermal, or actuation based on

shape memory alloys. Each principle presents specific properties so as to cover a wider range of possibilities and applications. MAGMAS' development is recent, rapid, and promising as most specific and limiting technological problems are progressively being solved. It combines magnetic materials now available on silicon: microcoils, soft magnetic materials, micromagnets, magnetostrictive thick layers, etc., with either an integrated or remote-control field resulting in numerous possibilities. MAGMAS deserve more credence and attention from MEMS designers, and materials scientists should continue to develop better thick-film patterned permanent magnets compatible with microsystem technologies.

Stress will be put on downscaling laws. Due to both new available materials and the impressive increase of current density in microcoils, it is demonstrated that downscaling actually results in more effective electromagnetic converters. That magnetic interactions actually improve on downscaling is quite new and revolutionary.

## 1. A Brief History of MEMS and Magnetism

Developments in microelectronics led to MEMS, where the first actuations of thin beams employed were electrostatic, aluminum conductors and electrodes being standard. Thermal bimorph actuation came later. Development of other actuation principles (electromagnetism, piezoelectricity, magnetostriction, shape memory, etc.) has been slower because basic components and specific materials are not standard.

Early on, it was felt strongly that electromagnetism would not be very relevant for MEMS. Based on the simplified interactions between conductors in air or between a conductor in air and a piece of iron, but no effective electromagnetic power conversion, downscaling is catastrophic! This is even more so when drastic changes of essential parameters such as gradients or current densities were not considered when downscaling! Obviously, many recently published "downscaling laws" still favor electrostatics considering electromagnetism in its less appropriate and less downscalable configuration. These theories did not consider direct and homothetic scale reduction of the familiar electrical machines in daily use.

Generally, the perspectives for downscaling of different types of actuation for MEMS were neutral or pessimistic for magnetism, whereas a rigorous electrical engineering approach led to very positive conclusions (Jufer 1994). In the late 1980s, the first teams designed and promoted magnetic micro-actuators (Wagner and Benecke 1990, Guckel *et al*. 1991, Benecke 1994). They wisely remarked that permanent magnets are vital to magnetic actuation but that unfortunately their integration needs to be mastered (Guckel 1996). This is still a bottleneck. Many other works deserve to be read (Nami *et al*. 1996, Busch-Vishniac 1992). More details on MAGMAS, principles, materials, and applications have been collected in the book of Cugat (2002). The reader is also referred to the Feynman (1992, 1993) articles for perspectives in the early 1990s.

## 2. Magnetic Interactions and Downscaling at Constant Current Density $\delta$

For simple energy considerations, electrical engineering clearly indicates that macroscopic devices (electrical engines and actuators that dominate the macroscopic world) are mainly composed of ferromagnetic materials (either soft magnetic materials or permanent magnets). Hence, the focus is on laws of scale reduction applied to such structures.

### 2.1 Magnetic Field of Magnets

A magnet of volume $v_1$ and magnetic polarization $J_1$ generates a scalar potential $V$ at any point $P$ located at a distance $r$ from the magnet. The magnetic field $H$ is the local gradient of the scalar potential $V$:

$$V(P) = \frac{v_1}{4\pi\mu_0}\frac{\boldsymbol{J}\cdot\boldsymbol{r}}{r^3}, \qquad \boldsymbol{H} = \nabla V \tag{1}$$

Homothetic miniaturization (all dimensions reduced by the same factor $k = 10, 100, 1000, \ldots$) of a given magnet (homogeneous material and constant polarization $J_1$) generates a constant magnetic field $H$, whereas the scalar potential $V(P)$ is divided by $k$. The relative geometry and magnitude of the field map around a magnet remain unchanged after scale reduction (Fig. 1). A direct and remarkable consequence is that the field gradients are multiplied by $k$. This has a tremendous impact on the interaction forces.

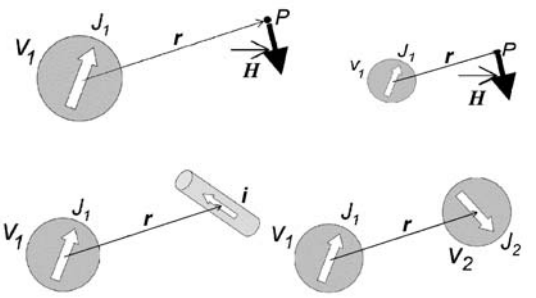

***Figure 1***
Top: Magnet—magnetic field unchanged with scale. Bottom: Interactions—magnet–current and magnet–magnet.

### *2.2 Interactions between Magnets and Current-Carrying Conductors*

Intuitively, one considers the forces of magnets on current-carrying conductors. Homothetical downscaling of the magnetic field maps due to the magnets leaves the Lorentz forces on conductors unchanged.

Obviously it is equivalent to consider the forces exerted by the conductors on the magnets. The Biot–Savart law states that the magnetic field $H$ created in point $P$ by a conductor of length $\mathrm{d}l$ and cross-sectional area $S$, carrying a current density $\delta$ (current $I = \delta \cdot S$), is

$$\boldsymbol{H}(P) = \frac{1}{4\pi}\frac{\delta \cdot \boldsymbol{S} \cdot \mathrm{d}\boldsymbol{l} \times \boldsymbol{r}}{r^3} \qquad (2)$$

Hence, scale reduction by a factor of $1/k$ decreases the fields $H$ due to the conductors by a factor of $k$. The magnetic force $F$ on the magnet derives from their mutual magnetic interaction energy $W_i$:

$$W_i = -\boldsymbol{J} \cdot \mathrm{v} \cdot \boldsymbol{H}, \qquad \boldsymbol{F} = -\nabla W_i \qquad (3)$$

Scale reduction by a factor $k$ reduces the energy $W_i$ by a factor $1/k^4$, $F$ by a factor $1/k^3$, and the force-to-weight (or force-to-volume) ratio does not change.

### *2.3 Torque on a Magnet Due to External Field*

The torque experienced by a magnet of polarization $J$ and volume $v$ immersed in a homogeneous field $H$ is proportional to $M$ and $H$ (where the magnetic moment equals $M = vJ$). During the homothetic $1/k$ reduction, both $H$ and $J$ remain constant, thus the torque-to-volume ratio also remains constant.

### *2.4 Magnet–Magnet and Magnet–Iron Interactions*

Once again, the magnetic field of magnets remains unchanged upon downscaling. Hence, for magnet–magnet or magnet–iron interactions, Eqn. (3) shows a decrease of $W_i$ by a factor $1/k^3$, $F$ by a factor $1/k^2$ and an increase by $k$ of the force-to-volume ratio.

Not only are macroscopic magnetic systems the most performing electric-to-mechanical converters but their scale reduction by $1/k$ can increase the force-to-weight ratio by $k$, allowing MAGMAS to provide large forces exactly as an ant can carry much heavier charges relative to its own weight than can an elephant.

### *2.5 Scale-reduction Laws on Magnetic Interactions*

Similar calculations can be done for the magnetic interactions involving soft ferromagnetic materials combined to currents, and time-variation-induced currents (Cugat 2002, see chapter 2); see Fig. 2.

| Reduction factor $1/k$ | Magnet | Current | Iron | Induction ($E = d\Phi/dt$) |
|---|---|---|---|---|
| Magnet | $\times k$ | | $\times k$ | $\times 1/k$ |
| Current | | $\times 1/k$ | $\times 1/k$ | $\times 1/k^2$ |

***Figure 2***
Effect of scale reduction $1/k$ on volume force for basic magnetic interactions, for a constant current density.

For a constant current density $\delta$, the following conclusions can be drawn:

- The main magnetic interactions benefit from scale reduction.
- The most efficient magnetic interactions in devices of small dimensions involve permanent magnets.
- The forces between two magnets or between a magnet and a soft iron core increase by a factor $k$ upon scale reduction by a factor $1/k$.
- The forces between a magnet and current-carrying conductors, when effective on a macroscopic scale, remain as effective once miniaturized.
- Inductive effects are to be avoided.

## *3. Permanent Magnets for MAGMAS*

The application of MAGMAS requires the integration of small but high-quality magnets. Material researchers are addressing this bottleneck and new results are presently being reported. Large availability of thick high-quality magnets in microtechnology will boost the performance of electrical-to-mechanical conversion and, more generally, of MEMS.

### *3.1 Micromagnet Fabrication Techniques*

The most common and most powerful micromagnets currently used in MAGMAS are those individually micromachined from bulk rare-earth permanent magnets (REPMs) such as Nd–Fe–B or Sm–Co magnets (see *Magnets: Sintered*), generally using machining by spark cutting. However, this method is hardly compatible with full integration or batch fabrication.

Many other ways to obtain micromagnets for MAGMAS are being developed (see *Magnetic Films: Hard*). These methods all provide good results but each suffers from a moderate or major drawback (Cugat 2002, chapter 5). Some techniques are well adapted to microfabrication (electroplating of Co–Pt, screen printing of bonded powders) but the resulting magnetic properties are relatively poor compared to

bulk REPMs (Zangari *et al*. 1996). Other techniques giving excellent magnetic properties are sputtering (Linetsky and Kornilov 1995), pulsed laser deposition (Cadieu *et al*. 1998), low-pressure plasma spraying (Rieger *et al*. 2000), or direct sintering (Yamashita *et al*. 2002). But either the thickness of the deposited layer is too thin, or it is difficult to adapt the process to microtechnology and batch fabrication (high deposition temperature, chemical pollution, slow deposition rate, small deposition surface). An important aspect currently emerging is the patterning of thick magnet films (Budde and Gatzen 2002). Optimal magnetic orientation of micromagnets is also studied (Kruusing 2002). The perspectives of achievements with low-temperature electroplated high-quality REPMs are discussed by Schwartz *et al*. (1998).

The large impact of the expected results justifies the increasing number of research efforts made in this field. However, perfect candidates for cheap, compatible, and fast integration of thick patterned layers of good-quality micromagnets remain to be found. Recently, technologies have improved rapidly and breakthroughs in this critical field are likely.

### *3.2 Equivalence between a Permanent Magnet and a Current-carrying Coil*

A magnet is equivalent to a current-carrying coil (current density $i$, radius $r$) whose circumferential current density ($i/2\pi r$) remains constant (Amperian current model). This means that the equivalent volume current density increases by $k$ when the magnet (or the equivalent coil) is downscaled by $1/k$.

## *4. Current Density in Microcoils*

Magnetic sensors use microcoils and MAGMAS require them for variable fields and forces. Microcoils of various shapes and sizes can stand very high current densities. In macro-applications, the limitation to 3–5 $A\,mm^{-2}$ is mainly due to thermal overheating. In micro-applications, thermal downscaling laws allow densities of $10^3$–$10^4\,A\,mm^{-2}$. While Joule conduction losses are volume related, the heat flow (for cooling) is proportional to the cross-section and inversely proportional to the thickness the heat flows through. Hence, heating scales as $k^3$, whereas heat flow dissipated by conduction scales as $k$. For the same temperature, Joule losses can increase by $k^3/k = k^2$. These Joule losses being proportional to the square of the current density, the current density can increase as $k$. Hence microcoil downscaling by $1/k$ can be done with the current density increasing by a factor of $k$. This is equivalent to a constant surface current density or, in other words, magnets and actual microcoils downscale in the same way. As forces and energies are proportional either to that current density or to the square of that density, this deeply boosts scale reduction laws.

The small volume-to-surface ratio of microcoils (planar geometry) and the direct contact with good heat-conducting substrates (e.g., Si), allows even higher DC currents, not to speak of pulsed currents (Cugat 2002, chapters 3 and 4, MacKay *et al*. 2000). However, it cannot be avoided that such increases in current densities and the concomitant increases of thermal losses in conductors can reduce both the efficiency and the autonomy (if used on batteries), and needs adapted heat sinks. These side-effects are practical limiting parameters for real design of MAGMAS.

## *5. Optimal Downscaling Laws ($\delta \sim k$)*

With good magnets and current densities increasing as $k$, the downscaling laws can become significantly modified (Fig. 3).

One can draw the following outstanding conclusions (see Table 1):

- All magnetic interactions benefit from scale reduction.
- Magnet–magnet or magnet–iron core forces increase as $k$.
- Current volume forces increase the same way and possibly faster (pulses). It depends on the specific characteristics of the application and the associated side-effects stated earlier.

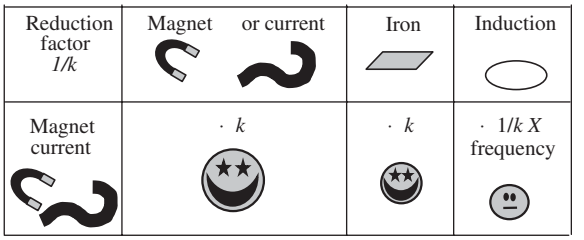

***Figure 3***
Effect of scale reduction $1/k$ on basic magnetic interactions, with current density increasing as $k$ (constant temperature).

***Table 1***
Optimal downscaling laws.

| Downscaling | $1/k$ |
|---|---|
| Volume, mass, or gravity force | $1/k^3$ |
| Heat flow dissipated by conduction | $1/k$ |
| Electrostatic forces | $1/k^2$ |
| Current density (constant temperature) | $k$ |
| Most magnetic interactions ($1/k^2$) | $1/k^2$ |
| Force/volume for most magnetic interactions | $k$ |

- Magnetic forces downscale as electrostatic forces. Here one has to bear in mind that magnetic forces largely dominate in the macroscopic world.
- Inductive effects could benefit from the increase of frequencies when downscaling. The smaller the object, the faster are thermal, mechanical, or electrical effects. However, size reduction increases resistances and decreases inductances, thus handicapping inductive effects.

## 6. Additional Characteristics of MAGMAS

In addition to high energy densities and forces, electromagnetic interactions present other advantages, but also drawbacks for the actuation of microscopic systems (Reyne 2002).

### 6.1 Permanent Forces, Bistability, and Suspensions

Permanent magnets provide constant magnetic fields. Hence, simple latching or bistability is achievable without supply. This ensures energy savings or guarantees excellent safety in case of power failure (Fisher *et al.* 2001, Ruan *et al.* 2001). Bistability combines particularly well with pulsed-switching currents. Such permanent forces can also be implemented into passive magnetic suspensions/bearings, providing an elegant solution to the problem of friction in MEMS (Klöpzig 1998, Cugat *et al.* 1996).

### 6.2 Long-range, Remote, or Wireless Actuation

- Magnetic fields and gradients can be effective over long distances relative to the size of MEMS. This allows integrated large-throw and/or wide-angular actuators.
- Contactless magnetic interaction allows remote actuation through sealed interfaces allowing wireless actuation or vacuum packaging of resonant systems for high $Q$ factors (no air viscosity dampening). Furthermore, remote actuation through sealed interfaces makes magnetic actuators very well suited to harsh environment (e.g., ABS sensors).
- External magnets or macrocoils can be added to power the microsystem thus avoiding integration of supply and most side-effects. It considerably simplifies fabrication. This characteristic is unique and deserves to be used for medical applications with implanted wireless MAGMAS actuated by distance external fields.

### 6.3 Possible Future Actuation Modes for MAGMAS

Major drawbacks of magnetic actuation are side-effects of Joule losses in conductors. One might overcome this problem by exploring new ways to modify magnetic fields:

- thermal demagnetization of a thermomagnetic material,
- magnetic "reprogramming" of semi-hard materials by demagnetization and remagnetization,
- strain-induced modulation of the magnetization of a magnetostrictive material (see *Magnetoelasticity in Nanoscale Heterogeneous Materials*) by hybridization with a voltage-actuated piezoelectric element, and superconducting films can be used for levitation (see *Magnetic Levitation: Superconducting Bearings*) and high-temperature superconductivity may be a future possible solution for magnetizing MAGMAS for specific applications (space, cryogenic systems, etc.).

### 6.4 Power Supplies, Control, and Coolers

Electrostatic actuators use high voltages and low currents, whereas MAGMAS require high currents and low voltages. Current pulses, if used, need faster command and control. Hence, final performances strongly rely on working conditions and development of appropriate integrated supplies and coolers.

## 7. Applications

Magnetic sensors are already well established in commercial products (HDD read-heads, fluxgates, transmission coils, ABS sensors, etc.). However, few MAGMAS have, so far, reached industrial production. Laboratory-developed prototypes include radio frequency $\mu$-switches for mobile phones, read/write heads and $\mu$-positionners, matrixes of optical $\mu$-commutators for fiber optic networks, $\mu$-motors for noninvasive surgery and $\mu$-robotics, $\mu$-pumps, and $\mu$-valves for lab-on-chip and $\mu$-fluidic devices, electrical $\mu$-generators for autonomous power supplies, $\mu$-mirrors for adaptive optics, magnetic suspensions for hard disk drives, etc.

## 8. Conclusion

Electromagnetic interactions deserve a larger interest from the MEMS community. MAGMAS offer large forces, large strokes, remote or distance control, bistability, and high robustness, all these properties offering great opportunities for new devices in many applications. The large current densities available at small scales, together with the development of magnetic thick films, specific supplies, and coolers should soon greatly promote the development of MAGMAS.

# Magnetic Microwires: Manufacture, Properties, and Applications

Amorphous metallic materials take a prominent position among metallic materials due to their unique and favorable association of physical properties related to the absence of long-range order. These materials possess superior mechanical, electrical, magnetic, and chemical properties (see *Amorphous Intermetallic Alloys: Resistivity*, and *Amorphous and Nanocrystalline Materials*). The use of preparation methods that allow rapid condensation of atoms or rapid solidification of liquid metallic melts in order to avoid crystallization is necessary to achieve the energetically metastable amorphous state. The formation of the amorphous state depends on the alloy composition as well as on the process conditions. Presently known amorphous metallic materials have been obtained in shapes like thin films (Cahn 1993), ribbons (Boll *et al*. 1983), wires (Hagiwara and Inoue 1993), powders (Yagi *et al*. 2000), and very recently bulk materials with dimensions in the range of millimeters (Inoue 2000). Amorphous metallic materials are used in applications based on their outstanding properties, but the most important are those based on magnetic properties, their soft magnetic behavior leading to high permeability and low coercivity.

Amorphous ribbons have been used in transformer cores, magnetic recording heads, and in sensing elements. The amorphous metallic wires have attracted much interest due to their more convenient shape, dimensions, and specific properties emerging from their degree of symmetry. Amorphous metallic wires with diameters ranging between 80 μm and 160 μm are obtained by the so-called in-rotating-water quenching technique (Ogasawara and Ueno 1995). This procedure implies a very high cooling rate from the molten alloy and gives rise to local magnetoelastic anisotropies from the coupling between internal stresses and magnetostriction. These internal stresses originate from the thermal gradient present during the quenching, and their order of magnitude, $\sim 10^2$ MPa, is determined by Young's modulus, the

Poisson coefficient, and the average temperature during fabrication.

The main interest of amorphous wires is related with the cylindrical geometry and magnetostriction constant. In the latter case, in Fe-rich alloys, the magnetization process is characterized by a single Barkhausen jump (Vázquez and Chen 1995) associated with a square hysteresis loop. This behavior, that it is observed above a critical length of $\sim 7$ cm, is determined by a particular domain structure originating from stresses induced in the wire during the fabrication procedure. Current and voltage transformers and magnetic sensors have been developed based on this effect (Mohri *et al*. 1984). On the other hand, Co-rich alloys exhibit vanishing magnetostriction and do not show bistability (Gómez-Polo and Vázquez 1993). Although the saturation magnetization is low, the outstanding properties of this material are related with a high initial susceptibility and with another effect, strongly connected with the geometrical shape, known as magneto-impedance effect. The latter induces wire impedance variations by magnetic field application (Beach and Berkowitz 1994, Panina and Mohri 1994). This effect can be used in magnetic sensors for detecting magnetic fields.

In contrast, glass-coated microwires are obtained by an extracting melt-spinning technique, based on Taylor's classical method (Taylor 1924). The tiny dimensions and the outstanding magnetic behaviors at low-, medium-, and high-frequency magnetic fields make them very useful for practical purposes.

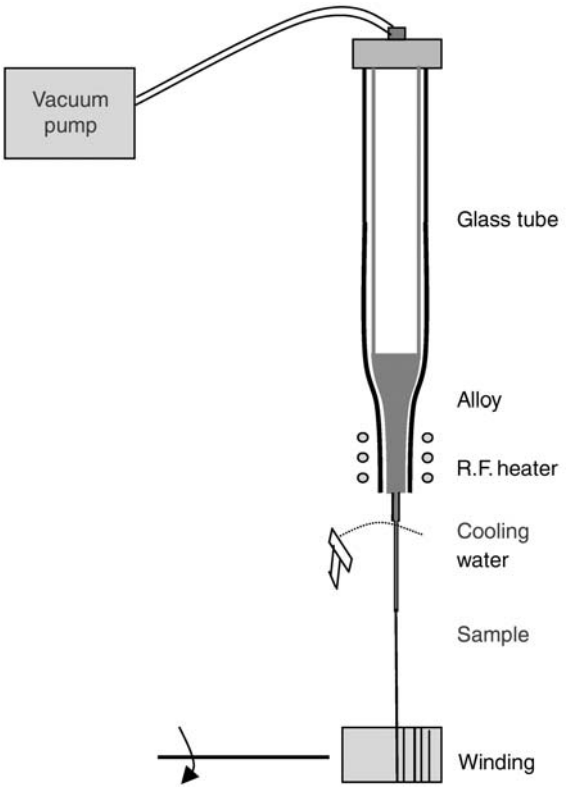

***Figure 1***
Schematic diagram of the glass-coated melt spinning method.

## *1. Material Preparation: Production Technique of Amorphous Glass-covered Metallic Microwires*

The production of glass-covered metallic microwires is presently achieved by the glass-coated extracting melt-spinning method. The basic idea of this method was initially proposed by Taylor (1924) and improved by Ulitovsky (1932) and Parkhachev (1966). Figure 1 shows a schematic diagram of the method. It consists in the rapid drawing of a softened glass capillary in which the molten metal is entrapped. The capillary is drawn from the end of a glass tube containing the molten alloy. Previously, a metallic pellet of the master alloy, prepared by induction melting of pure elements, has been placed inside the sealed end glass tube and then the alloy is melted by a high-frequency field of an inductive coil and the end of the glass tube is softened. Hence, around the molten metal drop, there is a softened glass cover which allows the drawing of the capillary. A low level of vacuum ($\sim 50$–$200$ Pa of an inert gas atmosphere) within the glass tube prevents metal oxidation. It also assures stable melt-drawing conditions, in conjunction with induction heating, employing the levitation principle. In order to ensure continuity of the process, there is a glass tube displacement with a uniform feed-in speed between $0.5\,\mathrm{mm\,min^{-1}}$ and $10\,\mathrm{mm\,min^{-1}}$. The rapid cooling rate required to obtain an amorphous structure, between $10^5\,\mathrm{K\,s^{-1}}$ and $10^6\,\mathrm{K\,s^{-1}}$, is reached by cooling the as-formed wire by a water jet at $\sim 1$ cm under the high-frequency induction coil.

It is clear both intuitively and from the available literature (Donald 1987) that the successful production of high-quality, continuous filaments of given dimensions by the Taylor-wire technique is dependent on a number of critical materials and process factors. These are summarized below.

The materials selection is crucial in order to be successful. In the case of amorphous metallic alloys the composition chosen should be that of a glass former. It is well known (Chiriac and Óvári 1997) that glass formation is favored at compositions for which the liquid is relatively stable compared to crystalline phases. This relative stability also correlates with the sizes of the atomic species in the alloy.

Once the alloy composition is chosen, the glass should be well selected in order to allow a properly glass-coated fabrication. It must be compatible with the metal or alloy at the drawing temperature to

avoid, as much as possible, chemical reaction between glass and metal. Its working (drawing) temperature must be higher than the melting point of the metal or alloy employed, but below its boiling point and below the temperature at which the metal vapor pressure becomes high enough to disrupt the process. The viscosity–temperature behavior of the glass must allow easy fiber drawing in the temperature range of interest and its crystallization temperature should be higher than the working temperature.

The thermal expansion coefficient of the glass should be matched to, or be slightly less than, that of the metal or alloy of interest. The viscosity of the glass coating must attain a high enough value, where further extension during drawing cannot occur before the metal core has solidified. Otherwise, if the core is solid and the coating continues to extend, metal core fracture will be initiated and a discontinuous product will be obtained.

In practice, because glass is used in the form of tubes of uniform dimensions in the Taylor-wire process, the choice of specific glass compositions is severely restricted due to the limited range of commercial offers. This restricts the choice to Pyrex-type borosilicate compositions or to fused silica.

As it will be reported later, two main factors are predominantly responsible for the microwire magnetic behavior, i.e., the metallic core microstructure and the ratio of the metallic core radius to the total radius of the microwire $\rho = R_m/R$ (Chiriac and Óvári 1997). These microstructural and geometrical factors can be controlled by process conditions. A good control of melting temperature allows the obtention of amorphous and partially nanocrystallized samples. The most important factor governing the core diameter of the filament seems to be the take-up speed; the higher the speed, the smaller the fiber dimensions obtained. Another important factor is the vacuum level. In practice, the metal thickness is indirectly controlled by a measurement device based on emission and reception antennas that acts on the vacuum pump when the metal diameter deviations are detected. The thickness of glass coating depends mainly on the feed-in rate of the glass tube, but also depends, to a lesser degree, on the thickness of the glass tube employed, and the take-up speed.

Figure 2 shows a photograph corresponding to a microwire scanning electron microscope (SEM) image. The composition is $(Fe_{30}Co_{70})_{72.5}Si_{12.5}B_{15}$ and corresponding dimensions are a total diameter $D$ of 12 μm and a metal nuclei diameter $D_m$ of 3.5 μm.

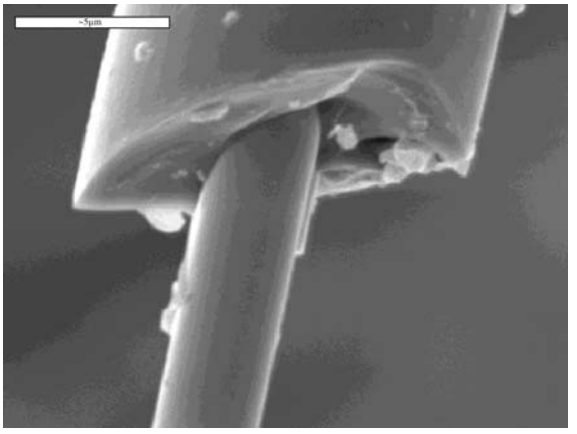

***Figure 2***

## 2. *Magnetic Properties*

A large variety of magnetic alloys (Hernando and Vázquez 1993) can be fabricated mainly based on iron and cobalt. The high mechanical strength and the ferromagnetic character make them attractive as reduced size components in electronics, for magnetic recording, biomedical implantations, etc. Their high-frequency behavior can also be exploited in devices for electromagnetic power absorption.

### *2.1 Magnetic Domains and Low-frequency Axial Hysteresis Loop*

The hysteresis loop shape is strongly dependent on the composition of the metallic core. The magnetization process is strongly dependent on the magnetostriction constant and the magnetoelastic anisotropy induced by internal stresses (Vázquez *et al.* 1996). Glass coating induces an extra radial internal stress due to the different thermal expansion coefficients of the nucleus and the glass. Besides, the extraction tensile stress induces an axial internal anisotropy. The coupling determines the domain structure, an inner axial single domain, and the outer shell.

As shown in Fig. 3, in positive magnetostrictive microwires (Fe-rich), the inner core has an easy magnetization direction along the axis and the outer-shell easy direction is perpendicular to the axis. In negative magnetostrictive microwires (Co-rich), the inner-core easy magnetization is perpendicular to the axis direction while the external shell adopts circular directions. Magnetic microwire behavior is determined by this type of domain structure.

Positive magnetostrictive microwires show a square hysteresis loop with large Barkhausen jump. This effect results from the magnetization reversal in the inner core at a given value of the axial magnetic field, called switching field, $H^*$. The value of the

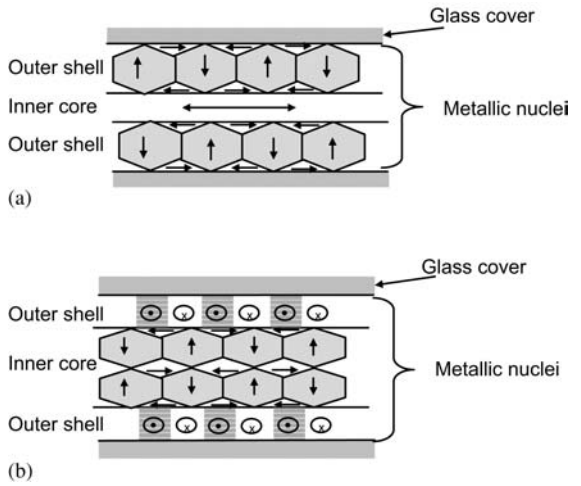

***Figure 3***
Schematic diagram of the estimated domain structure in positive (a) and negative (b) magnetostrictive amorphous glass-coated microwires (Chiriac *et al.* 1997).

switching field depends on the average value of the uniaxial anisotropy constant of the inner core, and consequently on the level of the internal stresses. These thermoelastic internal stresses depend on the mechanical, thermal properties and the cross-sectional ratio of glass and metal (Baranov 2001), $x = (R/R_{\mathrm{m}})^2 - 1 = (1/\rho^2) - 1$.

The general equation describing the internal stresses can be simplified, considering $n_1 = n_2 = \frac{1}{3}$ where $n_i$ are the Poisson coefficients of crystal and metal, respectively. They can be expressed as follows in a cylindrical coordinate system:

$$\sigma_z = \sigma_0 \frac{kx}{kx+1} \frac{(k+1)x+1}{(k/3+1)x+4/3} \tag{1}$$

$$\sigma_r = \sigma_\phi = \sigma_0 \frac{kx}{(k/3+1)x+4/3} \tag{2}$$

where $\sigma_0 = E_1(a_1 - a_2)(T^* - T)$, $k$ is the ratio of the Young's moduli $k = E_2/E_1 = 0.3{-}0.6$.

The internal stresses cause the appearance of magnetoelastic anisotropy, corresponding to a magnetic field:

$$H_{\mathrm{a}} = \frac{\lambda\sigma_0}{M} \frac{Kx}{Kx+1} F(k,x) \tag{3}$$

were $F(k,x)$ is a slowly varying function of $k$ and $x$.

Figure 4 shows the composition dependence of microwire hysteresis loops. Figures 4(a) and 4(b) are for microwires of the compositions $Fe_{70}Si_{10}B_{15}C_5$ and $Co_{60}Fe_{15}Si_{15}B_{10}$, respectively. Magnetic bistability is clearly observed in both cases. In turn, Fig. 4(c) shows a nonbistable loop for a $Co_{68.5}Si_{14.5}B_{14.5}Y_{2.5}$ alloy microwire. The main difference derived from the various compositions of the three microwires is the magnetostriction constant, $\lambda_{\mathrm{s}}$. The corresponding values for Figs. 4(a)–(c) are $2 \times 10^{-5}$, $1 \times 10^{-7}$, and $-2 \times 10^{-6}$, respectively. Accordingly, microwires with large and positive $\lambda_{\mathrm{s}}$ show magnetic bistability, whereas those having intermediate negative $\lambda_{\mathrm{s}}$ do not show that behavior. The microwire with nearly zero but positive $\lambda_{\mathrm{s}}$ (Fig. 4(b)) also shows bistable behavior. In fact, as reported by Baranov *et al.* (1995), the bistability disappears when $\lambda_{\mathrm{s}}$ changes its sign from positive to negative.

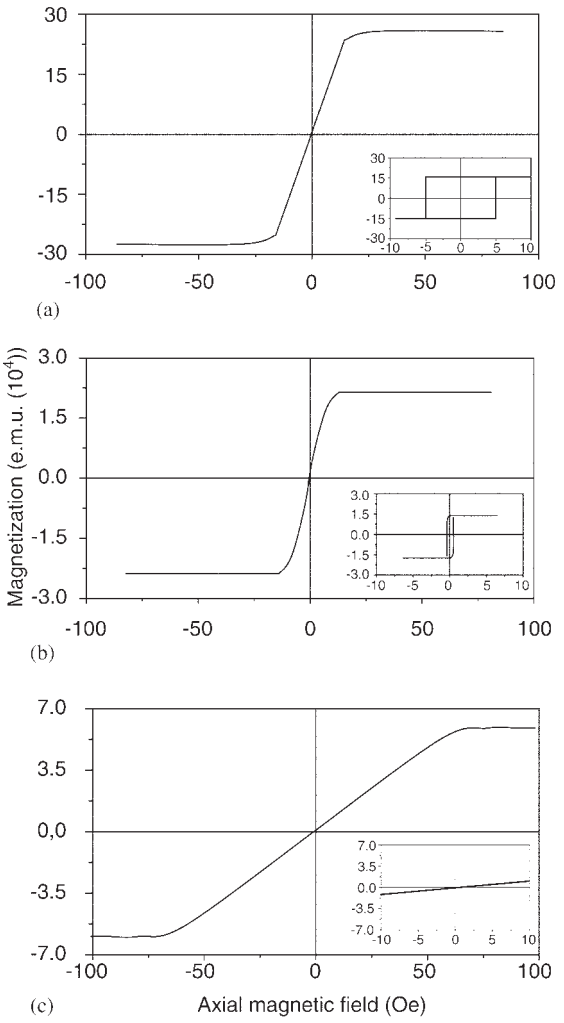

***Figure 4***
Low-field (inset) and high-field hysteresis loops for microwires of $Fe_{70}Si_{10}B_{15}C_5$ (a), $Co_{60}Fe_{15}Si_{15}B_{10}$ (b), and $Co_{68.5}Si_{14.5}B_{14.5}Y_{2.5}$ (c) alloys.

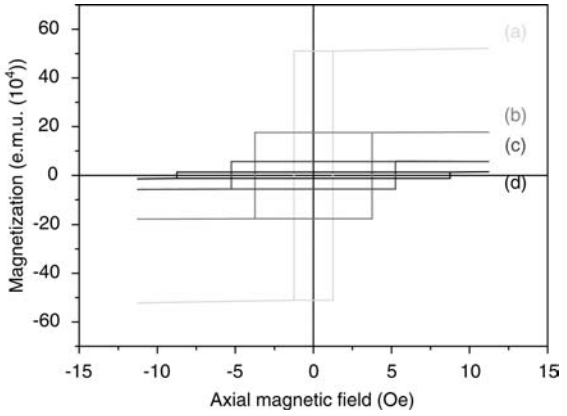

***Figure 5***
Hysteresis loops for $Fe_{89}Si_3B_1C_3Mn_4$ microwires with different ratio $\rho = R_m/R$ between the radius of the metallic core, $R_m$, and the radius of the microwire, $R$, for $\rho = 0.6$ (a), $\rho = 0.28$ (b), $\rho = 0.25$ (c), and $\rho = 0.2$ (d).

On the other hand, the ratio $\rho = R_m/R$ between the radius of the metallic core, $R_m$, and the total radius, $R$, of the microwire plays an important role in determining the parameters of the hysteresis loop. Figure 5 shows the bistable loops as a function of $\rho$. A higher longitudinal anisotropy due to thinner inner core is associated with a higher anisotropy field, $H_k$, and lower remanence.

The hysteresis loop behavior can be tailored by means of annealing. Amorphous structural relaxation and nanocrystallization (Vázquez *et al.* 1999, Marín *et al.* 1997) can change the microwire anisotropy field leading to a broad spectrum of magnetic behaviors with different hysteresis loops which is very interesting from the applications point of view.

### 2.2 *High Magneto-impedance Effect*

The magneto-impedance effect has been recently discovered in soft amorphous wires with very high circular permeability (Beach and Berkowitz 1994, Panina and Mohri 1994). It consists of a large relative change (up to $\sim$400%) of the impedance (both real and imaginary parts) upon application of a d.c. magnetic field or stress. In order to measure the impedance, typically a low-density current flows along the sample having a frequency in the range of MHz. This effect has been detected in nearly zero magnetostriction Co-base samples of the shape of a wire, ribbon, or thin film. It has been interpreted as arising from the classical skin effect, the penetration depth of which is defined as

$$\delta = (\rho/\pi\mu f)^{1/2} \tag{4}$$

$\rho$ being the electrical resistivity, $f$ the frequency, and $\mu$ the transverse permeability.

Upon application of a d.c. field, the permeability decreases, and accordingly $\delta$ increases until it reaches the radius of the wire which finally results in an effective change of the impedance, $Z$, considered for a magnetic conductor given by

$$Z = R_{dc}(kR)J_0(kR)/2J_1(kR) \tag{5}$$

with $k = (1 + j)/\delta$ where $J_0$ and $J_1$ are the Bessel functions and $R$ the radius of the microwire (Chen *et al.* 1998).

Amorphous microwires show also magneto-impedance effects and they are found to be more promising for several applications compared to wires and ribbons because of their tiny dimensions and protective glass coating. The influence of domain structure on this effect has been observed for vanishing negative (Vázquez *et al.* 1998) and positive (Mandal *et al.* 2000) magnetostrictive microwires.

Figure 6 (Vázquez *et al.* 1998) shows the magneto-impedance effect for $Co_{68.5}Mn_{6.5}Si_{10}B_{15}$ microwires with a metallic diameter of $\sim$14 μm and an insulating glass coating thickness of 5 μm. The wire displays a nonbistable hysteresis loop similar to that shown in Fig. 4(c) associated with a very low and negative magnetostriction constant ($\lambda_s \sim 10^{-7}$). The negative nature of $\lambda_s$ is deduced from the increase of the anisotropy field upon application of a tensile stress. A bamboo-like domain structure can be assumed, as in the case of negative magnetostriction amorphous wires obtained by the in-rotating-water quenching technique (Yamasaki 1992).

The existence of $(\Delta Z/Z)_m$ for a given $H_m$ has been reported for samples heated in the presence of a transverse magnetic field (Sommer and Chien 1996) or tensile stress (Tejedor *et al.* 1996) where a circular magnetic anisotropy is deliberately induced. In the present case such anisotropy spontaneously appears from the coupling between internal stress and magnetostriction. Then it seems likely that the appearance of $(\Delta Z/Z)_m$ is associated with the existence of a transverse circular anisotropy. In fact, the maxima in Fig. 6 should be ascribed to the maximum value of the circular permeability, where according to Eqn. (4) the penetration depth reaches a minimum.

The effect of applying an increasing axial field, $H$, is to balance the anisotropy field $H_k$. Consequently, $(\Delta Z/Z)_m$ is observed for $H = H_k$. Further increase of $H$ gives rise to reduction of the circular permeability and to a final decrease of impedance. The increase of $(\Delta Z/Z)_m$ with frequency (see inset of Fig. 6(a)) should be, in principle, ascribed to a stronger skin effect (Eqn. (4)).

The magneto-impedance effect has also been observed for very low and positive magnetostriction in a $Co_{83.2}Mn_{7.6}Si_{5.8}B_{3.3}$ microwire having a hysteresis loop similar to Fig. 4(b). As shown in Fig. 6(b)

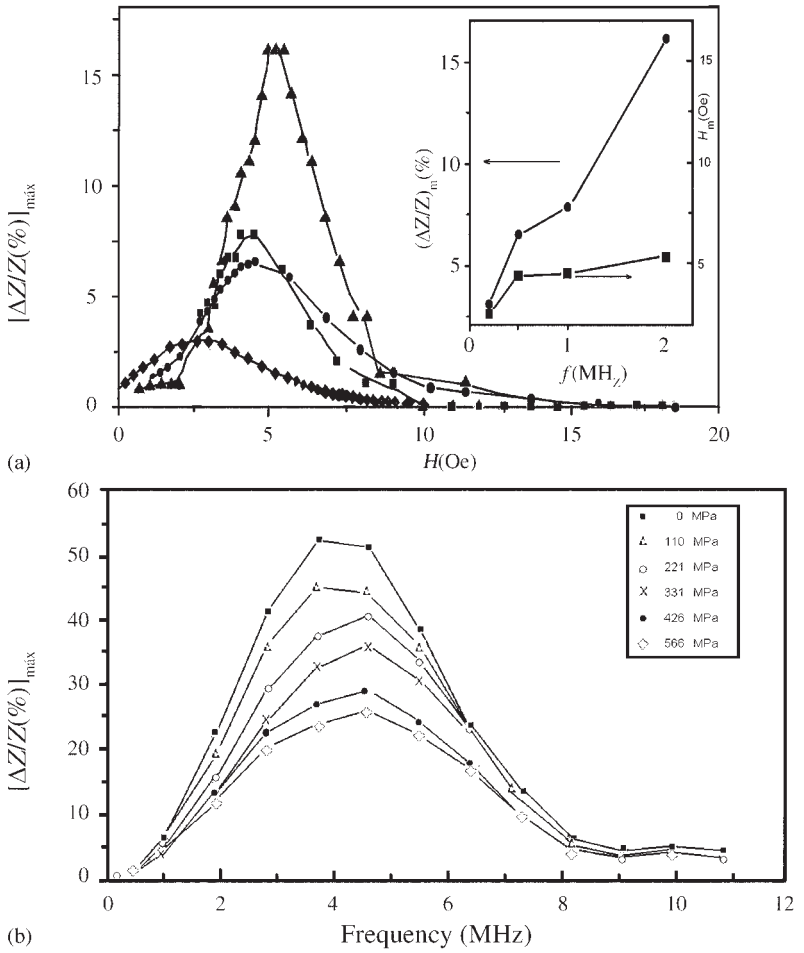

***Figure 6***
(a) Magneto-impedance effect of an as-prepared $Co_{68}Mn_7Si_{10}B_{15}$ sample at different frequencies ($I = 2.9$ mA) of a.c. current: 0.2 MHz (♦), 0.5 MHz (•), 1 MHz (■), 2 MHz (▲). The inset shows the dependences $(\Delta Z/Z)_m$ and $H_m$ on frequency of a.c. current (reproduced by permission of Vázquez *et al.* (1998) from *IEEE Trans. Magn.* **34**, 724–8; © IEEE). (b) The variation of maximum percentage change in magneto-impedance (i.e., the peak value of giant magneto-impedance), $(\Delta Z/Z)_m$ with frequency under different axial tensile stresses with 1 mA a.c. current through the sample (reproduced by permission of Mandal *et al.* (2000) from *Phys. Rev. B* **62**, 6598–602; © American Physical Society).

(Vázquez *et al.* 1998) a change of more than 50% in magneto-impedance has been observed for this sample. It has been obtained for a 140 Oe d.c. magnetic field along the length of the microwire. The application of external stress can change the magneto-impedance magnitude to a large extent, which opens the possible application of microwires as stress sensors.

In this case, the giant magneto-impedance can be explained by considering the change in penetration depth, $\delta$, due to the change in circular permeability according to Eqn. (4) caused by the application of a magnetic field. The applied d.c. magnetic field nearly compensates the axial magnetic anisotropy when it reaches the switching field of the sample. At this field, the quasi-free magnetization responds quickly to the external oscillating magnetic field and gives rise to a large circular permeability. As the switching field of our low-magnetostrictive sample is very small, a few mOe, the maximum value of the giant magneto-impedance is observed close to $H_{dc} = 0$. When the external d.c. field is increased beyond the switching field, the circular permeability decreases owing to the unidirectional magnetostatic anisotropy caused by $H_{dc}$. Therefore, with the increase of a d.c. magnetic field, the increase in penetration depth, $\delta$, results in a decrease in magneto-impedance.

The applied tensile stress generates a uniaxial anisotropy along the axis of the wire and increases the volume of the inner-core domain. As a result of it, the circular permeability and hence the value of magneto-impedance decreases with the increase of stress (Fig. 6(b)).

### *2.3 Ferromagnetic and Natural Ferromagnetic Resonance*

Technologically, the study of microwave properties is also very promising. In the microwave region (approaching GHz range), ferromagnetic resonance occurs, which is accompanied by absorption of energy at the resonance frequency.

Using the equation of Kittel for a plane (Kittel 1948), the resonance frequency $f_r$ can be calculated by means of

$$f_r = \frac{g}{2\pi}\sqrt{(H_a + 4\pi M)(H_a + H)} \tag{6}$$

Here $H_a$ is the anisotropy field, $M$ the magnetization, $g$ the gyromagnetic ratio, and $H$ the external applied magnetic field. At that frequency, the permeability increases dramatically and the skin depth is very small (less than 1 μm). Ferromagnetic resonance (FMR) is connected with spin precession about the magnetization vector due to the effect of a high-frequency electromagnetic field applied such that the magnetic component is perpendicular to the magnetization vector (Antonenko *et al*. 1997). As a rule, the observation of FMR needs the application of an external d.c. magnetic field which provides a uniform magnetization of the examined sample.

One of the most interesting phenomena observed in amorphous ferromagnetic cast microwire is natural ferromagnetic resonance (NFMR) (Kraus *et al*. 1981, Baranov 1988). The NFMR was observed in ferrite without the application of an external magnetic field. The cause of NFMR is the internal magnetic anisotropy. The frequency depends on the value of the magnetic anisotropy. In known materials, the NFMR frequency is less than 1 GHz.

The appearance of NFMR, in positive magnetostrictive microwires, characterized by a single well-distinguished line in the range 2–10 GHz indicates the existence of a large magnetic anisotropy. Generally, the magnetic component of the a.c. field is perpendicular to the microwire axis, so the internal magnetic anisotropy causes the microwire to be magnetized along its axis. This conclusion agrees with the axial magnetization presented by positive magnetostrictive microwires associated with bistable magnetic behavior.

Due to the high resonance frequency (up to 10 GHz) and the extremely large magnitude of the permeability ($\mu'' > 100$), microwires are of great importance for utilization as radio-frequency absorbing materials. The NFMR in the range from 2 GHz to 10 GHz is observed in all amorphous microwires with positive magnetostriction constant.

The NFMR frequency can be calculated by taking into account that the depth of the skin layer, $\delta$, is smaller than the radius of the microwire, $r$. Using Kittel's equation (Eqn. (6)) for plane and considering $H = 0$, one finds

$$f_r = \frac{g}{2\pi}\sqrt{(H_a + 4\pi M)H_a} \tag{7}$$

If $H_a \ll 4\pi M$, Eqn. (5) can be written as

$$f_r = \left(\frac{g^2 M H_a}{\pi}\right)^{1/2} \tag{8}$$

Considering $H_a$ as given by Eqn. (3) the resonance frequency can be given as

$$f_r = \left(\frac{\lambda\sigma_0 g^2}{\pi}\frac{kx}{kx+1}F(k,x)\right)^{1/2} \tag{9}$$

Equation (8) shows that there is a strong dependence of the resonance frequency on composition, through the magnetostriction constant, and on fabrication conditions, through $x$ and $\sigma_0$. Figure 7 illustrates the dependence of the anisotropy field, $H_k$, and the natural ferromagnetic resonance frequency on the ratio $\rho = R_m/R$ for the $Fe_{89}Si_3B_1C_3Mn_4$ microwires shown in Fig. 5.

## *3. Applications*

A broad number of applications can be developed using amorphous magnetic microwires (Marín *et al*. 1997) that are based on the magnetic properties

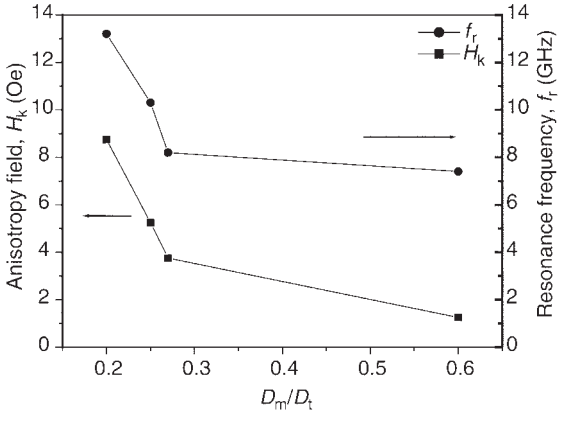

***Figure 7***
Dependence of anisotropy field, $H_k$, and natural ferromagnetic resonance on the ratio $\rho = R_m/R = D_m/D_t$ of $Fe_{89}Si_3B_1C_3Mn_4$ microwires shown in Fig. 5.

discussed above. Magnetic tags and magnetic detectors based on the bistable magnetic behavior or on the high magnetic susceptibility can be developed to work at low frequencies. Stress, current, position, liquid level or pressure sensors, and magnetic field detectors are based on giant magneto-impedance effect and would work at medium frequency. This type is employed in technologies such as car traffic monitoring, quality control of steels, vibrational detection of earthquakes, or biomagnetic sensors. Ferromagnetic resonance can be used to develop tags for article electronic surveillance and for electromagnetic wave shielding. In the following sections two particular applications are described.

### *3.1 Magnetic Tag*

One of the applications consists in the use of several Fe-based magnetostrictive microwires for sensing elements in magnetic tags. The tag contains several microwires with well-differentiated coercivity, all of them characterized by a bistable magnetic loop. Once the magnetic tag is submitted to an increasing magnetic field, each particular microwire reverses its magnetization resulting in an electrical signal on a coil system (Vázquez and Zhukov 1996). Figure 8 shows the schematic representation for a working system of a magnetic tag as described here.

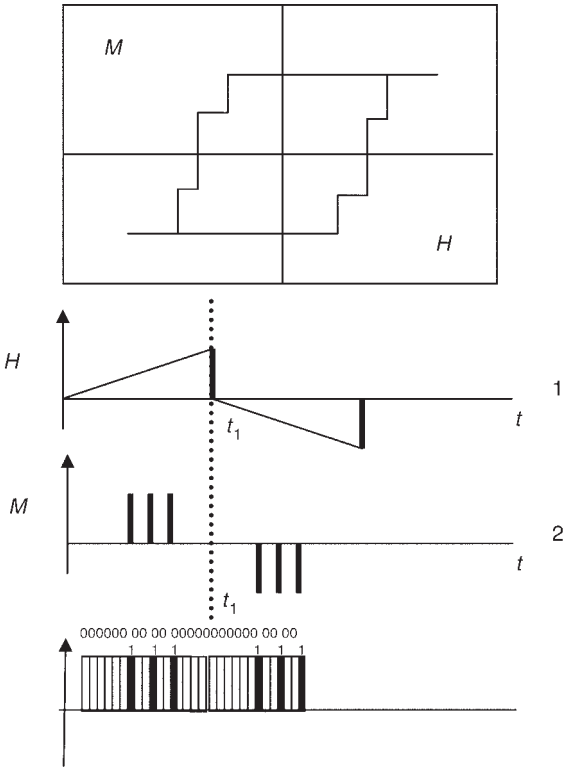

***Figure 8***
Schematic representation of the working system of a magnetic tag as described in the text (Vázquez *et al*. 1996).

### *3.2 Wireless Stress Sensor for Vehicle Tires*

This application is based on the stress dependence of the magneto-impedance effect. The sensor system

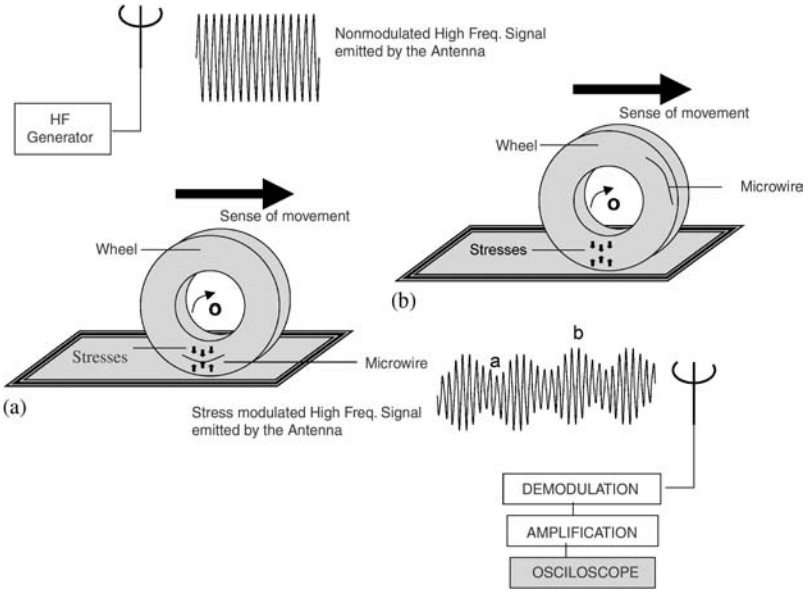

***Figure 9***
Schematic representation of a wireless stress sensors for vehicle tires.

monitors the frictional conditions between the tire and the roadway in order to enhance vehicle safety.

It has been shown that the stress measured at suitable positions in a car tire can be analyzed to give information on the frictional coefficient, the roadway conditions, and the tire inflaction. The sensor proposed here (Tyren *et al*. 2000) is based on a combination of magnetostriction and magneto-impedance. The stress produces a change in the permeability in the magnetoelastic microwire. Thus, the skin depth of this element is altered leading to a change in its electrical impedance. This results in amplitude variations measured by a radio-frequency link between the sensor and stationary antenna. Figure 9 shows a scheme of the basic principles of the sensor.

# Magnetic Phase Transitions: Field-induced (Order to Order)

This article is concerned with high magnetic field magnetization processes in ferrimagnets which are connected to the variation of mutual orientation of their magnetic sublattices and which reveal themselves through characteristic kinks and jumps in the magnetization curves. The magnetic symmetry of a crystal changes when the orientation of the magnetic sublattices spontaneously varies. In other words, a phase transition accompanied by a change of the magnetic symmetry takes place. In the present terminology such phase transitions are referred to as field-induced phase transitions (FIPTs), which may be of first or second order. It is evident that such phase transitions are accompanied by anomalous behavior of some physical properties and characteristics of the ferrimagnets (susceptibility, thermal properties, magnetostriction, magnetoelastic anomalies, Hall effect and magnetoresistance, magneto-optic phenomena, etc.). Comprehensive data and bibliography have been detailed in the survey of Zvezdin (1995).

FIPTs are traditional subjects in the physics of magnetic phenomena. The first examples attracting considerable attention were spin-flop transitions. The concept of these transitions was proposed by Néel in 1936, and they were found later in $CuCl_2 \cdot H_2O$ by Poulis and co-workers in 1951. In these transitions a collinear phase turns into a canted phase and further into a ferromagnetic one in an increasing field. A distinctive feature of the spin-flop transition in an ideal Néel antiferromagnet is that the differential susceptibility of the material in the angular phase is not dependent on the magnetic field or temperature. Later, similar phase transitions were investigated in ferrimagnets whose behavior turned out to be more sophisticated and interesting. The latter materials form typical examples to illustrate the general features of FIPTs.

That noncollinear magnetic structures may exist was first demonstrated theoretically by Tyablikov in 1956. He also defined the conditions of their existence in the case of isotropic ferrimagnets and calculated anomalies of the magnetization arising in the vicinity of such transitions. Perhaps the first experimental manifestations of these phenomena were observed in rare earth iron garnets by Rode and Vedyaev in 1963.

## 1. Magnetic Materials and H–T Diagrams

To comprehend FIPTs in a ferrimagnet and to obtain its phase diagrams, it is of prime importance to take the real magnetic anisotropy of the material into account. Consequently, various interesting phase diagrams result for ferrimagnets close to the compensation temperature. They include lines of first- and second-order phase transitions, critical points of the liquid–vapor type, and tricritical points, where the first-order phase transition line goes over to the second-order one on the line separating the phases, etc. (e.g., see Fig. 1).

### 1.1 Rare Earth Ferrite Garnets

FIPTs have been investigated rather closely in rare earth ferrite garnets where the critical fields of the transitions into the canted phase are not too large. Gadolinium iron garnet has been studied in much detail owing to the fact that application of the Néel model is well justified since the $Gd^{3+}$ ion, whose ground state is an orbital singlet $^8S$, has a comparatively small magnetic anisotropy (Fig. 2). The rare-earth sublattices in other rare earth ferrite garnets possess substantial magnetic anisotropy. The phase diagrams and the character of the phase transitions differ essentially from those of Néel ferrimagnets.

### 1.2 Intermetallic Compounds

Considerable attention has been devoted to intermetallic compounds R–TM, where R = rare earth and TM = transition metal (e.g., $RCo_5$, $R_2Fe_{17}$, $R_2Co_{17}$, $R_2Fe_{14}B$, $RFe_2$ etc.) (see *Alloys of 4f(R) and 3d(T) Elements: Magnetism*) (Fig. 3).

One of the various interesting phenomena inherent in these materials is the FIPT. Polycrystalline and powder samples have been the main objects for measurements. With the progress in both single-crystal growth and strong magnetic field production, crystal field effects and the role of magnetic anisotropy have become obviously of particular interest.

### 1.3 Free-powder Samples

Single crystals are not always available for the study of FIPTs and intrinsic magnetic properties. Free-powder samples are a good alternative. Verhoef *et al.* (1989, 1990a, 1990b) and de Boer and Buschow (1992) reported the elegant high-field free-powder method, which has been used to determine the intersublattice coupling strength in a fairly large number of intermetallic compounds. The particles of the free-powder sample, having a size of about 40 μm, are assumed to be small enough to be regarded as single crystalline and are free to rotate in the sample holder during the magnetization process, so that they will be oriented by the applied field with their magnetic moment in the field direction.

Verhoef *et al.* (1989) analyzed magnetization curves of $Er_2Fe_{14-x}Mn_xC$ compounds. These magnetization curves are the same as in the isotropic case. Only if both sublattices display magnetic anisotropy can an influence on the free-powder magnetization be observed. Figure 4 shows the free-powder

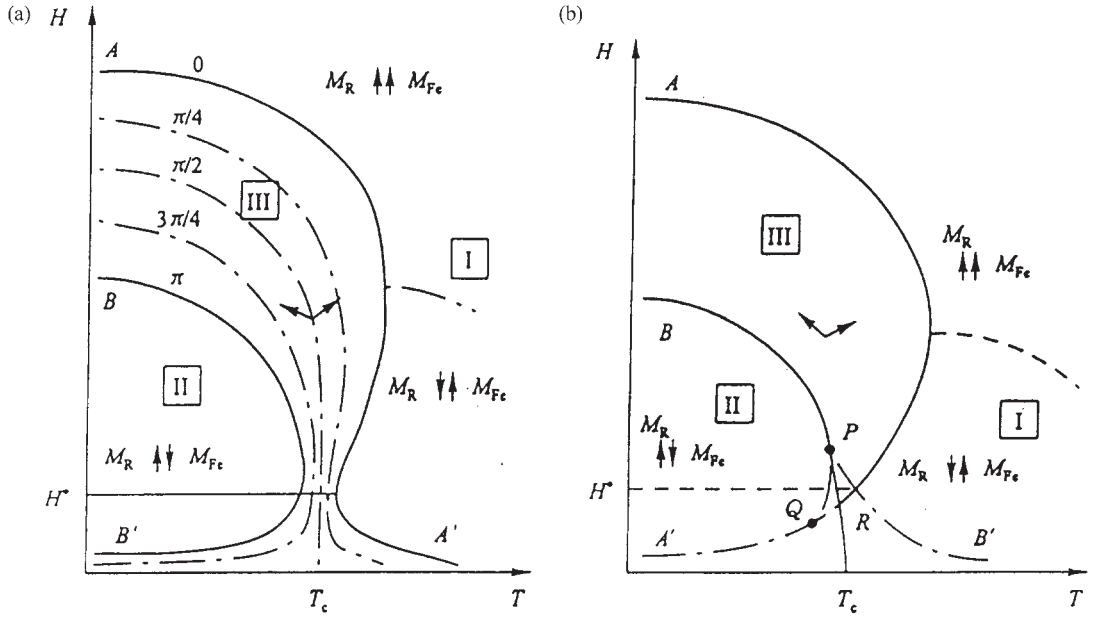

***Figure 1***
Phase diagram of a uniaxial ferrimagnet in a field (a) perpendicular and (b) parallel to the easy axis. In (a) the dashed curves are isoclines $\theta = \theta(H,T)$. The solid curves pertain to second-order phase transitions. In (b) BP and AR are curves of the second kind of phase transition, and A′R and PB′ are curves representing the loss of the collinear phase stability. PQ is a curve representing the loss of metastable canted phase stability, $PRT_c$ is a curve describing the first kind of phase transition, and P is the tricritical point (Zvezdin and Matveev 1972).

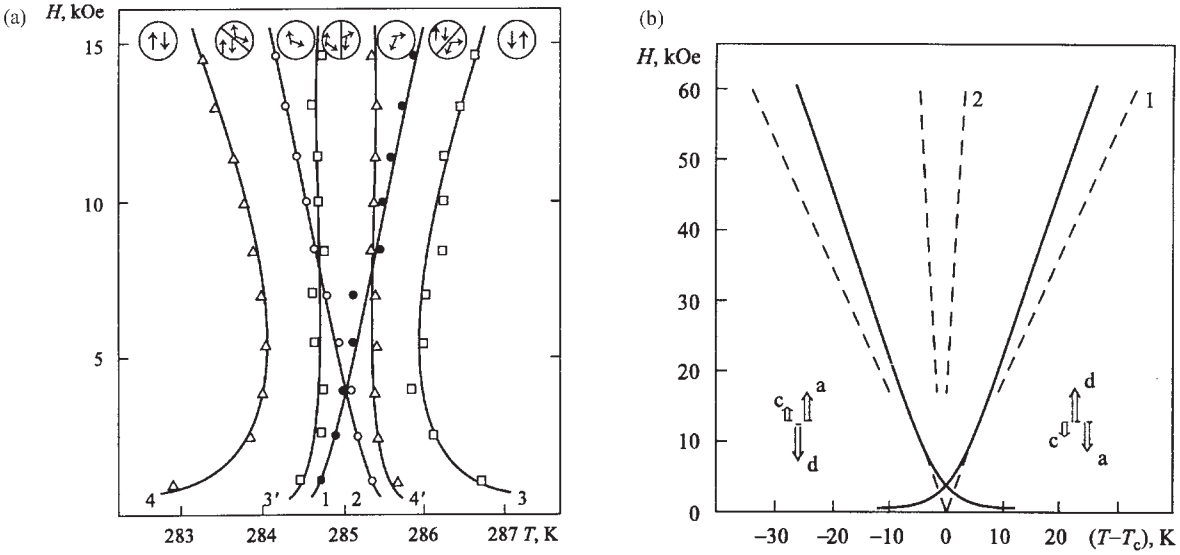

***Figure 2***
(a) Phase diagram of gadolinium ferrite garnet for $H^{\rightarrow} \psi$ [111] (Kharchenko *et al.* 1975a) and (b) the "reconstructed" high-field phase diagram of the epitaxial film $Y_{2.6}Gd_{0.4}Fe_{3.9}Ga_{1.1}O_{12}$ with $T_c = 183$ K (Gnatchenko *et al.* 1977).

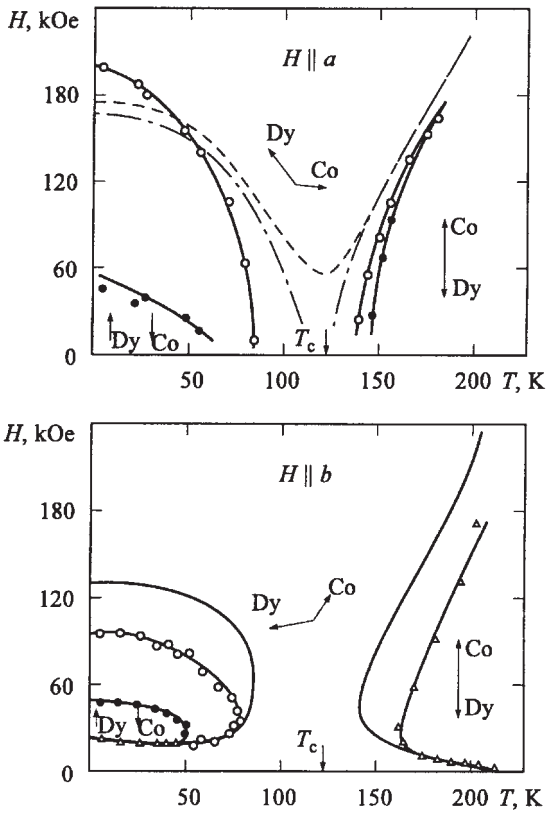

***Figure 3***
Experimental and theoretical phase diagrams of $DyCo_{5.3}$ in a field directed along the easy axis *a* and along the hard axis *b* in the basal plane: ○, experimental critical field ($H_{cr}^{'}$) and anisotropy field during increase of the external field; ●, critical field ($H_{cr}^{''}$) during decrease of the external field; <,critical fields coincide. The heavy lines are experimental phase diagrams, the thin solid lines are theoretical lines of phase transitions of the second kind, the dotted lines are theoretical stability curves of the collinear phase, and the dashed–dotted curves those of the noncollinear (high-field) phase (Berezin *et al.* 1980).

magnetization for $DyCo_{12}B_6$ at 4.2 K. This is a good example of the complete bending process in a ferromagnet. The magnetization curve in the canted phase is nearly linear indicating that the dysprosium sublattice anisotropy is much larger than that of the cobalt sublattice. It is seen that the effect of the magnetic anisotropy of the cobalt sublattice is rather small.

## 2. *Some General Features of FIPTs*

The phase transitions considered above are typical transitions with a magnetic symmetry change. For

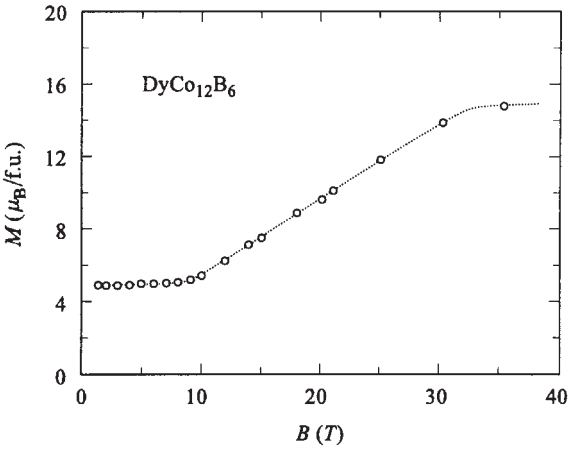

***Figure 4***
Free-powder magnetization curves of $DyCo_{12}B_6$ measured at 4.2 K. The circles represent measurements in a quasi-continuous field and the dotted lines represent a measurement in a field varying linearly with time (Zhou *et al.* 1992a).

instance, during the I–III transition (Fig. 1) the symmetry is relative to a rotation around the *z*-axis (i.e., parallel to the external magnetic field) with an angle $\pi$ (symmetry element $C_2^z$). This symmetry element is absent in phase III but double the number of equilibrium states in comparison with phase I are present here, which are transferred from one to the other by the "broken" symmetry element. Identical values of the free energy ("degeneration") correspond to these two states. It is accompanied by a division of the sample into domains of a low-symmetry phase.

There are peculiarities in the behavior of many physical properties near the transition point:

(i) The susceptibility goes to infinity. In this case the susceptibility describes the response of an order parameter to the thermodynamically conjugated field.

(ii) The occurrence of anomalies of thermodynamic quantities such as kinks, jumps, and $\lambda$-curves (the specific heat, magnetocaloric effect, Young's modulus and sound velocity, magnetostriction, and magnetooptical phenomena).

(iii) The conversion of the order parameter oscillation frequency to zero (soft mode) and the hindering of its relaxation.

(iv) The increasing order parameter fluctuations and their correlation radius.

(v) The expansion of domain walls and the rearrangement of domain structure in the sample.

Many theoretical studies devoted to FIPTs have been carried out using the mean field theory (or using equivalent approximations such as the Landau theory). These theories when constructing the free

energy of a system neglect, to some extent, the fluctuations of the order parameter. In the region of the transition temperature, i.e., in the region where the system stability is lost, the fluctuations increase strongly and these theories become inapplicable. A characteristic feature of the phase transitions studied is the fact that the Landau theory can be used for their description with practically no limitations. The region of inapplicability becomes extremely narrow: $\Delta T \approx 10^{-6}$– $10^{-8}$ K. This is a consequence of the fact that the fluctuations that occur in the region of the transition have a very large value of correlation radius.

## 3. Physical Anomalies Near FIPTs

### 3.1 Magnetization and Susceptibility

The magnetization isotherms $M_T(H)$ show a kink and the longitudinal susceptibility shows a jump at the transition into a noncollinear phase. This fact can be employed for the experimental determination of the critical fields. The field dependence of the magnetization in ferrite garnets of dysprosium, holmium, and erbium is shown in Fig. 5(a). The linear parts of $M_T(H)$ describe the magnetization in the collinear phase and the curved parts describe the

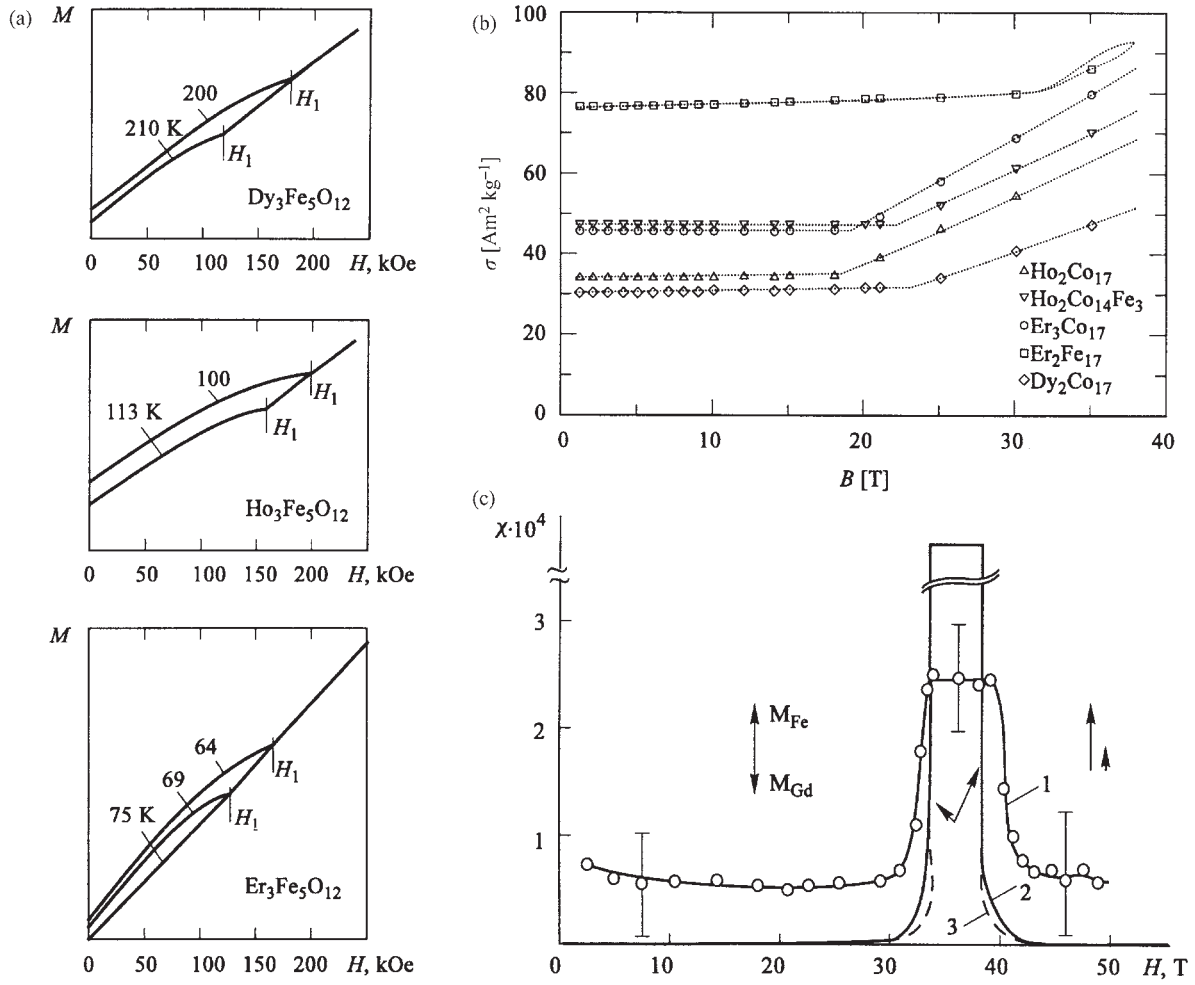

*Figure 5*
Field dependences of (a) the magnetization in ferrite garnets of dysprosium, holmium, and erbium (Levitin and Popov 1975), (b) high-field magnetization at 4.2 K of several $R_2M_{17}$ single-crystalline spheres that are free to orient themselves in the applied magnetic field (Verhoef 1990), and (c) differential susceptibility of $(GdY)_3Fe_5O_{12}$ iron garnet; ○, experiment; (– – –), theory (Gurtovoy *et al.* 1980).

magnetization in the noncollinear phase. Bend points (or the kinks) in the magnetization curves determine the values of the transition fields from collinear into the noncollinear phases. Much research has been devoted to the high-field magnetization of ferrimagnetic f–d intermetallic compounds. Many results have been obtained on oriented-powder samples. Figure 5(b) shows, for example, the typical curves for several 2–17 compounds clearly displaying the transitions from the collinear into the canted phase.

The effect of anisotropy on the $M_T$ and especially on the $\chi_d$ (differential susceptibility) behavior can be essential in the low-field part of phase diagrams and can give rise to additional anomalies. The region of canted phase narrowing (the "narrow throat" of the phase diagram, e.g., see Fig. 1) has to be taken as most "dangerous" on that count. In this area the angle rapidly changes with variation of the field and temperature, which results in anomalies in $\chi_d$.

The anomalous behavior of *the differential susceptibility* in the vicinity of the compensation point is attributed to the noncollinear structures in the field. Figure 5(c) illustrates the typical behavior of the differential susceptibility.

A *temperature hysteresis* of various physical quantities may arise during a transition into the noncollinear phase in the vicinity of the FIPTs. Butterfly-like temperature hysteresis loops as shown in Fig. 6 have been observed experimentally in the temperature dependence of the remanent magnetization in $ErFe_2$ near $T_c$.

The hysteresis of the magnetization vector in ferrimagnets near the compensation point leads to many anomalies in the behavior of other physical quantities, e.g., of kinetic effects. This concerns *galvanomagnetic* and *magneto-optical phenomena* (Hall effect

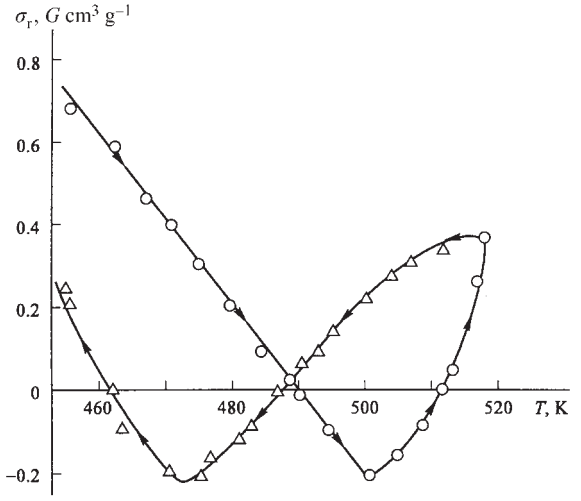

***Figure 6***
Temperature dependence of the magnetization of $ErFe_2$ in the vicinity of the compensation temperature (Belov *et al.* 1979).

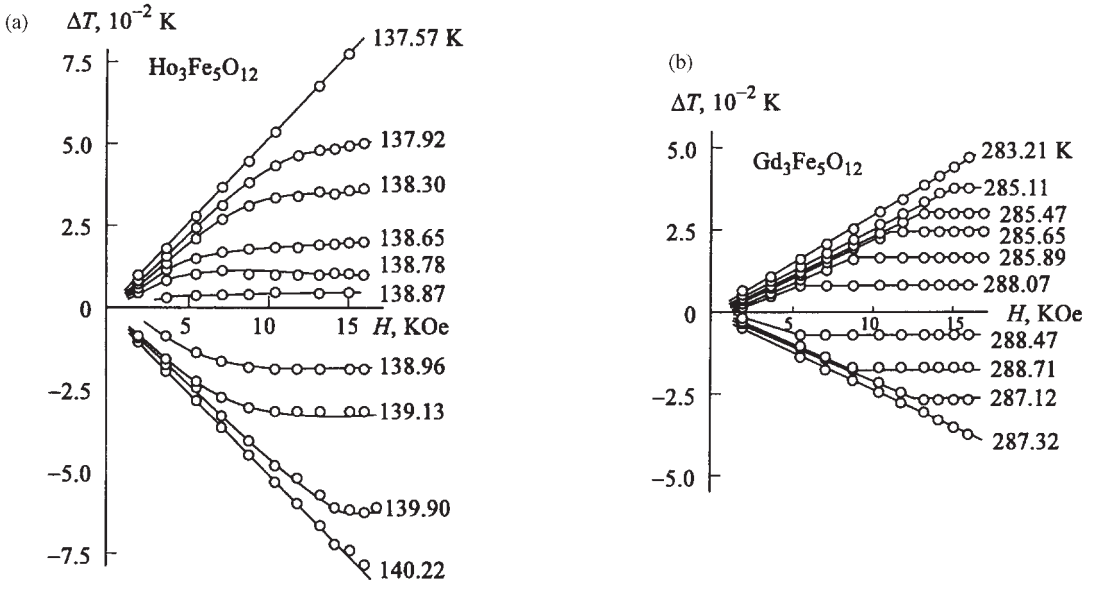

***Figure 7***
Magnetocaloric effect in (a) $Dy_3Fe_5O_{12}$ and (b) $Ho_3Fe_5O_{12}$ in the vicinity of the compensation temperature (Belov *et al.* 1979).

and magnetoresistence, Faraday effect) in the vicinity of the compensation point. These effects have been studied in ferrites, in amorphous R–Co (Fe) alloys, in the intermetallic compound $Mn_5Ge_2$, and in amorphous Dy–Co films.

### *3.2 Thermal Properties, Specific Heat, Magnetocaloric Effect*

A characteristic property of the second-order phase transition is the kink in the isotropic curve, i.e., the jump of $(dT/dH)_S$ at the boundary between the phases. Experimental data for some compounds are shown in Fig. 7. It is seen that $(dT/dH)_S = 0$ with good accuracy in some phases of the gadolinium ferrite garnets. This value perceptibly differs from zero in the noncollinear phase of holmium and dysprosium ferrite garnets. This is attributed to the large value of the anisotropy energy inherent in these materials.

There are also specific phenomena in the context of FIPTs related to magnetostriction, the thermal expansion coefficient, domain structure, and magnetic structure at the local defect (Zvezdin 1995).

## *4. Concluding Remarks*

Turning back to the question regarding the term "field-induced phase transition" let us note that a broader class of phase transition is described by this term:

(i) Ferrimagnetic–canted–ferromagnetic transitions, which are under consideration here. Occasionally these are referred to as spin-flop transitions by analogy with antiferromagnets.

(ii) Metamagnetic transitions in itinerant ferrimagnets of $YCo_2$ or $RCo_2$ type.

(iii) Crossover level transitions, which may be due to a field–induced crossing of the ground state levels of the f or d ions. It should be stressed that this crossing is accompanied by transformation of the magnetic structure of the crystal, i.e., a magnetic analog of the Jahn–Teller effect takes place.

(iv) First-order magnetic processes (FOMPs), which can be due to a competition between crystal field contributions of different order from the free energy.

It should be emphasized that there are no distinct boundaries between these FIPTs. Moreover, it is often possible to find some features inherent in one type of transition than in the others. For example, the mechanism of the spin-flop transitions considered in this survey is closely connected to the crossover-type transitions. Such inter-relations of different mechanisms of FIPTs are of great significance for strongly anisotropic ferrimagnets.

# Magnetic Properties of Dislocations

Magnetic properties originate from spin, orbital, and free motion of electrons, as well as from the nuclear magnetic moment. The existence of an angular momentum due to the orbital motion and to the spin of electrons was first identified based on the normal and anomalous Zeeman effects. In crystals, symmetry, periodicity, and ordering play an important role in determining the magnetic properties, which are therefore affected by crystal defects such as dislocations. Whereas the question of magnetism, directly or indirectly related to dislocations, has gained much attention in the past century, it is only in the recent years that a clear and straightforward explanation has been given to deformation-dependent magnetization, and this is largely due to electron microscopy studies.

## *1. Magnetisms*

### *1.1 Fundamental Properties*

According to the Einstein's special theory of relativity, de Broglie has shown that an electron can be equally regarded as a particle and as a wave packet consisting of the so-called de Broglie waves. The energy and momentum of an electron are given by

$$E = h\nu = mc^2(1 - v^2/c^2)^{-1/2} \tag{1a}$$

and

$$P = h/\lambda = mv(1 - v^2/c^2)^{-1/2} \tag{1b}$$

where $h$ is the Planck's constant having the dimension of action equal to energy multiplied by time. Then, the phase velocity of the de Broglie wave ($u = \lambda\nu$) is obtained by dividing Eqn. (1a) by Eqn. (1b) as

$$u = \lambda\nu = c^2/v = c(c/v) > c \tag{2a}$$

The inequality comes from a principle that the electron velocity $v$ never exceeds that of light $c$. Since the velocity of the wave packet is given by $\mathrm{d}\nu/\mathrm{d}(1/\lambda) = \mathrm{d}E/\mathrm{d}P$, it follows from Eqns. (1a) and (1b) that

$$\mathrm{d}E/\mathrm{d}P = (\mathrm{d}E/\mathrm{d}v)/(\mathrm{d}P/\mathrm{d}v) = v \tag{2b}$$

(see Yukawa and Toyoda 1977). An electron is, thus, shown to move at the velocity of a wave packet consisting of de Broglie waves. The motion of an electron engenders a magnetic moment that interacts with external and internal fields of electronic and magnetic origins. These interactions are accounted for by quantum mechanics (Schiff 1955, Dirac 1963, Raimes 1967, Kittel 1971, Bullett *et al.* 1980).

When a material is magnetized under an external magnetic field $\boldsymbol{H}$, the magnetization $\boldsymbol{M}$ is written as

$$\{\boldsymbol{M}\} = \chi\{\boldsymbol{H}\} = (\mu - \mu_0)\{\boldsymbol{H}\} \tag{3}$$

where $\chi$ and $\mu$ are the magnetic *susceptibility* and *permeability* of the materials, and $\mu_0$ the *permeability in vacuum*.

Equation (3) defines the magnetic properties of materials, which are classified into the following.

(i) *Ferromagnetism*. A strong magnetization due to electron spins all aligned within a magnetic domain sufficiently below the Curie temperature. The resistance from the crystal to the motion of domain walls induces some hysteresis on a magnetization curve as shown in Fig. 1. $\chi_{\mathrm{I}}$ is the initial susceptibility and $\chi_E$ is that measured under a high magnetic field, and $H_{\mathrm{C}}$ is the cohesive force.

(ii) *Antiferromagnetism*. A weak magnetization induced by application of a magnetic field due to spins which are aligned antiparallel by superexchange interaction in absence of the applied field (Anderson 1950). $\chi^{-1}$ decreases with $T$ below the Néel temperature (Néel 1948).

(iii) *Ferrimagnetism*. A magnetization due to antiparallel electron spins as for *antiferromagnetism*, but with different strength for opposite spins. It was found in a magnetite $FeO \cdot Fe_3O_4$ composed of ferrous ions ($Fe^{2+}$) with *ferromagnetism* and ferric ions ($Fe^{3+}$) with *antiferromagnetism* (Néel 1948).

(iv) *Paramagnetism*. A weak magnetization proportional to a magnetic field with $\chi^{-1}$ increasing with $T$ in the absence of interaction among spins (Langevin *paramagnetism*), or by spin bands near the Fermi

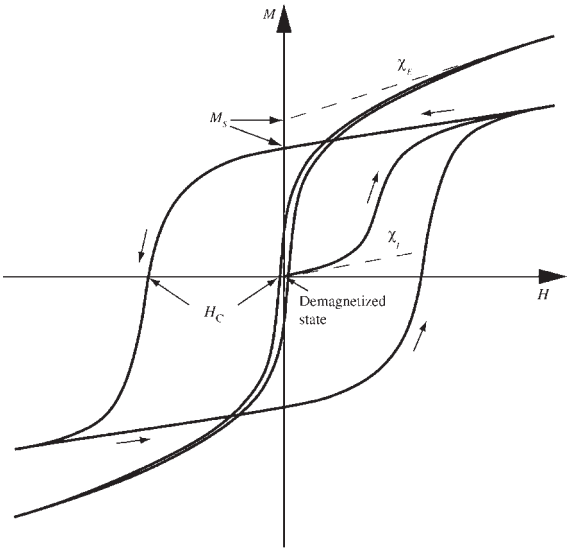

***Figure 1***
Magnetization curves of ferromagnetic samples with large and small $H_C$. $M_S$ is defined at $H = 0$ by linear interpolation from large $H$. $\chi_{\mathrm{I}}$ and $\chi_E$ are the susceptibilities at initial and high magnetic field (Izumi 2003).

surface due to the splitting of energy levels for opposite spins under a magnetic field (Pauli *paramagnetism*). Transition metals showing no spontaneous magnetization belong to this category (Kittel 1971). A material comprised of extremely small ferromagnetic domains may also show Langevin-type behavior (*superparamagnetism*).

(v) *Diamagnetism*. A weak magnetization characterized by a negative value of $\chi$ and observed in metals and organic materials without spin (feeble *diamagnetism*). When $\chi/\mu_0 = -1$, the transition from *paramagnetism* to perfect *diamagnetism* causes superconductivity, leading to the expulsion of the magnetic field and known as the Meissner effect (Meissner and Ochsenfeld 1933).

### *1.2 Magnetic Measurements*

(i) *Electromagnetic induction*. An induction coil is used to detect magnetization. For example, a vibrating sample magnetometer (VSM), which uses a secondary coil placed around a sample, is designed to detect an alternating voltage induced by a vibrating sample magnetized in an applied magnetic field.

(ii) *Electron spin resonance* (ESR). The momentum $\boldsymbol{J}$ or equivalently the magnetization $\boldsymbol{M}$ of an electron is detected by resonant absorption. The application of a magnetic field forces $\boldsymbol{J}$ to undergo Larmor precession, and this is amplified by superimposition of an electromagnetic wave with appropriate frequency. The spectrum and intensity of the absorption peaks provide useful information about $\boldsymbol{M}$. ESR is alternatively called *electron paramagnetic resonance* (Bowers and Owen 1955, Ingram 1968, Wertz 1968).

(iii) *Nuclear magnetic resonance (NMR)*. Resonance arising from the magnetic spin in the nucleus. This method picks up nuclear magneton as small as 1/1840 of the Bohr magneton. The shift of a resonance peak (Knight shift) in NMR provides detailed information about the behavior of electrons in metallic and nonmetallic crystals including Heusler alloys (Khoi *et al*. 1978). NMR is also applied to visualize a biologic organ by construction of a three-dimensional image (Gadian 1982) and to analyze the structures of proteins, nucleic acids, DNA fragments, etc. (Sarkar 1996).

(iv) *Mössbauer effect*. $\gamma$-rays with variable wavelength are generated by Doppler effect and utilized to detect by resonance small energy gaps induced by nuclear spins. The magnetic states of atoms can be analyzed by Mössbauer (1958) spectroscopy. Since the gaps are closely related to the motion of outer shell electrons, it can, for example, differentiate between $Fe^{2+}$ and $Fe^{3+}$. It has also permitted to identify a transition from *ferromagnetism* to *superparamagnetism* induced in Cu–Co by cold rolling (Nasu *et al*. 1968).

(v) *Diffraction*. Crystal structures and ordering are commonly examined by x-ray, electron, and neutron diffractions. Neutron diffraction provides direct information about electron spins interacting with nuclear magnetic moments. It has been used, for example, to analyze dislocation arrangements in deformed Fe (Göltz *et al*. 1986) and to discriminate between *ferromagnetic* and *antiferromagnetic* properties of Heusler alloys (Natera *et al*. 1970).

### *1.3 Observation of Magnetic Structures*

Electrons accelerated at high voltages are commonly employed to observe microstructures and to analyze physical and chemical properties. Various types of electron microscopes (EMs) or of electron microscopy modes have been developed in the last several decades, in particular, transmission EM (TEM), scanning EM (SEM), reflection EM (REM), scanning TEM (STEM), high-voltage EM (HVEM), high-resolution TEM (HRTEM), convergent beam electron diffraction TEM (CBEDTEM), Lorentz TEM (LTEM), and analytical TEM.

Electrons have both particle- and wave-like properties as described in Sect. 1.1. They are deflected mainly by protons and this is at the origin of a contrast in EM images and of diffraction patterns in the case of crystals as well as quasicrystals. During electron deflection, atoms may behave as secondary sources of signals such as x-rays, secondary electrons, Auger electrons, and inelastically scattered electrons. These signals serve to derive three-dimensional information, and of even higher order in the case of a quasicrystal, on local physical and chemical properties of the material. Image and diffraction properties are analyzed by electron wave mechanics (Thomas 1966, Hirsch *et al*. 1971, Williams and Carter 1998, Fultz and Howe 2002).

The TEM method utilized to visualize magnetic domains and domain walls is called Lorentz microscopy or LTEM. The magnetic domains appear upon defocusing of electron beams diffracted from different domains (Fuller and Hale 1960, Hirsch *et al*. 1971, Williams and Carter 1998, Graef and Zhu 2001). It differs from the optical methods achieved by $Fe_3O_4$ colloid or by using magneto-optical Kerr effect (Fowler and Fryer 1954), since the accelerated electrons are capable of penetrating through thin crystals. For example, LTEM is used to visualize Néel (1954) walls in a thin foil: the fine structure called crosstie walls in a Permalloy foil: (Huber *et al*. 1958) and the fine ripples introduced by thinning of Fe, Ni, Co and their alloys (Tsukahara 1967).

## *2. Dislocations*

### *2.1 General Remarks*

Dislocation is a line defect defined along the periphery of a surface, which is cut, displaced uniformly,

and then glued in an elastic continuum. The uniform displacement, called the Burgers vector, reflects crystal properties of periodicity, symmetry, and ordering. Atomic displacements around a dislocation and rearrangements of atoms carried by dislocation motion disturb the crystal properties mentioned above and therefore affect magnetic properties. There are excellent textbooks of elementary and advanced theories of dislocations (Read 1953, Friedel 1964, J. Weertman and J.R. Weertman 1967, Nabarro 1967, Hirth and Lothe 1968, Mura and Mori 1976, Mura 1987).

### 2.2 Stress and Strain around a Dislocation

The Burgers vector comes into an expression of eigendistortion $\beta^*_{ij}$ defined in the half plane (Mura and Mori 1976, Mura 1987) as

$$\beta^*_{23}(\{\boldsymbol{x}\}) = bH(-x_1)\delta(x_2) \quad \text{for a screw dislocation} \tag{4a}$$

and

$$\beta^*_{21}(\{\boldsymbol{x}\}) = bH(-x_1)\delta(x_2) \quad \text{for an edge dislocaiton} \tag{4b}$$

Other $\beta^*_{ij}$ are zero and $b$ is the magnitude of the Burgers vector $\boldsymbol{b}$. Displacements due to a screw and an edge dislocation are shown in Figs. 2(a) and 2(b) where the dislocation line is taken along the $x_3$-axis. $H(-x_1)$ and $\delta(x_2)$ are the Heaviside step function and the delta function, respectively, defined by

$$H(-x_1) = \begin{cases} 1, & x_1 < 0 \\ 0, & x_1 > 0 \end{cases} \tag{5}$$

and

$$\delta(x_2) = \begin{cases} 0, & x_2 \neq 0 \\ \infty, & x_2 = 0 \end{cases} \tag{6}$$

When $b$ is an integer multiple of the crystal periodicity, the dislocation is called perfect and if not, imperfect or partial. The Hooke's law is written as (see Mura and Mori 1976, Mura 1987)

$$\sigma_{ij} = C_{ijkl}(u_{k,l} - \beta^*_{lk}) \tag{7}$$

Here, commas denote partial derivatives of the displacements and Einstein's summation rule is adopted for the repeated subscripts. $C_{ijkl}$ are the elastic constants given for a cubic crystal by

$$C_{ijkl} = \lambda\delta_{ij}\delta_{kl} + \mu\delta_{il}\delta_{jk} + \mu\delta_{ik}\delta_{jl} + \mu'\delta_{ijkl} \tag{8}$$

where $\delta_{ij}$ and $\delta_{ijkl}$ are the Kronecker delta and $\lambda$ and $\mu$ are the Lame constants. Crystal anisotropy can be defined by $A = 2C_{2323}/(C_{1111} - C_{1122}) = 2\mu/(2\mu + \mu')$, with $\mu' = 0$ for an isotropic material. By solving the equations of static equilibrium given by

$$\sigma_{ij,j} = 0 \quad (i = 1, 2, 3) \tag{9}$$

one obtains $u_i(\{\boldsymbol{x}\})$ and $\sigma_{ij}(\{\boldsymbol{x}\})$ around a dislocation at rest. For a mixed dislocation $u_i(\boldsymbol{x})$ and $\sigma_{ij}(\{\boldsymbol{x}\})$ are given by superposition of its screw and edge components.

### 2.3 Dislocation Cores

Core configurations are usually determined by displacement of atoms from the positions determined by elasticity in the immediate vicinity of the dislocation center so as to minimize the total energy iteratively.

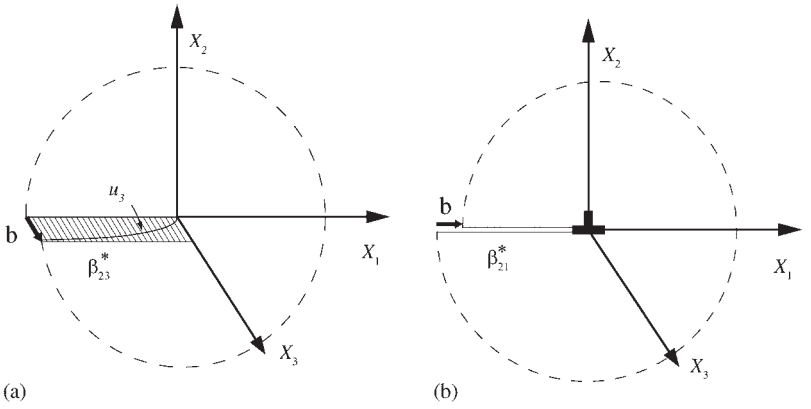

***Figure 2***
Schematic illustrations of (a) a screw and (b) an edge dislocations. See text for the explanation of $u_i$ and $\beta^*_{ij}$.

Dislocation core energy is an important factor but its evaluation by means of atomic simulations is somewhat ambiguous for the results are often affected by boundary conditions. It is nevertheless established that the energy stored in the dislocation core is usually smaller by an order of magnitude than the total energy of a dislocation. Elastic anisotropy must be taken into account upon setting boundary conditions for the computer simulations of dislocation cores when $|\mu'|$ is large. According to Yoo (1987), $\mu'$ contributes to the strength of intermetallic compounds notably in conjunction with the cross-slip from {111} to {001} in $L1_2$ ordered alloys. Dislocations in ordered intermetallics have been studied by many researchers and reviewed, for example, by Yamaguchi and Umakoshi (1990) and by Vitek (1998).

## 3. *Magnetic Properties Affected by Plastic Deformation*

### 3.1 *General Remarks*

Historically, studies of the effects of plastic deformation on magnetic properties were initiated in the early 1900s with no knowledge of the existence of dislocations (Rhoads 1901, Nagaoka and Honda 1902). These studies were focused on the "Permalloy problem" and "Isoperm problem" in 1930–40. The high *permeability* of a Permalloy (Arnold and Elmen 1923) is closely related to ordering (Dahl 1936) and disordering (Kaya 1938). Anisotropy in the magnetization arises from the alloy crystallinity as demonstrated by Honda and Kaya (1926). The "Isoperm problem" was raised in the course of the development of a permanent magnet with high $H_C$. Magnetization is also affected by a magnetic field applied during heat treatments (Dillinger and Bozorth 1935, Oliver and Shedden 1938, Tomono 1948, Chikazumi 1950). Typical permanent magnets with high $H_C$ are KS steel, MK steel, Alnico 5, Cunife, Cunico, Silmanal, and $RCo_5$. For example, fine rods of ordered precipitates aligned along $\langle 100 \rangle$ are responsible for the magnetic anisotropy in Alnico 5 (Heidenreich and Nesbitt 1952).

The basic studies on the crystalline nature, electron motion, and magnetostriction, which were rather advanced before 1950 in spite of several years of interruption, have contributed greatly to the recent understanding of the magnetic properties of dislocations. Some of the pioneering researches will be found in the Bibliography section (Rhoads 1901, Nagaoka and Honda 1902, Einstein 1905, Volterra 1907, Ewald 1917, Laue 1918, Arnold and Elmen 1923, de Broglie 1925, Pauli 1925, Schrödinger 1925, 1926, Dirac 1927, Fermi 1928, Heisenberg 1928, Bloch 1929, Fock 1930, Wigner and Seitz 1933, Kramers 1934, Dillinger and Bozorth 1935, Dahl 1936, Van Vleck 1937, Oliver and Shedden 1938, Kaya 1938, Brown 1940, 1941, Ralhenau and Snoeck 1941, Néel 1948, Chikazumi 1950, Anderson 1950).

Investigations of the effects of dislocations on magnetic properties have focused on the subjects of initial and high-field magnetization in ferromagnetic materials. In his pioneering work, Brown (1940, 1941) has given evidence that the displacements of atoms around a dislocation (Taylor 1934, Sect. 2.2) forces spin axes to rotate, influencing ferromagnetic properties. Although the effect of an isolated dislocation is small, a high density of dislocations introduced by plastic deformation affects the magnetic properties quite significantly (Seeger and Kronmüller 1960, Kronmüller and Seeger 1961, Kronmüller 1967, Umakoshi and Kronmüller 1981a). Therefore, in cyclic deformation less dominant effect appears on the magnetic anisotropy due to reversible motion of dislocations slowing down their accumulation (Mughrabi *et al.* 1976). Aspects related to the stress $\sigma_{ij}(\{\boldsymbol{x}\})$ around a dislocation will be described in more detail in Sect. 3.2.

Another important effect is that caused by dislocation motion. A strong magnetization asymmetry was found in cold-rolled $Ni_3Fe$ (Ralhenau and Snoeck 1941, Chikazumi 1950, Chikazumi *et al.* 1957), in cold-rolled $Ni_3Mn$ (Taoka *et al.* 1959), and in filed powder of $Pt_3Fe$ (Bacon *et al.* 1963). These properties are related to the changes in atomic ordering as described in Sect.3.3 and cyclic deformation amplifies the magnetic effects markedly in ordered alloys (Yasuda *et al.* 2000, 2003, Yamamoto *et al.* 2003, Izumi 2003), at variance from the above-mentioned observations in pure Fe (Mughrabi *et al.* 1976).

### 3.2 *Role of Stress-fields around Dislocations*

Magnetic measurements are useful in analyzing the dislocation structures in deformed crystals by nondestructive testing. In measuring $\chi_I$, $\chi_E$, $H_C$, and $M_S$ (Fig. 1) one should take the geometry of $\boldsymbol{b}$ and $\boldsymbol{t}$ into account and then compare to corresponding theoretical values (Brown 1940, 1941, Seeger and Kronmüller 1960, Kronmüller and Seeger 1961, Kronmüller 1967, Gessinger 1970, Willke 1972, Schroeder 1978, Umakoshi and Kronmüller 1981a). The magnetic energy arises from the exchange interaction between the spins ($\phi_A$), the magnetocrystalline anisotropy ($\phi_K$), the magnetization in the applied field ($\phi_H$), the long-range stray-field interaction coming from divergences of magnetization ($\phi_S$), and the magnetoelastic coupling ($\phi_M$). The last term describes the interaction between the spontaneous magnetization and the stress field around a dislocation.

For a cubic crystal, the magnetoelastic coupling energy $\phi_M$ depends on the direction cosines $\gamma_i(\{\boldsymbol{x}\})$ of the spontaneous magnetization as

$$\phi_M = -\frac{3}{2}[(\lambda_{100} - \lambda_{111})\delta_{ijkl}\gamma_k(\boldsymbol{x})\gamma_1(\boldsymbol{x}) + \lambda_{111}\gamma_i(\boldsymbol{x})\gamma_j(\boldsymbol{x})]\sigma_{ij}(\{\boldsymbol{x}\}) \quad (10)$$

where $\lambda_{100}$ and $\lambda_{111}$ are the magnetostriction constants reflecting the elastic property of $\lambda$, $\mu$, and $\mu'$. Here, Einstein's summation rule is adopted for the repeated subscripts as in Sect. 2.1. In order to determine $\gamma_i(x)$, the total energy must be minimized and this is written as

$$\delta \int [\phi_A + \phi_K + \phi_H + \phi_S + \phi_M] \mathrm{d}v = 0 \qquad (11)$$

where the integration is taken over the specimen. Under a high field of near saturation, since directions of the $M_S$ are nearly parallel to applied magnetic field, the partial differential equations derived from Eqn. (11) can be solved by means of Fourier transformation under a linear approximation (Seeger and Kronmüller 1960, Kronmüller and Seeger 1961, Umakoshi and Kronmüller 1981a). The spin distribution, $\gamma_i(\{\boldsymbol{x}\})$, is most conveniently visualized in the dislocation coordinates (Seeger and Kronmüller 1960, Kronmüller and Seeger 1961, Kronmüller 1967, Gessinger 1970, Umakoshi and Kronmüller 1981a, Yasuda *et al*. 2000). This is exemplified in Fig. 3 for an edge dislocation (after Kronmüller 1967). Here, the deviation of $\gamma_i(\{\boldsymbol{x}\})$ from the direction of the magnetic field applied along $\boldsymbol{b}$ is shown by arrows.

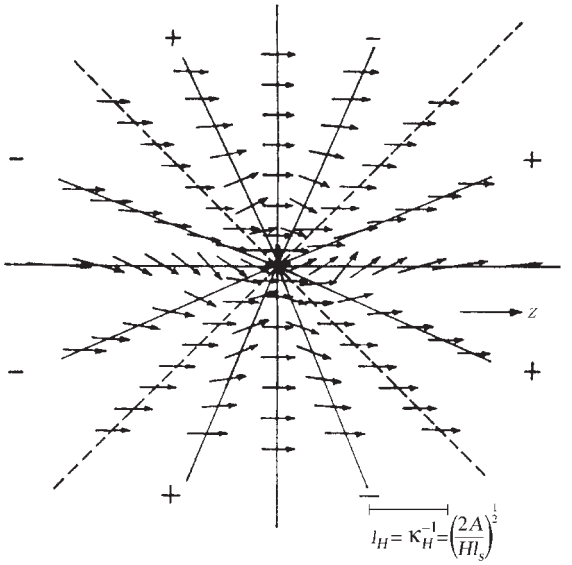

***Figure 3***
Distribution of the spontaneous magnetization (spins) around an edge dislocation in Ni. The magnetic field of $H = 100$ Oe is parallel to the Burgers vector. The arrows indicate directions magnified along the vertical axis by a factor of 5 (Kronmüller and Seeger 1961) (reproduced by permission of Kronmüller (1967) from *Can. J. Phys.* **45**, 633).

A method to obtain $u_i(\{\boldsymbol{x}\})$ and $\sigma_{ij}(\{\boldsymbol{x}\})$ around a dislocation in an anisotropic material is given in the literature (Stroh 1958, Nabarro 1967, Hirth and Lothe 1968, Mura and Mori 1976, Mura 1987). For simplicity though, $\mu'$ is set to zero in most of the calculations of $\sigma_{ij}(\{\boldsymbol{x}\})$ used to analyze the crystallographic characteristics of magnetism. Since dislocations may pile up against obstacles, the equilibrium of linear arrays of dislocations must be known and this problem was solved by (Eshelby *et al*. 1951).

*(a) B.c.c. Fe*

Plastic deformation in b.c.c. transition metals and in some covalent crystals is controlled by the motion of screw dislocations that overcome a large Peierls–Nabarro stress (Nabarro 1967) by thermally activated nucleation of double kinks (Celli *et al*. 1963, Dorn and Rajnak 1964). Such a motion is assisted by dispersed misfit strain centers at low temperatures, whereas the motion of edge portions is opposed by the same strain centers at high temperatures (Sato *et al*. 1970, Sato and Meshii 1973). This explains why TEM observations show that the dislocation structure strongly depends on deformation temperature (Foxall and Statham 1970).

Another characteristic feature to be noted in plastic deformation is that as dislocations are generated at some multiplication sources (Read 1953), they tend to pile up against obstacles. In the b.c.c. Fe, dislocation interaction with other obstacles takes over the double kink nucleation mechanism at a higher temperature so that dislocations are introduced as groups. In general, the susceptibility under a high magnetic field is proportional to $\sim b^2 N$ where $N$ is the total number of dislocations but this is modified by dislocation pileups as follows. In a pileup containing $n$ dislocations, $b$ is effectively increased to $nb$ and $N$ is decreased to $N/n$, thus changing the proportionality factor into $(nb)^2(N/n) = nb^2N$. Consequently, $\chi_E$ is increased by a factor $n$ (Kronmüller and Seeger 1961, Kronmüller 1967, Gessinger 1970, Willke 1972, Schroeder 1978, Umakoshi and Kronmüller 1981a, Göltz *et al*. 1986).

This property has been utilized to identify the number of dislocations contained in pileups. According to the orientation dependence of the high-field $\chi_E$ measured on a disk sample cut either parallel to the slip plane or perpendicular to the Burgers vector, Schroeder (1978) showed that $n = 16-17$ for the primary dislocations and $n = 12$ for the secondary dislocations in Fe single crystals deformed to stage III at room temperature. On the other hand, isolated edge dislocations are identified to be responsible for the orientation dependence of $\chi_E$ after deformation to stage I.

Umakoshi and Kronmüller (1981a) have examined the changes of $\chi_E$ in b.c.c. Fe due to primary edge and conjugate screw dislocations at successive stages of

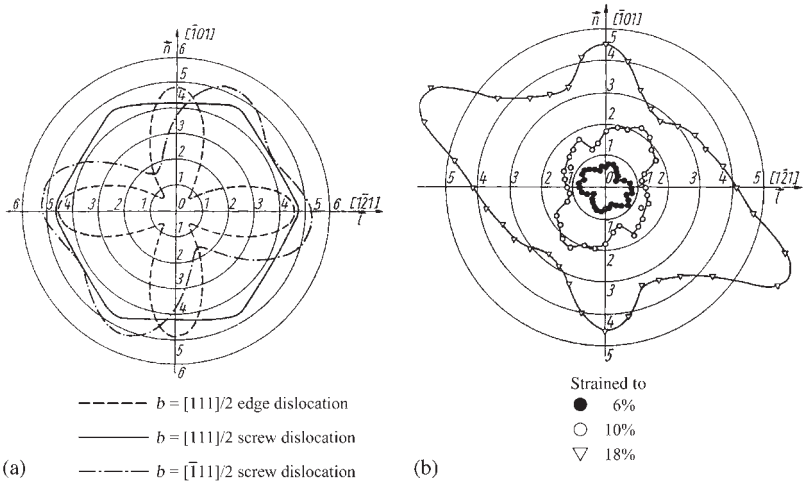

***Figure 4***
Comparison of the calculated (a) and measured (b) high-field $\chi$ shown by polar diagrams on a (111) plane perpendicular to the primary Burgers vector. It can be noted that $\chi$ conjugate Burgers vector $[\bar{1}11]/2$ becomes notable in addition to the contribution of the primary screw dislocations at a large strain in (b) (reproduced by permission of Umakoshi and Kronmüller (1981a) from *Phys. Stat. Sol. (a)* **66**(2), 509–520).

deformation at 77 K after pre-straining at 295 K. Figure 4 shows an example of their study. The orientation dependence of $\chi_E$ measured on a disk sample sliced perpendicular to the primary Burgers vector (after Umakoshi and Kronmüller 1981a) shows asymmetry due to introduction of conjugate screw dislocations. By comparison with the calculated contribution shown in (a), it can be seen that the measured $\chi_E$ in (b) is contributed by all dislocation characters. For a better understanding of the figure, it is required to incorporate the results of other disks sliced along different orientations (Umakoshi and Kronmüller 1981a).

Long-range internal stresses due to piled-up dislocations may alter the magnetic domain patterns. Umakoshi and Kronmüller (1981b) have examined the domain structures of Fe single crystals deformed at 77 K and 195 K by using the magneto-optical Kerr effect (Fowler and Fryer 1954). They showed that the structure is finer after deformation at 77 K than at 195 K in accordance with the operation of a double kink nucleation mechanism at low temperatures. Schroeder (1978) has examined domain patterns in Fe single crystals deformed at room temperature and explained the structure as a compromise between (i) the stray-field energy that forces spins to align parallel to each other and (ii) the Bloch wall energy that governs spin rotation in domain walls under the influence of stress field from piled-up dislocations. Magnetic measurements, thus, provide a wide range of information about dislocations introduced into ferromagnetic b.c.c. Fe by plastic deformation without damaging a sample.

*(b) F.c.c. Ni and $Ni_3Fe$*

In 1960s, it was questioned if the forest dislocations contribute to the work hardening in f.c.c. metals. In his review on the question, Kronmüller (1967) pointed out that magnetic measurements are useful as a nondestructive testing method to delineate the dislocation arrangements and to get some insight into the work-hardening mechanism. In spite of the fact that investigations are restricted to ferromagnetic materials and that interpretation of experimental results require some solid theoretical background, several researchers have taken advantage of magnetic measurements to identify the dislocation types, densities, and their distribution in f.c.c. Ni in a wide range of plastic deformation.

According to Eqn. (11), $\chi_I$ and $H_C$ are shown to be proportional to $N^{-1/2}$ and $N^{1/2}$, respectively (Seeger *et al.* 1964, Willke 1972). Since the work-hardening $\Delta\sigma$ is proportional to $N^{1/2}$ in a polycrystal (Taylor 1934) or in stage II of a single crystal, $\chi_I$ and $H_C$ are proportional to $\Delta\sigma^{-1}$ and $\Delta\sigma$, respectively (Seeger *et al.* 1964), as is observed in Ni single crystals (Hayashi 1967). Hayashi (1967) also shows experimentally that $\chi_I^{-1}$ is proportional to $\Delta\sigma^{1/2}$ in stage I in agreement with the work-hardening theory (Mott 1952). Dislocation structures in deformed Ni single crystals have been studied in more details by analyzing the high field $\chi_E$ due to edge, screw, and 60° dislocations (Gessinger 1970). The information about dislocation distribution can also be obtained from the domain structure by differentiating the dislocation-induced anisotropy of $\phi_M$ from the magnetocrystalline anisotropy of $\phi_K$ on the ground of theoretical analysis of the high-field $\chi_E$ (Willke 1972).

In ordered alloys, dissociated superdislocations may also contribute to the magnetic anisotropy. In a deformed $Ni_3Fe$, the anti-phase boundary the (APB) strip alters the orientation dependence of $\chi_E$ measured on the disks sliced along the low index planes in the dislocation coordinates (Yasuda *et al.* 2000). The magnetic anisotropy induced by the APBs differs from that due to the $\sigma_{ij}(\{\boldsymbol{x}\})$ around dislocations. More importantly, introduction of the APBs alters the absolute magnitude of the $M_S$ as described below.

### 3.3 Role of Atomic Rearrangements

The motion of partial dislocations affects magnetic properties in various ways depending on crystal structure, chemical composition, deformation temperature, strain rate, etc. The Néel and Curie temperatures are different in deformed specimens, basically due to the change in spin–orbital interactions (Kramers 1934, Van Vleck 1937, Anderson 1950). Microscopic observations, diffraction analyses, and spectroscopy are useful in studying magnetic properties that can be strongly affected by interchanges of atoms as exemplified below for some popular intermetallics.

#### *(a) B.c.c.-based superlattice*

There are three main types of b.c.c.-based superlattices as shown in Fig. 5. Plastic deformation increases magnetization most evidently for $\sim$35 at.% Al in Fe–Al intermetallics (Taylor and Jones 1958, Huffman and Fisher 1967, Gengnagel *et al.* 1972, Takahashi *et al.* 1996). In this composition, although both the B2 and $D0_3$ phases coexist, dislocations generated in the B2 phase control the plastic deformation as well as magnetic properties (Yamashita *et al.* 1998). The local change in ordering introduced by deformation increases the magnetization (Chikazumi *et al.* 1957, Takahashi and Umakoshi 1990, Takahashi *et al.* 1996). Mössbauer spectroscopy shows that the number of first-nearest neighbor (FNN) Fe–Fe pairs contributes to $M_S$ (Huffman and Fisher 1967).

In contrast, plastic deformation reduces the magnetization of a Heusler alloy of $L2_1$-ordered $Pd_2MnSi$ (Takahashi and Shinohara 1982), whose structure sketched in Fig. 5 was first found in a Cu–Mn–Al system (Heusler 1934). NMR analyses of various Heusler alloys show that *antiferromagnetic* and *ferromagnetic* properties come from the interaction between atoms in the second- (SNN) and the third-nearest neighbor positions (TNN), namely by B–C and B–B interactions where B is Mn (Khoi *et al.* 1978). The motion of a partial dislocation $\langle 111 \rangle/2$ on a $\{110\}$ plane in the $L2_1$ structure introduces the FNN Mn–Mn pairs at the expense of the TNN Mn–Mn pairs reducing *ferromagnetism*. This is because the Mn–Mn magnetic interaction is *antiferromagnetic* when they are located close (Néel 1948) and *ferromagnetic* when they are located apart (Kasper and Roberts 1956).

#### *(b) F.c.c.-based superlattice*

$L1_2$ and $D0_{22}$ are the most popular structures as shown in Fig. 6. The $L1_2$ structure originally found in an Au–Cu system (Johansson and Linde 1925) has gained much attention because of the good symmetry and ductility. Although slip takes place on $\{111\}$ planes in general at a low temperature, limited motion of $\langle 110 \rangle/2$ superpartial dislocations on cube planes introduces $D0_{22}$ structure locally. Plastic deformation reduces the susceptibility of $Pt_3Fe$ and

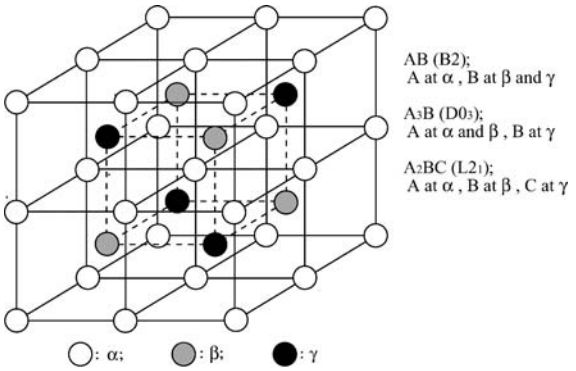

***Figure 5***
B2, $D0_3$, and $L2_1$ in b.c.c.-based superlattices. The figure contains eight unit cells for the B2 structure. A Heusler alloy assumes the $L2_1$ structure.

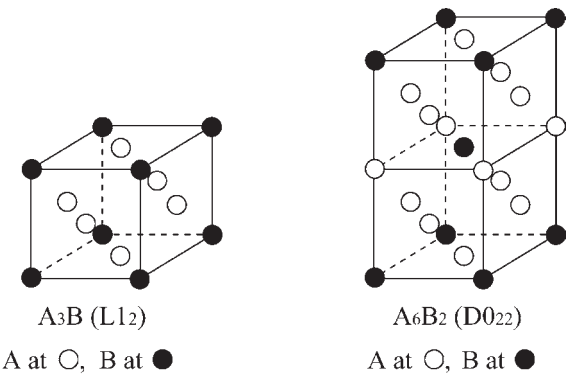

***Figure 6***
$L1_2$ and $D0_{22}$ in f.c.c.-based superlattices. The motion of a [110]/2 superpartial dislocation on a (001) plane induces the phase transformation $L1_2 \Rightarrow D0_{22}$, which does not involve interchanges of the FNN atoms (Flinn 1960).

introduces spontaneous magnetization (Bacon *et al.* 1963, Takahashi and Umakoshi 1990). On the contrary, spontaneous magnetization in ferromagnetic $Ni_3Mn$, $Ni_3Al$, and $Ni_3Ge$ disappears by plastic deformation (Taoka *et al.* 1959, Bacon *et al.* 1963, Takahashi and Ikeda 1983, Izumi 2003). This subject will be discussed more in Sect. 3.4(b).

### *3.4 Contribution of APB Tubes*

Vidoz and Brown (1962) have introduced the concept of APB tubes to explain the work hardening in superlattices. APB tubes were then observed and discussed by many researchers in both B2 (Crawford 1976, Chou and Hirsch 1981, 1983, Yamashita *et al.* 1998, Yamamoto *et al.* 2003) and $L1_2$ alloys (Chou *et al.* 1982, Shi *et al.* 1996, Murakumo *et al.* 2000a, 2000b). The APB tubes disappear upon annealing at a relatively low temperature, thus providing a simple means to discriminate their contribution to the magnetization (Yang and Baker 1997, Yamashita *et al.* 1998, Yang *et al.* 1999) from that due to APB ribbons bound by superpartials within a dissociated superdislocation (Takahashi *et al.* 1996, Takahashi and Umakoshi 1990).

APB tubes can be formed in any given ordered alloy whenever the leading and trailing partials that belong to a perfect dislocation are forced to move on different slip planes, and this may occur locally at jogs or at kinks. It is important to notice that APB tubes are free from dislocations except at their ends. Another point to be recalled is that change in ferromagnetism is essentially determined by spin–orbital interactions (Kramers 1934, Van Vleck 1937, Anderson 1950) related strictly to the atomic elements at APB tubes and APB ribbons in the ordered intermetallics. Formation of the APB tubes is favored by high deformation rates (Murakumo *et al.* 2000b, Yoneyama 2002) as well as by cyclic deformation (Yamamoto *et al.* 2003, Yasuda *et al.* 2000, 2003, Izumi 2003). Since the latter case is regarded as heavy deformation in the sense of accumulated strain, it is speculated that APB tubes might have also been introduced at high densities in crashed Fe–Al (Gengnagel *et al.* 1972) and in filed $Pt_3Fe$ (Bacon *et al.* 1963).

#### *(a) APB tubes in b.c.c.-ordered superlattices*

The introduction of APB tubes by plastic deformation in an Fe–Al alloy increases magnetization substantially (Yang and Baker 1997, Yamashita *et al.* 1998, Yang *et al.* 1999). Furthermore, $M_S$ increases markedly by cyclic deformation as shown in Fig. 7 (after Yamamoto *et al.* 2003). Here, the cyclic deformation corresponds to 33.7% of accumulated strain achieved by changing the mutually orthogonal compression axes. A constraint was imposed on the side surfaces to limit the operative shear systems

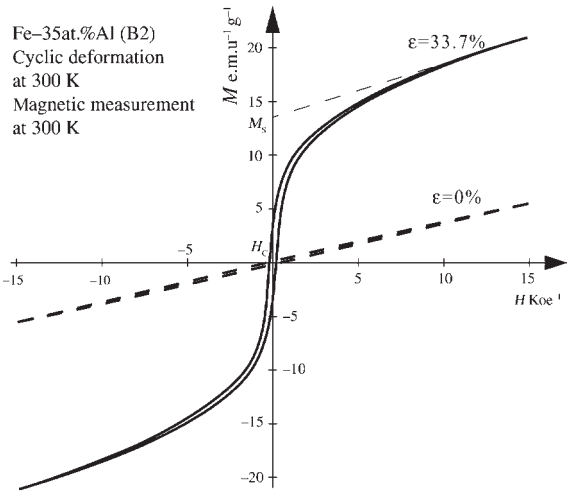

***Figure 7***
Strong magnetization in B2-ordered Fe–Al induced by cyclic deformation to an accumulated strain of 33.7%. Note that the small value of $H_C$ is about the same as that in deformed and nondeformed $Fe_3Ge$ shown later in Fig. 11 (Yamamoto *et al.* 2003).

(Murakumo *et al.* 2000a) and to hold the specimen dimension unchanged.

The observed evolution of $H_C$ can be attributed to the introduction of APB tubes. The small value of $H_C$ is reasonable since APB tubes are rather narrow without accompanying long-range stress. $H_C$ is approximately the same as that in $Fe_3Ge$, but substantially larger than that in $Ni_3Ge$, as shown later in Figs. 9 and 11. The APB tube density is several times higher than the dislocation density as shown in Fig. 8 (after Yamamoto *et al.* 2003). $M_S$ decreases by 80% after annealing at 573 K for 30 min, which, as shown by TEM observations, coincides with the disappearance of APB tubes (Yamamoto *et al.* 2003).

#### *(b) APB tubes in f.c.c.-ordered superlattices*

In contrast to what is observed in B2-ordered Fe–Al, plastic deformation reduces $M_S$ markedly in $Ni_3Ge$ cyclically deformed at 4.2 K as shown in Fig. 9 (after Izumi 2003). Superpartial dislocations are forced to glide on both {111} and {001} planes as a result of compression being applied along [100] and [011] axes alternatively. Generation of a high density of APB tubes by cyclic deformation is illustrated in Fig. 10, confirming that introduction of APB tubes is the main origin of the reduction in $M_S$ (Izumi 2003).

At this point, it is interesting to compare the above result on $Ni_3Ge$ with that on $Ni_3Al$ (Takahashi and Ikeda 1983) that shows a similar decrease in $M_S$ at 4.2 K. In the latter, $M_S$ decreases proportionally to the strain in the early stages and to the square root of

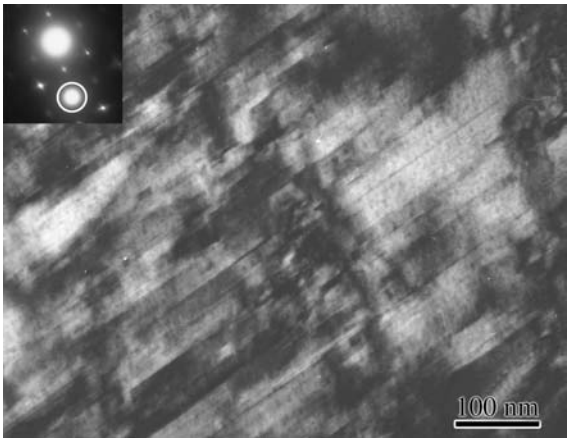

***Figure 8***
APB tubes introduced into the deformed Fe–Al of Fig. 7. The beam direction is nearly along [0$\bar{1}$1] and the dark-field image is taken under the 111 order spot (Yamamoto *et al.* 2003).

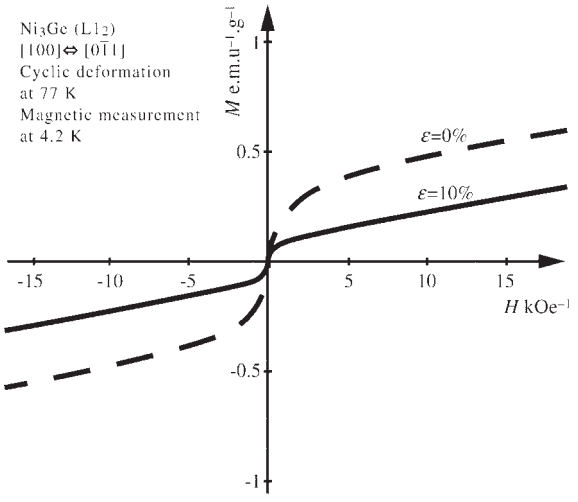

***Figure 9***
The spontaneous magnetization in $Ni_3Ge$ measured at 4.2 K decreases notably by cyclic deformation given at 77 K to accumulated strain of 10.0% (Izumi 2003).

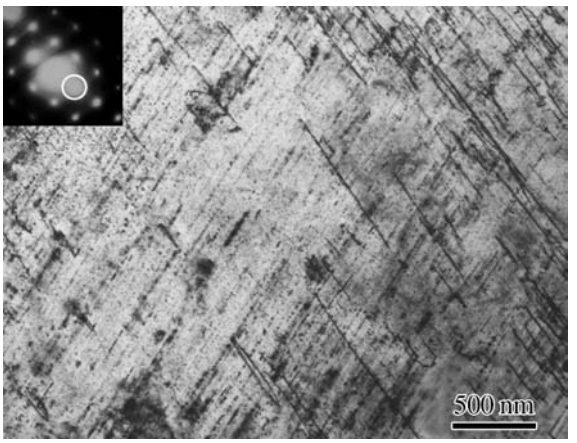

***Figure 10***
APB tubes introduced into the deformed specimen of Fig. 9. Irradiation-induced secondary defects are formed preferentially along the APB tubes which facilitates the visualization of the latter (Murakumo *et al.* 2000). The inset shows the 111 ordered spot used in the dark-field image. The beam direction is taken nearly along [0$\bar{1}$1] (Izumi 2003).

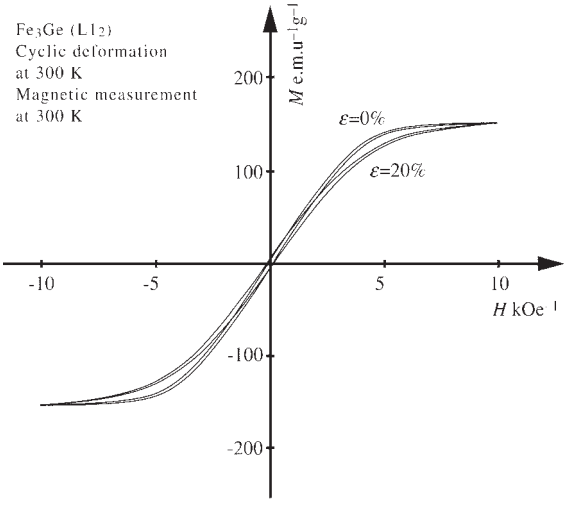

***Figure 11***
Magnetization curves obtained in nondeformed and cyclically deformed $Fe_3Ge$ at room temperature. Plastic deformation at room temperature does not change either $M_S$ or $H_C$ in visible amount, but it increases the high-field $\chi_E$ notably (Taniguchi 2003).

the strain at higher strains. It is known that APB tubes are also formed in $Ni_3Al$ (Chou *et al.* 1982, Shi *et al.* 1996, Murakumo *et al.* 2000b) and it is likely that they contribute to the ferromagnetic to paramagnetic transition through changes in environmental atoms as discussed for APB ribbons by Takahashi and Ikeda (1983).

It should be emphasized that plastic deformation does not reduce $M_S$ in $Fe_3Ge$ at 300 K as shown in Fig. 11 (after Taniguchi 2003). The effect of plastic deformation on $Fe_3Ge$, thus, differs from that observed in $Ni_3Ge$ and $Ni_3Al$, despite that they are all ferromagnetic at the temperatures examined. The origin may be ascribed to the difference in activated

slip planes. The preference for {111} versus {001} slip has been discussed and the anomalous strengthening of $L1_2$-ordered alloys is commonly attributed to the K–W locks (Kear and Wilsdorf 1962). More precise arguments are founded on the dislocation core structure (Yamaguchi *et al.* 1982, Paider *et al.* 1984, Umakoshi *et al.* 1984, Mryasov *et al.* 2002), APB energies (Flinn 1960, Saada and Veyssiére 1992, 1994), elastic anisotropy (Stroh 1958, Yoo 1987), super intrinsic stacking fault (SISF) (Fang *et al.* 1994), and complex stacking fault (CSF) (Hemker and Mills 1993, Balk *et al.* 2001).

It is interesting that $Fe_3Ge$ is one of a few $L1_2$ intermetallics, which does not exhibit anomalous strengthening and this has been interpreted as a result of the operation of cube slips in a wide temperature range (Ngan *et al.* 1992). Recently, production of $\langle 110 \rangle/2$ {001} partial dislocations and their multiplication have been confirmed by semi-*in-situ* experiments of a thin foil of stoichiometric $Fe_3Ge$ (Taniguchi 2003). Since the structural change from $L1_2$ to $D0_{22}$ in Fig. 6 or equivalently motion of $\langle 110 \rangle/2$ superpartial dislocations on {001} planes does not involve interchanges of the FNN pairs (Flinn 1960), it is natural that plastic deformation does not affect $M_S$ in $Fe_3Ge$ if FNN pairs are important. Concurrently, the high-field $\chi_E$ increases due to introduction of superdislocations as shown in Fig. 11.

On the other hand, plastic deformation induces spontaneous magnetization in $Pt_3Fe$ (Bacon *et al.* 1963, Takahashi and Umakoshi 1990) and in $Ni_3Fe$ (Yasuda *et al.* 2000) mainly by introduction of the FNN Fe–Fe pairs as evidenced in neutron diffraction study (Bacon *et al.* 1963). The spontaneous magnetization can be attributed to the introduction of APB tubes and APB ribbons as in the case of Fe–Al (Sect. 3.4.(a)). The dissimilar properties of $M_S$ in $Pt_3Fe$ and $Ni_3Ge$ ($Fe_3Ge$) can be ascribed to the difference in the sites A and B occupied by ferromagnetic atoms: B for the former and A for the latter as shown in Fig. 6. Ferromagnetic FNN pairs are absent before deformation in $Pt_3Fe$ and introduced by superpartial dislocation motion, whereas FNN pairs of ferromagnetic atoms are readily present in $Ni_3Ge$ and $Fe_3Ge$. The FNN pairs are destroyed by {111} slip in $Ni_3Ge$ but not by {001} slip in $Fe_3Ge$. The APB tubes are not found in $Fe_3Ge$, whereas $\langle 110 \rangle/2$ superpartial dislocations are found in {001} planes after both bulk and thin foil deformation (Taniguchi 2003), in support of the predominant operation of {001} slip in $Fe_3Ge$ (Ngan *et al.* 1992).

### *3.5 Magnetic Transition Involving Large Strain*

Both for practical and academic purposes, ferromagnetic shape-memory alloys (SMAs) have gained much attention in the recent years. Interest started after the discovery of a large strain in a tetragonal Ni–Mn–Ga induced by application of a magnetic field at a low temperature (Ullako *et al.* 1996). The elongation strain becomes as large as 6% in $Ni_{50}Mn_{28}Ga_{22}$ (Murray *et al.* 2000), 0.6% in $Fe_{70}Pd_{30}$ (James and Watting 1998), and −2.3% in $Fe_3Pt$ (Kakeshita *et al.* 2000). These values are strikingly larger than usual strain values for magnetostriction, e.g., 0.001% (Rhoads 1901, Nagaoka and Honda 1902) ∼0.17% (Clark *et al.* 1988). The effects of a magnetic field on the cubic-to-tetragonal phase transformation have also been discussed in the presence of hydrostatic (Kurisu *et al.* 1987) and unidirectional (Muto *et al.* 1987) stresses, raising a question of a distinction between mechanical and magnetic forces.

Steuwer *et al.* (2003) have compared the energies dissipated during 6% elongation in the two experiments of $Ni_{50}Mn_{28}Ga_{22}$ (Murray *et al.* 2000), one under a stress and the other under a magnetic field. The estimated energy dissipation is markedly larger for the stress–strain closure than for the magnetic hysteresis curves. The discrepancy may result from combination of the following two factors: (i) Evolution of such a large strain may be ascribed to motion of a line defect that carries uniform displacement or uniform rotation of the tetragonal lattice. The latter line defect is called disclination for which the eigendistortion $\beta^*_{ij}(\{\boldsymbol{x}\})$ is written in different manner from a dislocation (see Mura 1987). (ii) The variables controlled in the two experiments are different in terms of thermodynamics (Callen 1960); the parameter under control in the magnetic measurements is a magnetic field, $H$, which is intensive, whilst it is the length of the sample that is extensive, that is controlled in the mechanical tests.

Regarding the point (i), the so-called "giant magnetostriction" expressed by $\phi_M$ would be localized at the line defect. The large strain induced either by magnetic or mechanical force must be attributed to reorientation of the tetragonal lattice variants either from the magnetically hard to soft variants, or from the stress-free to stress-induced variants. Application of a sufficient magnetic field will move the line defect to reduce the magnetocrystalline anisotropy energy by the variant conversion, whereas application of a stress will do work to change the material dimension. These motions will accompany energy dissipation. The magnetic driving force required for the motion would be supplied by the asymmetric distribution of spins around the line defect under a high magnetic field, similar to that calculated for a dislocation (Seeger and Kronmüller 1960, Kronmüller and Seeger 1961, Seeger *et al.* 1964, Umakoshi and Kronmüller 1981a, Göltz *et al.* 1986). The point (ii) comes into the evaluation of the magnetic energy dissipated by motion of the line defect. In practice, the variant conversion takes place from one domain to another in discrete steps under a high magnetic field (Steuwer *et al.* 2003). The sudden change in the magnetic field caused by rotation of the spin direction would be

adjusted instantaneously by the power supply to maintain the magnetic field set in the experiment. Steuwer *et al*. (2003) suggest that the energy dissipation may be found only by measuring the energy consumed in the power supply that generates magnetic field.

From practical purposes, the large strain induced by a magnetic force is useful, for example, as an actuator that responds quickly by application of a magnetic field. The property differs from the usual SMA, which requires heat for the shape change. The quick response certainly comes from the characteristic properties of magnetism controlled by motion of electrons. However, it must be reminded that the shape change occurs by motion of a line defect, accompanying a friction. The energy dissipated in the shape deformation measurable on a stress–strain curve should provide useful information about the switching when such a material is used as an actuator.

## 4. Conclusion

Magnetic properties are affected by plastic deformation as a result of the introduction of perfect and imperfect dislocations and of the motion of these. Magnetic moments interacting with stress and strain around dislocations change $\chi$ and $H_C$ offering a nondestructive method to investigate dislocation structures in ferromagnetic materials. The observation of APB tubes by electron microscopy shows that the large effects of plastic deformation on the magnetic properties come from the interchanges of atoms in the wake of jogs and kinks, and this is not necessarily linked to the dislocation density generated by deformation. Giant magnetostriction in a ferromagnetic SMA is a current problem whose interpretation is certainly also founded on the motion of a line defect.

# Magnetic Recording Devices: Future Technologies

The ability to electronically access stored programs and data was the enabling technology in the development of general purpose computers a little over 50 years ago. One of the first practical electronic memory devices was a tank of mercury, roughly the size of an oil barrel, in which data was "stored" dynamically in the form of acoustic pulses passing through the mercury from a transmitter on one end to a receiver on the other. Less than 10 000 bits could be stored for only a few milliseconds at a cost of several dollars per bit and, of course, the data was lost when the power was shut off. Now for less than US$1000, one can obtain a desktop computer operating at 700 MHz with 128 Mbytes of high-speed semiconductor random access memory (RAM) supported by a 30 Gbyte magnetic hard drive.

This incredible improvement in performance and cost has been driven in both semiconductor and magnetic technology primarily by dimensional scaling of critical geometries, the sizes of which are now rapidly approaching fundamental limits. This article surveys new concepts which have been proposed to replace traditional magnetic disk systems. Only those which are nonvolatile are considered. These include patterned media, probe-based storage, and optical storage.

## 1. Storage Metrics and Recording Limits

Storage density is the most important metric driving both capacity and cost. Conventional longitudinal disk storage, for which new world records are being announced on the internet every few weeks, has been demonstrated at $>50\,\text{Gbit in}^{-2}$. Recent projections (Bertram and Williams 2000) suggest limits of $100\,\text{Gbits in}^{-2}$ for longitudinal recording and $500\,\text{Gbits in}^{-2}$ for perpendicular recording. In fact, values as high as $1000\,\text{Gbits in}^{-2}$ seem theoretically possible for perpendicular recording (Wood 2000). At $100\,\text{Gbits in}^{-2}$, the bit cell size is only $80\,\text{nm}^2$. Thus, new technologies which should realistically promise factors of 10 or more greater density to justify investment must immediately confront dimensions beyond the limits of established processing technology.

Capacity is the number of bytes (8 bits) which can be accessed directly. Drives with capacities $>70$ Gbytes are being sold today and by extrapolation should reach capacities of $>700$ Gbytes. The range of capacities, however, will extend as low as 1–10 Gbytes in physically smaller drives targeted for increasingly important portable applications.

The ultimate metric is the cost/byte. In 1999, the average cost per Gbyte for hard disk storage was $\sim$\$20 and by 2001 had dropped to $\sim$\$4. Again by extrapolation, the cost of disk storage will certainly be reduced to $<$\$1/Gbyte for high capacity drives.

Access time is the time required on average to reach a random bit. Because they are mechanical, even the highest performance hard drives have relatively slow access time of $>6$ ms. Even when rotation speeds are increased to 20 000 rpm or higher, the cost of reducing the head positioning time will probably limit access times to $\sim 4$ ms.

The rate at which data can be either written or read is the same in hard drives but in other technologies may not be. For fundamental reasons relating to the dynamics of magnetization switching and available head materials, data rates $>5$ GHz will be difficult to achieve in drives using only a single head. Multiple head systems could, of course, provide high data rates at a cost and power penalty.

Reliability will be used here to include error rate, archivability, and environmental resilience. For all technologies, corrected error rates of $\leqslant 1 \times 10^{-15}$ and a 10-year storage life are required. Resilience, e.g., shock resistance, will define market size. Hard drives have shown considerable improvement in this area and are now being considered for demanding applications such as portable cameras.

## 2. Patterned Magnetic Media

In conventional continuous polycrystalline thin film magnetic media, transition noise is reduced by reducing the grain size and the coupling between grains (see *Magnetic Recording Technologies: Overview*, *Micromagnetics: Basic Principles*). To circumvent superparamagnetic effects which limit the minimum grain size, it has been proposed to pattern media composed of highly coupled grains into discrete single domain-size bits. Then, the transition noise would be determined by the accuracy with which the pattern edges could be defined. In various embodiments, this concept is critical to several potential technologies discussed below. In this section, we address it in its simplest implementation as a direct replacement for continuous media in an otherwise conventional disk system.

Using direct write e-beam lithography (DWEL), magnetic circular dot arrays of 65 Gdots in$^{-2}$ (Chou *et al.* 1994) and holes at $>300$ Gholes in$^{-2}$ (Xu *et al.* 1995), close to the e-beam lithography limit, have been prepared. The highest density array in which individual elements have been characterized magnetically had only 29 Gdot in$^{-2}$ produced by DWEL and showed a surprisingly large $\pm 58\%$ variation in coercivity (Haginoya *et al.* 1999). This is a serious problem which must be investigated further. There are, however, no convenient techniques to characterize individual elements with dimensions $<50$ nm, the present practical limit of magnetic force microscopy. It is also prohibitively expensive to routinely make arrays with DWEL large enough to be characterized on standard magnetometers.

In fact, the highest density array which has been examined magnetically had 65 Gdots in$^{-2}$ (Fig. 1) over $\sim 10$ mm$^2$ and was produced by interference lithography (Ross *et al.* 1999). This is an interesting technique for producing 2D periodic patterns over large areas with a periodicity somewhat greater than half the wavelength of the illumination. Although available sources and photoresists have limited the periodicity to 100 nm, experiments are in progress to reduce this by a factor of 2–4. If a periodocity of 25 nm could be achieved, it would seem to offer a cost-effective process for producing patterned media with densities of 1000 Gbit in$^{-2}$. However, it is not clear how this can be done in a circular array compatible with conventional disk technology.

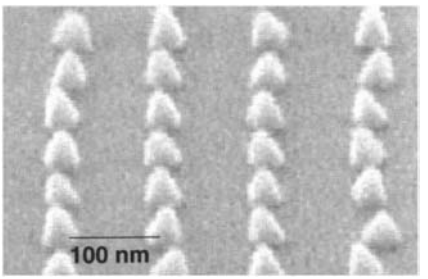

***Figure 1***
Electron micrograph of evaporated Ni pyramids with base 35 nm and height 40 nm. The pyramids form a 100 nm period square array, which appears foreshortened in the micrograph (from Ross *et al.* 1999).

To minimize the lithography cost, another imaginative approach is to write the desired pattern on a large area die and then use the die repeatedly to transfer the pattern by printing a masking material (Wang *et al.* 1997) or by imprinting the pattern into a masking material. Using the latter technique to form a template, Cui *et al.* (1999) were able to prepare arrays of Ni particles 70 nm in diameter at a density of 18 Gbits in$^{-2}$ over an area of 16 cm$^2$. Recalling that contact lithography was plagued historically by resist pull-outs, mask damage, and nonuniform contact, considerable ingenuity will be required to obtain high yield at nanometer dimensions especially with processes which require high temperature or pressure. However, recent results (Colburn *et al.* 1999) using a photopolymerizable liquid between the substrate and the template to form the etch mask demonstrate reliable replication of features as small as 60 nm. A key feature is the release coating on the template formed from a self-assembled monolayer.

Still another clever idea is the possible use of patterned structures which can act as electron emitters in the presence of large electric fields. An additional magnetic field in combination with the electric field is used to focus the electrons onto a closely spaced resist film, thus forming an image of the pattern in the resist. This has the potential for rapidly reproducing high-resolution images over large areas. Resolution better than 50 nm has been demonstrated (Tromp 2000).

The development of a reliable head/disk interface, which allows heads to fly less than 25 nm above the media surface, is a major factor in the continuing increases in disk storage density. Providing a suitably robust surface is a challenge for patterned media which significantly complicates additive or subtractive fabrication processes. A more attractive approach in which the pattern is formed magnetically rather than geometrically has recently been demonstrated (Devolder *et al.* 1999). Ion implantation of perpendicularly oriented Co–Pt multilayers with

30 keV $He^+$ ions through a mask significantly reduced the coercivity and allowed regions as small as 50 nm to be defined in a planar film. In other experiments, the Curie temperature was also reduced, suggesting the possibility of leaving magnetic islands in a nonmagnetic matrix.

An elegant way to avoid the lithography problem would be to have the patterning done by nature through a process of self-assembly. This is now the subject of intense study across many disciplines well beyond the focus of this review. However, one very relevant scheme relates to the self-ordering of pores in alumite. It is well known that the anodization of aluminum can produce a disordered porous structure. For many years, workers used the structure as a template to study electroplated magnetic nanowires with diameters as small as 10 nm. Extended multiple anodization has been shown to produce beautifully ordered hexagonal arrays of pores (Fig. 2). This suggested immediately the possibility of self-assembled perpendicular media obtained by electroplating magnetic wires into the ordered pores.

Despite considerable efforts, however, it has not been possible to increase the size of the ordered domains to more than 100 $\mu m^2$ and that only after lengthy anodization of up to 87 hours. In addition, conditions for ordering constrain the periodicity to $\sim$100 nm (64 Gpores $in^{-2}$). Remarkable progress in circumventing the first of the two problems has been demonstrated, however. Ordered pores over 20 $mm^2$ were produced by anodization of an Al surface initially decorated by imprinting with a SiC die. The highest density achieved was 64 Gpores $in^{-2}$, limited by the resolution of the die, patterned with DWEL. If this can be extended to higher densities and circular arrays, it would offer another route to a practical media process.

A chemical method for preparing self-assembled thin film arrays with either cubic or hexagonal symmetry of highly uniform spherical FePt single crystal particles has been described by Sun *et al.* (2000). After annealing above 500 °C to obtain the high anisotropy FCT phase, randomly oriented 4 nm particles on 6 nm centers with coercivities in excess of 4000 Oe were obtained. This exciting development has enormous potential both in the near term where a single bit in a conventional rotating disk system could include many particles and in the future where particles might be addressed individually. The latter would translate to densities in excess of 10 Tbits $in^{-2}$.

In summary, lithography limits are a major obstacle to producing cost-effective patterned media with densities $>$100 Gbits $in^{-2}$. However, new developments in interference lithography, imprint technology and patterned implantation could extend this to 1000 Gbits $in^{-2}$. Self-assembly offers the potential for even higher densities. It is, of course, assumed that processing technology will allow heads with commensurate dimensions to be fabricated.

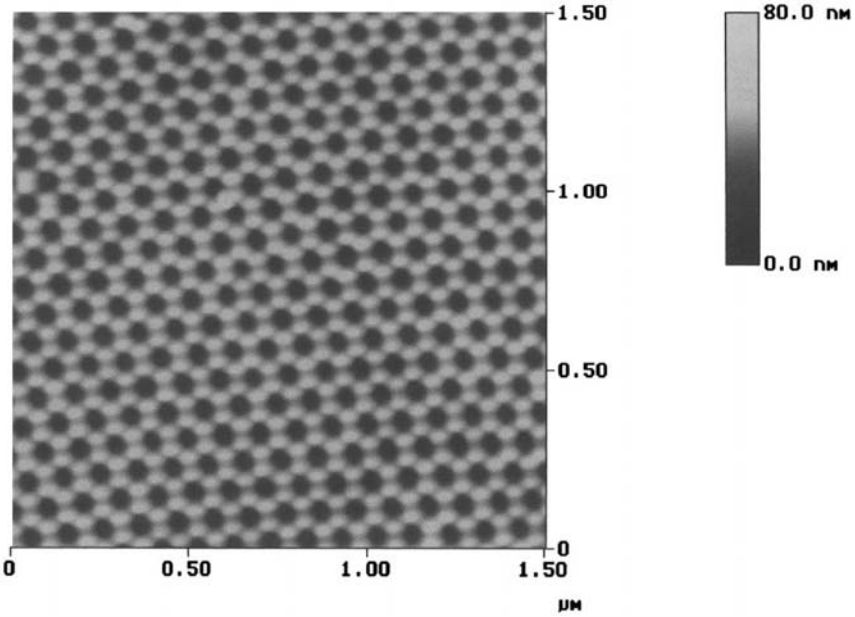

***Figure 2***
Atomic force micrograph (1.5 × 1.5 $\mu m^2$) of ordered aluminum Al (plus $Al_2O_3$ formed in air) after anodizing in $H_2C_2O_4$ for 25 hours, then stripping $Al_2O_3$ porous film with $H_3PO_4/H_2CrCo_4$. The darker spots are the pore bottoms.

### *3. Probe-based Storage*

The development in the last 15 years of scanning probe microscopy (SPM) based on precisely positioned micromechanical cantilevers has resulted in a variety of techniques for characterizing, imaging, and manipulating surface layers with resolutions and positioning accuracies ranging from $1 \times 10^{-1}$–$1 \times 10^{2}$ nanometers (Wiesendanger 1998). The potential application to high-density storage has been widely recognized although inherent speed limitations posed what initially appeared to be a fatal weakness. However, equally rapid developments in microelectromechanical system (MEMS) devices suggest the possibility of operating multiple probe heads in parallel to achieve acceptable data rates.

The ability to fabricate probes with tips a few nanometers in size is a key element to SPM. Furthermore, since the probes and their supporting cantilevers are usually formed by etching from a silicon wafer, it is possible to integrate active devices into the probe structure allowing a wide range of functionality based on electrical, magnetic, mechanical, optical, and thermal phenomena. Four implementations are of particular interest for storage: scanning tunneling microscopy (STM), atomic force microscopy (AFM), magnetic force microscopy (MFM), and scanning near-field optical microscopy (SNOM). In STM, the tunneling current between the probe tip and the surface is used to measure the topography and electronic characteristics of the surface with atomic resolution. In AFM, the probe tip is kept close to or in contact with the surface and the force on the tip used to detect topography. Special AFM probes have also been used to mark the surface mechanically or thermally or to make electrical contact.

Carbon nanotubes attached to probes are particularly attractive because of their size, flexibility, and electrical and magnetic characteristics. Although atomic resolution is also possible with AFM, it is typically not less than a few nanometers in the contact mode, limited by the size of the probe tip. In the most common form of MFM, the probe tip is coated with magnetic material and the force (or force gradient) measured between the tip and the stray field above the surface of the sample arising from a divergence of the magnetization in the sample (see *Magnetic Force Microscopy*). Since all the magnetic material on the probe contributes to the force, the resolution of MFM is 30–50 nm, the poorest of the four techniques. Instruments using other magnetic interactions such as magnetic resonance or torque have been developed but their applications to storage have not been discussed. In SNOM, special lenses or apertures in close proximity to a surface are used to provide resolution in the near field several times less than the wavelength of the illumination. In one configuration using interference, the resolution observed was an extraordinary $\lambda/800$ (Zenhausern *et al.* 1995).

While the use of STM for surface analysis has become ubiquitous, the realization of a practical storage scheme still faces enormous challenges. Although STM has the highest resolution, its extreme sensitivity to tip-to-surface spacing and the likelihood of required operation in UHV to avoid surface contamination, makes STM the least explored of the four methods at this time. One recent report (Hou *et al.* 1999) however, claims the record for the smallest observable induced features, 1.4 nm on 9 nm centers (10 T features $\text{in}^{-2}$). They were obtained in ambient conditions by applying a voltage pulse to an organic thin film which caused a local transition from insulating to metallic for reasons not yet understood. In another very beautiful piece of work, Heinze *et al.* (2000) used spin-polarized STM to image the antiferromagnetic superstructure on the surface of a Mn film with a periodicity $<0.5$ nm. Although these demonstrations are far from a storage system, they do highlight the advantages STM has in resolution and in electronic access.

In contrast, considerable work on the utilization of AFM and MFM has been reported. Much of it has focused only on the formation of some observable array of features particularly with contact AFM. For example, Cooper *et al.* (1999) formed 8 nm titanium oxide dots on 20 nm centers by anodizing a titanium film through the tip of a carbon nanotube. While this remarkable achievement corresponds to 1.6 Tdots $\text{in}^{-2}$, it would appear to be limited to write-once applications and at the reported writing speed of 5 kHz, would require massive parallel operation. The difficulties in reducing an array of nanodots to a practical AFM storage system have been considered most completely by Mamin *et al.* (1999). They developed a cantilever probe (Fig. 3) which could be used both to write features thermally in a polymetric film on a rotating disk and also to read the features with an integrated piezoresistive sensor.

Successful operation was obtained with 120 nm marks written at 50 kbits $\text{s}^{-1}$. (It is ironic to note that thermal effects which limit magnetic storage can easily be detected in the noise spectrum at the resonant frequency of a few megahertz in these sensitive cantilevers.) The authors extended the study to a read-only system in which 100 nm marks preformed in a disk were read at 10 Mbits $\text{s}^{-1}$ with a probe/disk velocity of 1 $\text{ms}^{-1}$. In another test at only 30 $\text{mms}^{-1}$, sufficient probe wear occurred after 148 hours to cause an observable reduction in output. The critical problem of tracking was also considered and the authors concluded that pre-written timing marks smaller than the present limit of DWEL would be required for track pitches below 100 nm.

Improvements in writing thermally have been reported by Binnig *et al.* (1999) who produced 40 nm pits on 40 nm centers (400 Gbits $\text{in}^{-2}$) (Fig. 4) in a 40 nm thick film of polymethylmethacrylate (PMMA) with 2 μs pulses (500 kbits $\text{s}^{-1}$). Using the

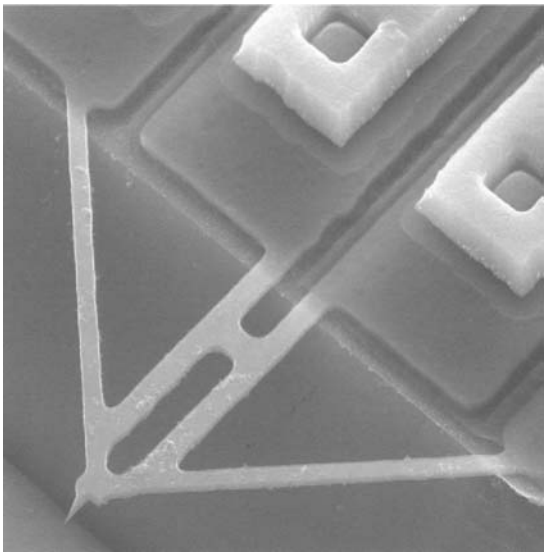

*Figure 3*
SEM images of a 29 μm long piezoresistive cantilever with a separate resistive heater for writing (after Mamin *et al.* 1999).

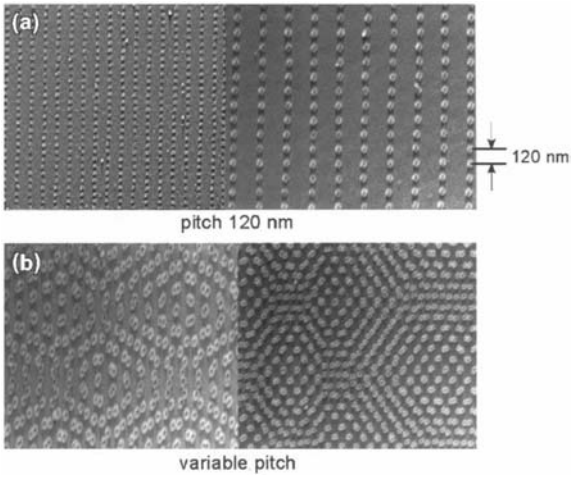

*Figure 4*
(a) Series of 40 nm data pits formed in a uniform array, demonstrating reliable thermal writing. (b) Different arrangement of data pits, with some pits written virtually next to each other with no merging. This results in bit areal densities of $\sim 400\,\text{Gbits in}^{-2}$. All images obtained by the thermal readback technique (after Binnig *et al.* 1999)

temperature-dependent resistance of the cantilever, they were also able to read with the same probe at $100\,\text{kbit s}^{-1}$ limited by the 10 μs thermal response time of the 1 μm thick cantilever. It was estimated that to reduce the response time to 1 μs, levers with thicknesses measured in nanometers would be required. The possibility that repeated block erasure of the pits could be achieved by heating local regions to 150 °C for a few seconds was also demonstrated.

This concept was combined with a remarkable advancement in MEMS technology, the 1000 probe 'Millipede' (Vettiger *et al.* 2000) to test feasibility (Lutwyche *et al.* 2000). The "Millipede" (Fig. 5) is a $32 \times 32$ array of AFM probes on 92 μm centers with integrated read/write capability. Rows and columns of probes can be accessed to allow 32 probes to write and read in parallel. The array was positioned globally with respect to the polymer film medium without separately controlling the height of each probe. Data was written and read back at $1\,\text{kbits}^{-1}$ per probe giving a total data rate of only $32\,\text{kbits s}^{-1}$. However, this limit was set by the test system and it is believed that higher data rates are possible. The density was varied from $15\,\text{Gbits in}^{-2}$ with $>80\%$ of the probes operational to $300\,\text{Gbits in}^{-2}$ with a lower probe yield. No information on erasure or reliability was given.

Electrical phenomena for probe-based storage such as charge trapping (Terris and Barrett 1995) or nonlinear conduction in Langmuir-Blodgett films (Sakai *et al.* 1988) have been investigated but more recent reports are not available. One would also expect that phase change or ferroelectric materials should be candidates for probe-based media, but few results have been presented.

The conspicuous advantages of magnetic materials for re-writable storage applications makes MFM a natural choice for investigation. Indeed, most of the work on patterned magnetic media has used MFM to characterize the elements with a significant effort demonstrating that individual elements could be switched with the field from the probe tip alone and/or with an external field. Curiously, no results on prototype MFM system comparable to those available for AFM have appeared. This may reflect a combination of the difficulty described above in preparing suitable patterned media, the relatively low resolution of MFM probes, and the complexity of an integrated active bipolar probe for writing.

However, Carley *et al.* (2000) presented a comprehensive and imaginative design paper on the implementation of a small capacity (2 GB) miniature ($2.5\,\text{cm}^3$) re-writable system with a data rate of 20 MB. It relies heavily on MEMS technology to position a media sled relative to a highly integrated array of 1000 probes in which the height of each probe is controlled individually relative to the media (Fig. 6). An important feature is the assumption of continuous perpendicular media for which it is asserted that superparamagnetic effects will be less severe than in conventional longitudinal media.

A bit size of $50\,\text{nm} \times 50\,\text{nm}$ is specified which corresponds to an intrinsic density of $>250\,\text{Gbits in}^{-2}$,

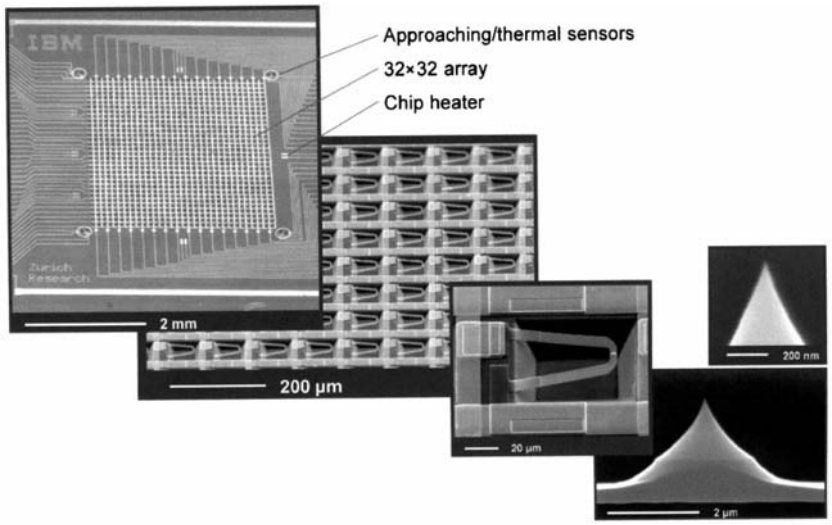

***Figure 5***
SEM images of the cantilever array section of the millipede with approaching and thermal sensors in the corners, array and single cantilever details, and tip apex (after Vettiger *et al.* 2000).

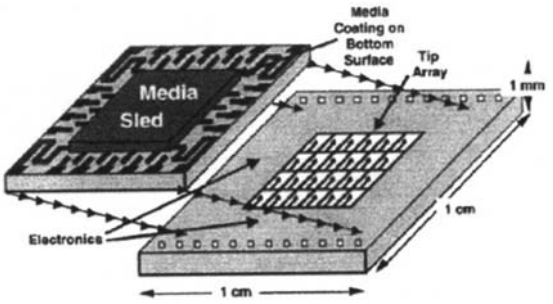

***Figure 6***
Conceptual diagram MEMS-actuated data storage devices with $x$–$y$ motion of the media and $z$ motion of a $4 \times 5$ array of probe tips (after Carley *et al.* 2000).

although the effective density in the system is reduced to 155 Gbits in$^{-2}$. The large number of probes operating in parallel increases the data rate to $>20$ MB. It is envisioned that each probe would incorporate a write coil and a recessed GMR sensor using the magnetic material on the pole tip to guide the flux from the bit to the sensor. Calculations not presented in detail suggest that the total write power would be practical and that reasonable output signals could be obtained. No discussion of the interconnect problem which would seem quite formidable is presented.

In reflecting on the difficult technical challenges inherent in a massively parallel MFM system, it is sobering to recognize that an existing disk product announced in 1999 had a capacity of 340 MB, a data rate of 3 MB, a volume of 7.8 cm$^3$ and could be purchased off the Internet for $<$\$450. Given the evolutionary improvements expected in disk technology, it is clear that the target for future probe-based systems must be even more aggressive than that set by Carley *et al.* (2000). Furthermore, if continuous perpendicular media can be used to extend the superparamagnetic limit, it would seem that a single conventional head with no greater level of processing complexity than an array of MFM probe heads could be used in a rotating disk system to achieve higher performance at lower cost.

The use of SNOM was much heralded in several commercial ventures to offer a factor of ten improvement in density relative to conventional magnetic storage. To date this has not been realized for reasons that are best discussed elsewhere. However, the unique capability of the microscope described by Zenhausern *et al.* (1995) has been tested for a read-only application by Martin *et al.* (1997) (Fig. 7). By observing the modulation of the light scattered from a sharp probe due to the dipole–dipole coupling between the probe and the surface being scanned, a resolution of $\lambda/800$ can be achieved with visible light. The authors were able to detect 50 nm pits and estimated that it should be possible to detect 2 nmbits ($>40$ Tbits in$^{-2}$) at 100 MHz with 50 dB SNR.

In summary, probe-based technologies allow very small features to be resolved and therefore offer the potential for storage densities of $1 \times 10^{12}$–$1 \times 10^{14}$ bits in$^{-2}$. However, while present work suggests this could be achieved in write-once systems, re-writable technologies competitive with disk storage will be

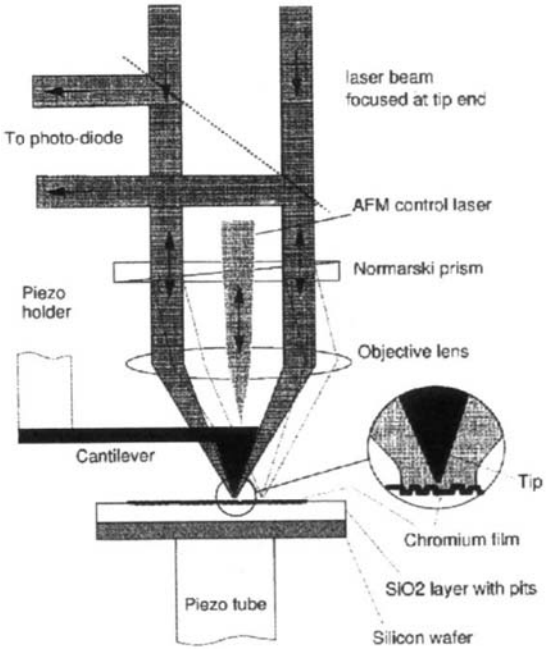

*Figure 7*
Principle of scanning interferometric apertureless microscope in reflection mode (after Martin *et al*. 1997).

more difficult. In all cases, data rate remains a major obstacle and the use of probe arrays as a solution is at this time largely conceptual. Finally, probe systems that require contact between the probe tip and the media may be restricted to considerably lower densities due to tip wear.

## 4. Optical Storage

The complex optical properties of many materials offer a rich opportunity for exploitation in data storage. To circumvent the constraint on areal density imposed by the wavelength of light in conventional optical storage, it has been proposed either to store multiple bits in a single location using spectral hole-burning or to store bits in three dimensions using holography or two-photon absorption.

The possibility of using selective spectral absorption to store data has been considered for more than 20 years but after an intense but relatively unsuccessful international effort to find appropriate materials, interest has declined. The basic concept, present status and challenges have been reviewed recently by Maniloff *et al*. (1999). In a variety of materials, so-called *inhomogeneous absorption* occurs over a relatively broad band of optical frequencies due to local nonuniformities (Fig. 8(a)). However, selective absorption can also occur if the material is illuminated

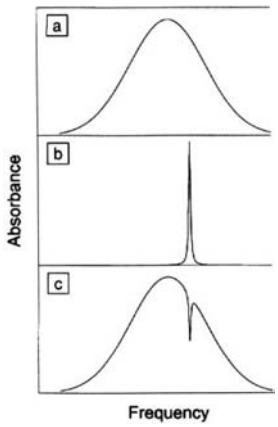

*Figure 8*
An illustration of a material's (a) inhomogeneous absorption and (b) homogeneous absorption. If the material is illuminated by narrow-band light, a spectral hole is produced in the inhomogeneous distribution, as shown in (c) (after Maniloff *et al*. 1999).

with narrow band light (Fig. 8(b)) which can be detected later as reduced absorption referred to as a hole at that frequency in the inhomogeneous absorption spectrum (Fig. 8(c)). This raises the possibility of storing many bits represented by different frequencies inside a single volume of material since the ratio of the two bandwidths could be several orders of magnitude.

Bulk erasure would presumably be required. Unfortunately, the lifetimes of the excited states are limited, ranging from milliseconds to a few hours even in the best rare-earth doped materials and then only at cryogenic temperatures. Also, interactions between the excited states significantly reduces the ratio of the bandwidths and the fast tunable lasers which would be required are not available. The best result that has been achieved is a few thousand bits in a $30\,\mu m \times 30\mu m$ spot ($\sim 3\,Gbits\,in^{-2}$). Finally, the rate at which data can be recorded or read is limited fundamentally to be less than or equal to the spectral channel width. This has led to significantly more complex systems using holographic spatial modulation as well to write and read data blocks in parallel. Until solutions to these fundamental problems are found, spectral hole-burning will not pose a challenge to disk storage.

Holography is another technology with a long unrealized promise for data storage. The concept (Fig. 9) is basically the same today as it was 30 years ago. Instead of storing data as bits in a localized spot, a 2D array of bits composed as a page is illuminated with a laser and the holographic image caused by the interference between the array image and a reference beam captured in a photosensitive material. The data

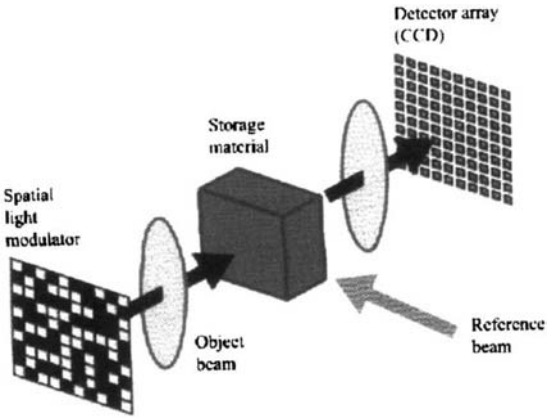

***Figure 9***
Basic holographic data storage system. Data are imprinted onto the object beam with a pixelated input device called a SLM. A pair of lenses image the data through the storage material onto a pixelated detector array such as a CCD. A reference beam intersects the object beam in the storage material, allowing the storage and later retrieval of holograms (after Ashley *et al.* 2000).

is read by illuminating the hologram and capturing the image of the reconstructed data on a 2D detector. Because the data is written and read in parallel, very high data rates should be possible. By varying the angle of the reference beam, multiple holograms can be stored in the same volume giving the potential for very high volume storage densities. When holographic storage was first conceptualized, every component in the system faced significant practical limitations so interest shifted to other less demanding optical schemes. However, significant improvements in laser light sources, spatial light modulators (SLMs) and charge-coupled device (CCD) light detectors led, in the last few decades, to a re-examination of holographic storage particularly by a consortium of industry and university researchers funded in part by DARPA. A comprehensive review of some of this work placed in historical context has been presented recently by Ashley *et al.* (2000).

Of the several problems still preventing the development of a practical holographic storage system, the recording material continues to be the most serious. Although other major components need further improvement, their usefulness in other applications has paced their development. One can expect smaller, higher power, lower cost solid state lasers; continued progress in displays means higher capacity, faster SLMs for page composers; newly developed CMOS detectors promise lower cost and higher performance than CCD devices. However, although new photopolymer materials with improved sensitivity are attractive for write-once applications, no materials are known which meet the stringent characteristics required for high data rate, high-density rewritable storage competitive with hard disks.

Holographic materials capable of storing many holograms must have high optical quality in layers several millimeters thick, a large refractive index change per unit exposure measured by the sensitivity $S$, and a large dynamic range measured by the $M$-number, which is defined as the sum of the diffraction efficiency over $M$ holograms in one location. Ashley *et al.* (2000) estimate to achieve data rates of $\sim 1\,\mathrm{Gb\,s^{-1}}$ and densities of approximately $100\,\mathrm{Gb\,in^{-2}}$ under practical conditions, values of $S \cong 20\,\mathrm{cm^2 J^{-1}}$ and $M \cong 5$ are required. They also provide values of $S$ and $M$ for several potential media candidates. The classic material has been bulk single crystals of photorefractive Fe-doped lithium niobate. However, its values of $S = 0.02$ and $M = 1$ fall well below the target values. In addition, since the refractive index change is linear in light intensity, data can be erased during the read operation. Photopolymers with $S = 20$ and $M = 1.5$ have recently been reported. However, their thicknesses are limited to $< 1\,\mathrm{mm}$ and they are not rewritable.

In summary, the realization of practical holographic systems will require continued improvement in all major components. The most serious problem is the storage material which, at the present time, is limited to write-once applications.

Another scheme to achieve volumetric optical storage is the so-call *two photon* process. The idea is conceptually simple and based on a well-documented effect in many materials in which the absorption of energy in the form of photons produces a measurable chemical change from an initial state A to a final state B. Then, A can be used to represent a ''one'' and B to represent a ''zero.'' If the energy $E_w$ required to write, i.e., cause the transition from A to B, is provided by two photons, each with energy $< E_w$ then writing will occur only at those locations where both photons are coincident in time. Thus, writing can be made to occur at any point in a 3D matrix by steering two optical beams to the desired location. In order to read optically, the optical characteristic of A and B must be distinguishable in some way which does not disturb the stored data.

The reduction to practice of the two-photon concept has been discussed in several papers. One proposed material system was photochromic spiropyran for A, which after absorption at 350 nm ($E_w$) converts to merocyanine (B). For reading, the latter conveniently has an absorption peak of $\sim 550\,\mathrm{nm}$. After absorption of an incident ''read'' photon, it fluoresces immediately back to the ground state of B. Detection of the fluorescence identifies the site as a 'zero'. The reverse conversion from B to A is less straightforward. Since (apparently) A is a lower energy state than B, the addition of sufficient energy to B will

result in its transformation back to A. Bulk erasure by heating the storage medium may be necessary.

Very little information about the practical operating characteristics for a two-photon re-writable system have been given. The asymmetry between the $A \rightarrow B$ and $B \rightarrow A$ transitions suggests that these materials may be more suited to write-once applications. Certainly, the reliability of rewriting has not been demonstrated. No information has been given on the speed of either the write or read process or the timing margin for writing.

The problem of achieving spatial and temporal coincidences is not trivial so more recent work (Zhang *et al*. 2000) has used a single beam with variable focus depth to achieve vertical spatial resolution on a rotating disk. Data bits $3.5 \times 3.5 \times 20\,\mu m^3$ were recorded in an undefined material using a Ti:sapphire laser on 25 layers with a 75μm layer spacing. Using a continuous 532 nm laser, a CNR of 42 dB in a bandwidth of 1 kHz was achieved at a laser power of $5\,kW\,cm^{-2}$. At $20\,kW\,cm^{-2}$, significant data erasure was observed after multiple read cycles. Erasure or re-writability were not discussed.

Clearly, while the two-photon concept is elegant, the performance is severely hampered by available materials. Systems may be limited to write-once applications and are not competitive with hard disks.

## 5. Concluding Remarks

The continued improvement in cost and performance of magnetic hard drives poses an extremely difficult challenge for new technologies. Lithographically patterned media may offer only an incremental improvement over continuous media. 2D optical technologies face fundamental wavelength limitations and 3D concepts require materials which do not yet exist. At the present time, practical storage systems using self-assembled media addressed with multiple probe heads cannot be realized. However, enormous progress is being made both in understanding the fundamental aspects of self-assembly and in the fabrication of complex MEMS devices. Together, they may provide the next revolution in storage especially suited for the miniaturization of personal computing devices expected in the 21st century.

# Magnetic Recording Devices: Head/Medium Interface

Magnetic storage and retrieval devices include tape, flexible disk, and rigid disk drives used for audio, video, and data processing applications. The magnetic recording process involves relative motion between a magnetic medium (tape or disk) and a stationary or rotating read/write magnetic head. For construction and materials used in magnetic head and medium components see Bhushan (1996a, 1999a, 2000). The need for ever-increasing recording densities requires that surfaces should be as smooth as possible and flying height (physical separation or clearance between a head and a medium) be as low as possible. In modern tape and flexible and rigid disk drives, flying height ranges from about 25 nm to 50 nm, and roughness of the head and medium surfaces ranges from about 1.5 nm to 5 nm r.m.s. As an analogy, a magnetic head slider flying over a disk surface with a flying height of 25 nm with a relative speed of 20 $ms^{-1}$ is equivalent to an aircraft flying 0.2 μm above the ground at 900 $kmh^{-1}$ (Fig. 1). This is what a disk drive experiences during its operation.

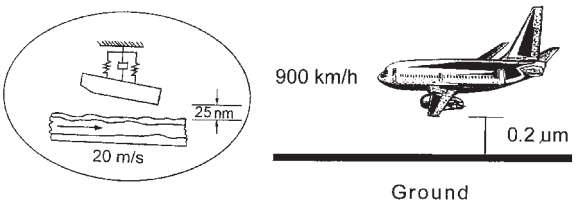

***Figure 1***
Magnetic head slider flying over a disk surface compared with an aircraft flying over ground with a close physical spacing.

The ultimate objective in magnetic storage devices is to run two surfaces in contact (with practically zero physical separation) if the tribological issues can be resolved. Smooth surfaces lead to an increase in adhesion, friction, and interface temperatures, and closer flying heights lead to occasional rubbing of high asperities and increased wear (Bhushan 1999b). Friction and wear issues are resolved by an appropriate selection of interface materials and lubricants, by controlling the dynamics of the head and medium, and by the environment Bhushan (1996a, 1999a, 2000). A fundamental understanding of the tribology (friction, wear, and lubrication) of the magnetic head/medium interface, both on macro- and micro/nanoscales, becomes crucial for the continued growth of the more than US$80 billion a year magnetic storage industry.

In this article magnetic storage devices and components are introduced first. Results for selected tribological problems important for the reliability of magnetic storage devices are then presented. Finally, results are presented of micro/nanotribological studies conducted using atomic force/friction force microscopy to better understand the fundamental mechanisms of friction and wear.

## *1. Magnetic Storage Devices and Components*

Schematics of tape and rigid disk drives and the construction and materials used in magnetic heads and media are shown in Figs. 2 and 3. In a linear data processing IBM 3490/STK4490 tape drive as shown in Fig. 2(a), after loading the cartridge into the drive,

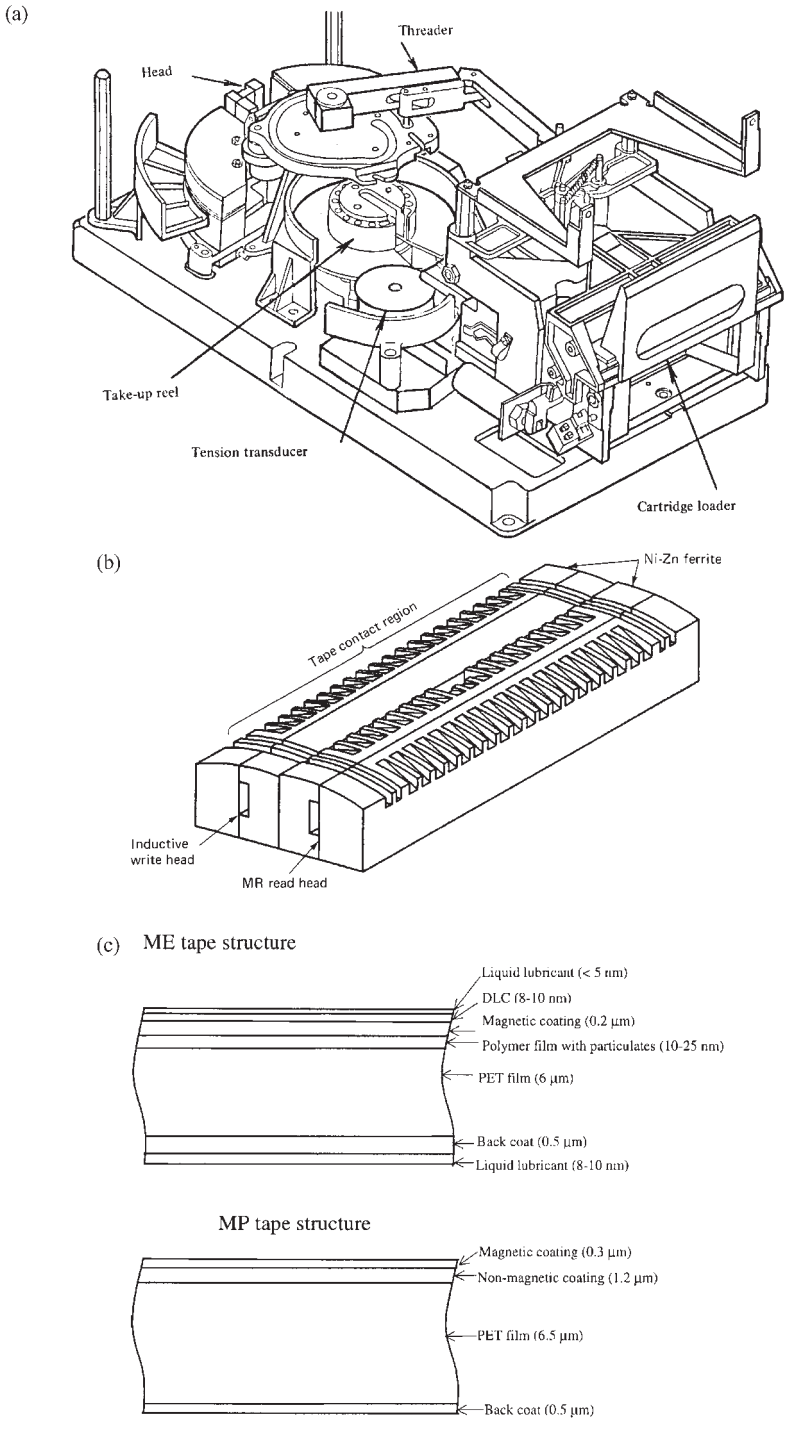

***Figure 2***
Schematics of (a) a tape path in an IBM 3490 data processing tape drive, (b) an inductive/MR thin-film head (with a radius of cylindrical contour of 20 mm), and (c) sectional views of metal-particle (MP) and metal-evaporated (ME) magnetic tapes.

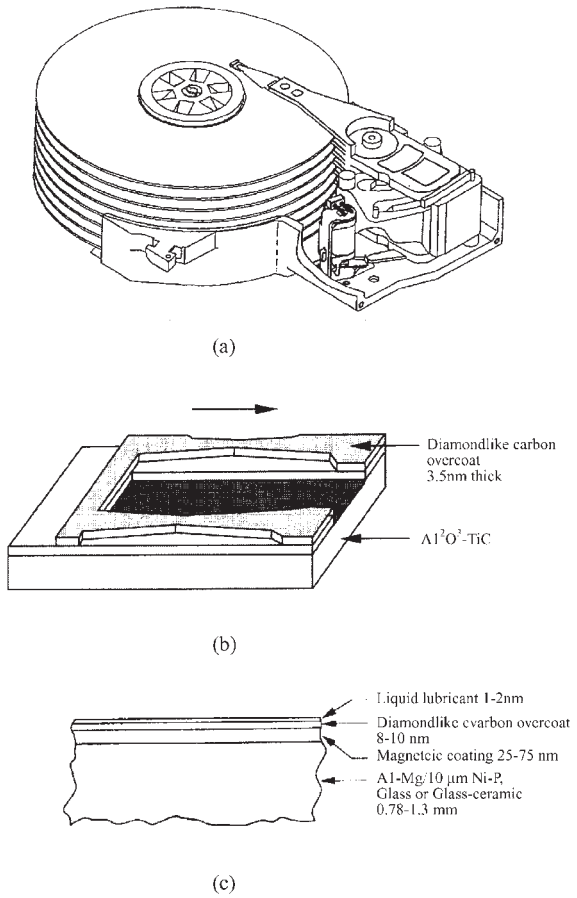

***Figure 3***
Schematics of (a) a rigid disk drive, (b) an inductive/MR thin-film picoslider, and (c) sectional view of a thin-film rigid disk.

the tape leader is threaded into the drive over a read/write head to the take-up reel by a pentagon threading mechanism. A decoupler column placed near the cartridge entrance decouples any tape vibrations that may occur inside the cartridge. The tension is sensed and controlled by a tension transducer. In a rigid disk drive as shown in Fig. 3(a), a stack of disks is mounted on a sealed, grease lubricated ball-bearing spindle. The disk stack is rotated by a d.c. motor at speeds ranging from a few thousand rpm to a maximum speed of about 10 000 rpm. A head slider is supplied for each disk surface. The slider suspension assembly is actuated by a stepping motor or a voice-coil motor for read/write operation (Bhushan 1996a, 2000).

Magnetic heads consist either of conventional inductive or inductive/magnetoresistive (MR) devices (Bhushan 1993, 1996a, 2000). If MR head design is used, it is only used for read purposes. Air-bearing surfaces of tape heads are generally cylindrical in shape (Fig. 2(b)). The tape is slightly underwrapped over the head surface to generate hydrodynamic lift during read/write operations. The head sliders used in rigid disk drives are either two- /three-rail, taper-flat design or two-rail, step, negative pressure design (Fig. 3(b)). The sliders are supported by a nonmagnetic steel leaf spring (flexing) suspension to allow motion along the vertical, pitch, and roll axes. The front taper or step pressurizes the air lubricant, while some air leaking over the side boundaries of the rail results in a pitch angle.

Magnetic media fall into two categories: (i) particulate flexible media, where magnetic particles are dispersed in a polymeric matrix and coated onto the polymeric substrate (Fig. 2(c)); and (ii) thin-film media, where continuous films of magnetic materials are deposited by vacuum techniques onto the polymeric substrate or flexible media (Fig. 2(c)) or onto a rigid substrate such as aluminum, glass, or glass ceramics (Fig. 3(c)) (Bhushan 1993, Miller and Bhushan 1996).

## 2. *Macrotribology of Magnetic Storage Devices*

Friction and wear of two surfaces in relative motion is governed by the real area of contact and interfacial adhesion. In addition, for wet contacts with a tiny amount of liquid present at the interface, ''stiction'' (or high static friction) can occur owing to meniscus/viscous effects (Fig. 4). Generally, any liquid that wets or has a small contact angle on surfaces will condense from vapor in the form of an annular-shaped capillary condensate in the contact zone. The negative (attractive) pressure of the liquid films of the capillary condensates or pre-existing film of lubricant can significantly increase the adhesion between solid bodies. Liquid-mediated adhesive forces can be divided into two components: meniscus force ($F_M$) owing to surface tension and a rate-dependent viscous force ($F_V$). The total tangential force ($F$) required to separate the surfaces during sliding is equal to intrinsic friction force ($F_A$) and stiction force ($F_S$, a combination of friction force owing to the meniscus

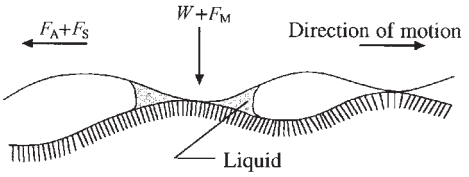

***Figure 4***
Schematic of a wet interface with meniscus formation, showing various forces being applied during sliding. $F_M$ is the meniscus force, $W$ is the normal force, and $F_A$ and $F_S$ are intrinsic friction and stiction forces, respectively.

effect and the peak viscous force) (Bhushan 1999b):

$$F = F_A + F_S = \mu_r(W + F_M) + F_V \qquad (1)$$

where $\mu_r$ is the "true" static coefficient of friction and $W$ is the normal the load. It turns out that since the surfaces in magnetic storage devices are smooth and the normal load being applied is relatively low, frictional effects because of meniscus and viscous forces are significant. Optimization of surface topography of head and medium and overcoats and lubricant films needs to be achieved for long-term reliability of magnetic storage devices.

### 2.1 Contact Modeling

Numerical techniques are used to solve contact problems of rough surfaces under dry and wet conditions (Bhushan 1996b, 1996c, 1998, 1999b, Tian and Bhushan 1996a, 1996b, Peng and Bhushan 2001). The numerical model does not require an asperity model and makes no probabilistic assumptions such as distribution of asperity heights, slopes, and curvatures, as required in analytical models. The numerical techniques allow analysis of a large number of contact spots that go through elastic and elastic/plastic deformations. The numerical model provides useful information on the number of contact spots, their sizes and distributions, and the spacing between contacts. Furthermore, wet contact analysis for contact of rough surfaces with a liquid film can be carried out. In the wet contact analysis, elastic/plastic dry contact of rough surfaces is first analyzed. In the next step, a liquid film of known mean thickness is introduced over the deformed rough surfaces. Wetted areas are determined by selecting the area where asperities of both contacting surface touch the liquid. The total projected meniscus area is then used for the calculations of meniscus forces. The model can be used to develop optimum surface roughness distributions for the head and medium surfaces. Figure 5 shows representative contact area and meniscus area maps for a computer-generated random rough surface in contact with a smooth surface in the presence of water film. As expected, the meniscus area is larger than the contact area and the meniscus force is three times that of the normal force.

Tian and Bhushan (1996b) and Poon and Bhushan (1996) used the model to predict the effects of relative humidity and liquid film thickness on the meniscus force (see also Bhushan 1998). The effect of relative humidity on the meniscus force at an interface is shown in Fig. 6(a). The effect of liquid film thickness and interface roughness on computer-generated rough surfaces in contact with a smooth surface is shown in Fig. 6(b). An increase in either relative humidity or liquid film thickness increases the liquid present at the interface. The thicker a liquid film, the more asperities touch the liquid surface and the more menisci form on a larger number of asperities. In addition, with a thicker film, a larger volume of liquid is present around the asperities resulting in a greater amount of meniscus volume accumulated at the contact interface and a greater meniscus height. These effects lead to larger meniscus forces. There is a critical film thickness for a surface with given roughness above which the meniscus force increases rapidly. The critical film thickness is of the order of three-quarters of the composite r.m.s. roughness of the mating surfaces ($\sigma$).

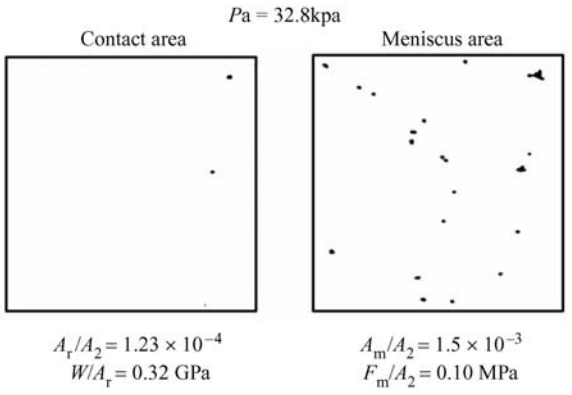

***Figure 5***
Contact area and meniscus area for the case of computer-generated rough surface ($\sigma = 1$ nm, $\beta^* = 0.5$ μm) in contact with a smooth, flat surface with a composite elastic modulus of 100 GPa and a water film ($\gamma = 73$ dyne cm$^{-1}$ ($7.3 \times 10^{-4}$ N cm$^{-1}$), $\theta = 60°$) thickness of 1 nm and meniscus height of 1 nm (after Poon and Bhushan 1996).

Bhushan and Chilamakuri (1996) and Chilamakuri and Bhushan (1998a) used the numerical model to study contact between flat rigid surfaces and non-Gaussian rough surfaces with known skewness ($Sk$) and kurtosis ($K$). Rough surfaces with different skewness and kurtosis were generated using a two-dimensional digital filter technique. Figure 7 shows the probability density functions of surfaces with various skewness and kurtosis values. Figure 8(a) shows the effect of skewness and kurtosis on the fractional real area of contact ($A_r/A_a$, where $A_r$ is the contact area and $A_a$ is the apparent area) and relative meniscus force ($F_M/W$) at different nominal pressures ($p$). A positive skewness between 0 and 0.2 at low pressure and about 0.2 at higher pressures results in the lowest real area of contact and meniscus force. Contact area and meniscus force decrease with an increase in the kurtosis. Fewer peaks present on a surface with a range of positive skewness values or high kurtosis can explain the trends. Figure 8(b) shows the variation of relative meniscus force with $h/\sigma$ ratio for different skewness and kurtosis values. Note that the sensitivity of $h/\sigma$ to the meniscus force decreases at a range of

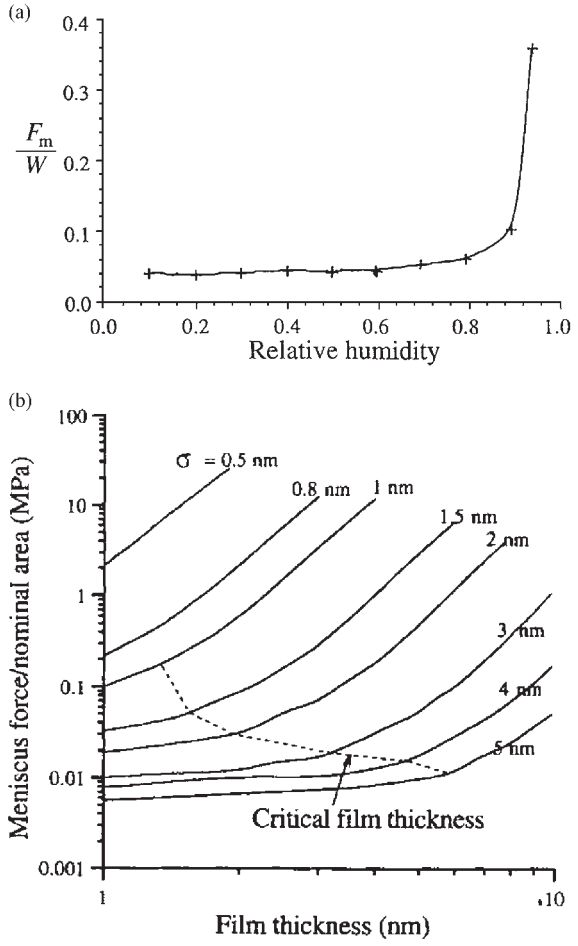

*Figure 6*
(a) Effect of relative humidity on the relative meniscus force for a glass/ceramic disk substrate in contact with a smooth surface (after Tian and Bhushan 1996b). (b) Effect of water film thickness and surface roughness on the relative meniscus force for computer-generated Gaussian surfaces (correlation distance $\beta^* = 0.5\,\mu m$) in contact with a smooth surface. The dotted line defines the critical film thickness for different $\sigma$ (after Poon and Bhushan 1996).

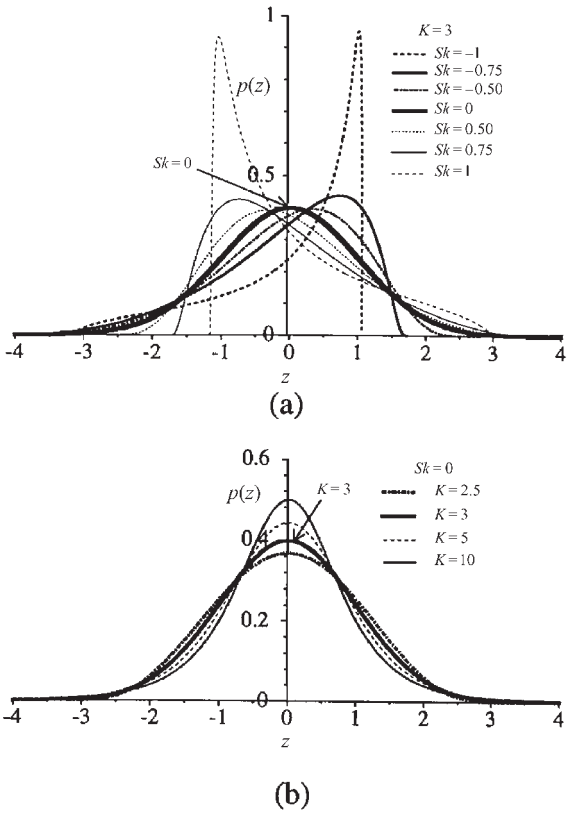

*Figure 7*
Probability density functions for surfaces with (a) different skewness and (b) different kurtosis values (after Chilamakuri and Bhushan 1998a).

positive skewness of 0–0.2, and kurtosis of about five or larger is optimum.

Laser-textured disks are becoming increasingly popular in the design and manufacture of rigid disks. In the laser-texturing technique, discrete topographic features with either rounded, dome-like protrusions (sombrero shaped) or craters (V or W types or donut shaped) usually known as bumps are generated over the disk surface. In laser-textured disk surfaces, these microscale features are placed in the landing zone to reduce friction/stiction during the start and stop operations. Typical sombrero-, V-, and W-type bumps have about 10–15 μm rim diameter and height of about 15–25 nm with a $50\,\mu m \times 50\,\mu m$ pitch. This gives of the order of $4 \times 10^5$ bumps in the landing zone of a 95 mm diameter disk. V- or W-type bumps are more commonly used because they can be reproducibly manufactured. The stiction phenomena at the head/disk interface can be controlled by controlling the size and shape of the laser bumps. Studies to identify an optimum bump shape and the relationship between the optimum number of bumps as a function of the bump geometry for a given bump shape have been conducted (Chilamakuri and Bhushan 1997, 1998b, 1999a, 1999b, Chilamakuri *et al.* 2000).

The following design methodology has been used to determine an optimum number of bumps. For a given size and shape, the meniscus force increases with an increase in the number of bumps, so it is important to minimize the number of bumps to control the stiction phenomena. However, too few bumps can result in

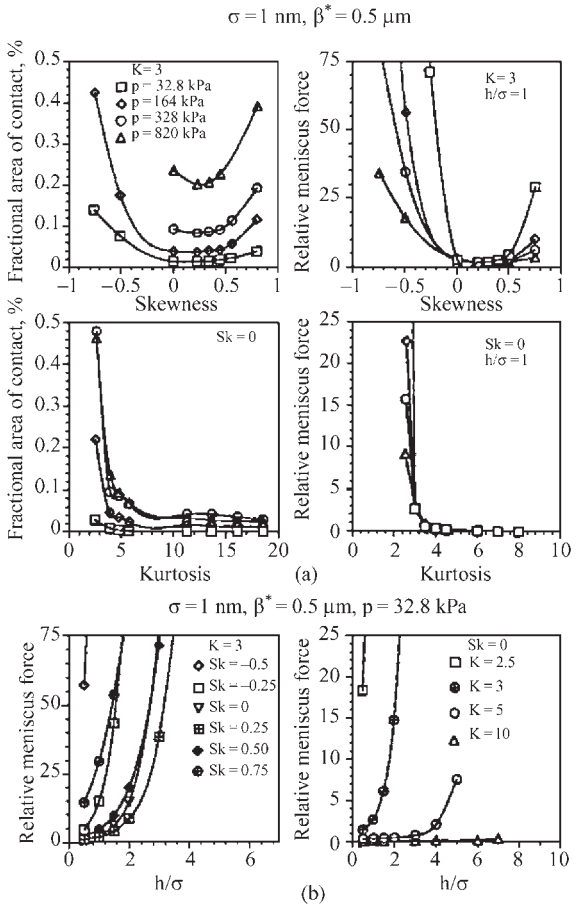

***Figure 8***
(a) Fractional real area of contact and relative meniscus force as a function of skewness and kurtosis at various nominal pressures, and (b) relative meniscus force as a function of $h/\sigma$ for different skewness and kurtosis values, for an interface in the presence of perfluoropolyether film ($\gamma = 25\,\text{dyne cm}^{-1}$ ($2.5 \times 10^{-4}\,\text{N cm}^{-1}$), $\theta = 10^{\circ}$) (after Chilamakuri and Bhushan 1998a).

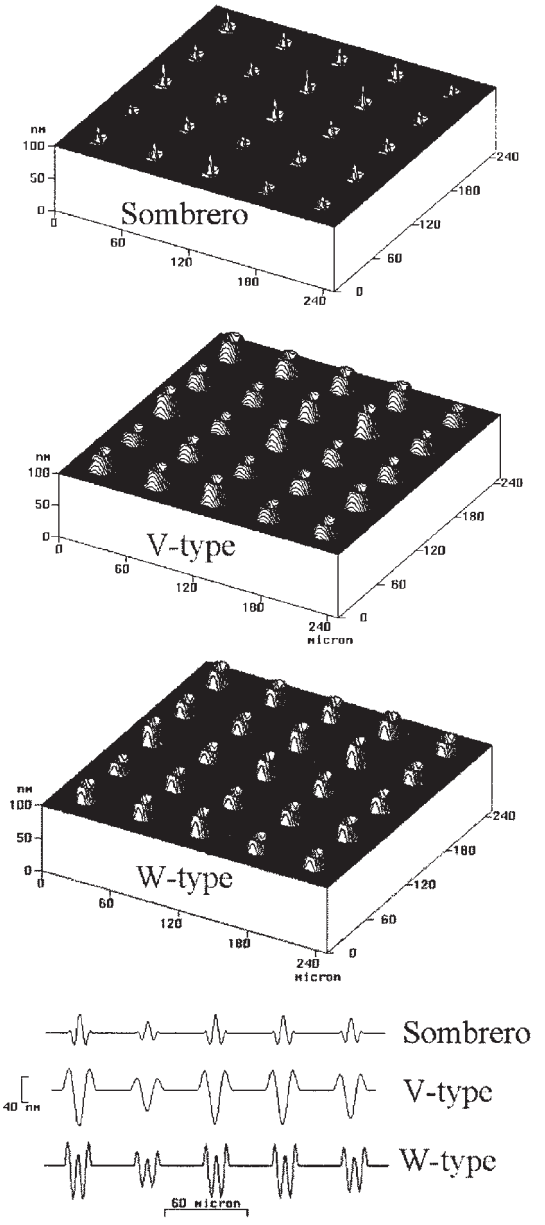

***Figure 9***
Three-dimensional surface plots and two-dimensional line plots of sombrero-, V-, and W-type laser surfaces ($R_{\text{rim}} = 7.5\,\mu\text{m}$, $H_{\text{mean}} = 25\,\text{nm}$, $\sigma = 5\,\text{nm}$) with a Gaussian height distribution.

the failure of the disk surface owing to plastic deformation and wear. To prevent the bumps from yielding, the number of bumps on the disk surface should be greater than a certain minimum, which would also give a lower bound for the stiction. Numerical analyses of computer-generated surfaces are used to predict an optimum number of bumps. Figure 9 shows typical computer-generated surfaces with various bump types and variable heights. The three-dimensional numerical contact model mentioned earlier is used to perform contact analysis of a computer-generated laser-textured surface against a flat surface. Figure 10 shows an optimum number of bumps, contact area, and meniscus force as a function of yield stress at different values of coefficient of friction. As expected, the optimum number of bumps increases with an increase in the coefficient of

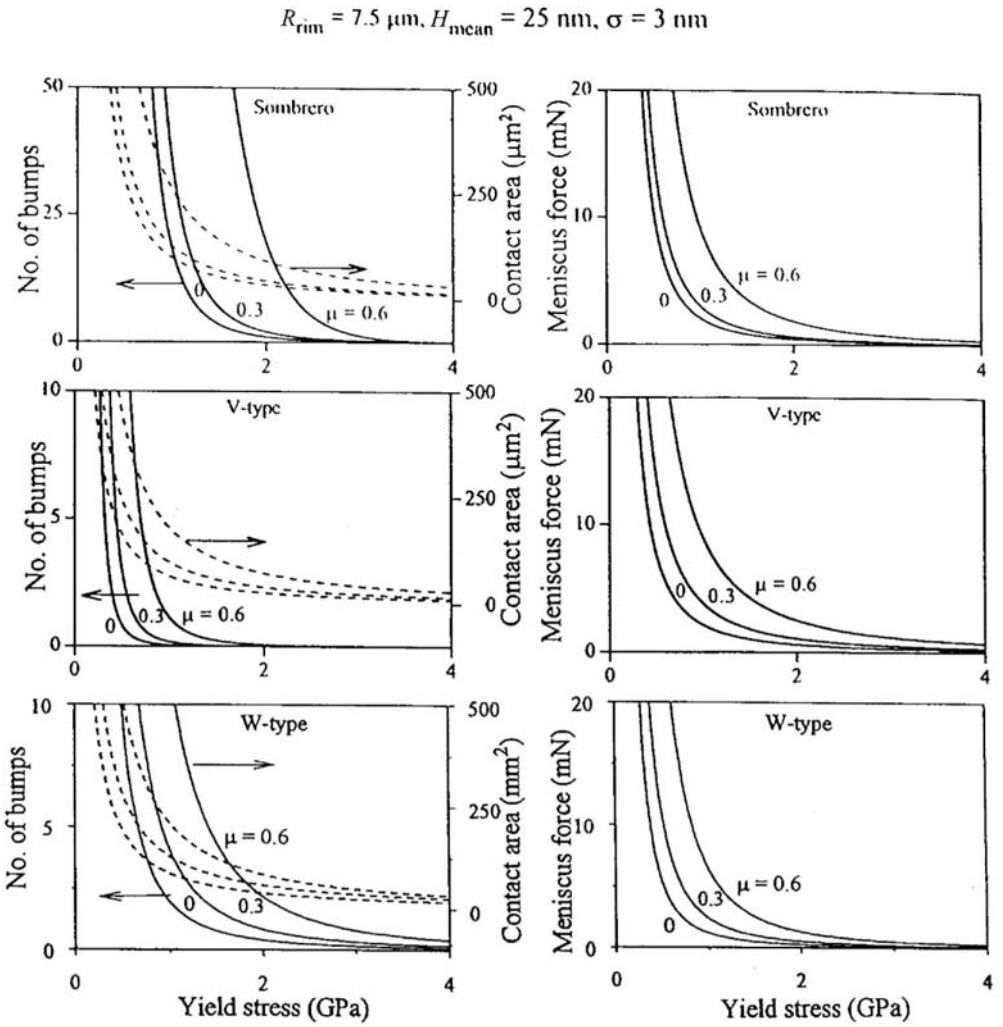

***Figure 10***
Effect of coefficient of friction, $\mu$, on number of bumps, contact area, and meniscus force for sombrero-, V-, and W-type bumps at $\sigma = 3$ nm.

friction. Contact area and meniscus force also follow similar trends. Measurements made on experimental disks verify numerical predictions (Bhushan 2000).

### 2.2 *Overcoats and Lubricants*

The carbon overcoat is almost exclusively used as an overcoat for thin-film disks and metal tapes (Bhushan 1999c). It has to be chemically active in order to attach to lubricant molecules, whereas the lubricant molecules should be hydrophobic so that they repel water from the environment. Lubricants can attach to the carbon surface by one or more of the following mechanisms: physisorption, conformational rearrangement, and chemisorption. The type and degree of attachment depends on the molecular structure and end groups of the lubricants and surface groups on the carbon surface. A hydrogenated carbon surface is highly functional and consists of many oxygen-containing surface groups which include –C–O–C– (ether), >C═O (carbonyl), –COOR (ester), –COOH (carboxyl), and –COH (hydroxyl) groups, as well as unpaired electrons (dangling bonds). Figure 11 shows schematically the adsorption of a polar perfluoropolyether (PFPE) (Z-Dol) molecule on a carbon surface at 20 °C. The C═O bond and the hydroxyl groups in the case of Z-Dol interact with functional groups and dangling bonds on the carbon surface. The

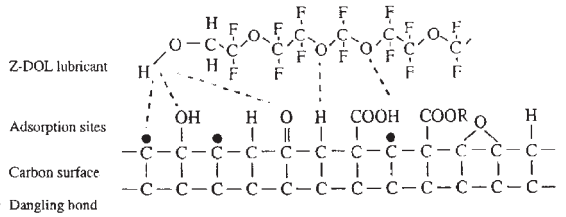

***Figure 11***
Schematic of Z-Dol molecules adsorbed on a carbon surface at 20 °C.

functional groups behave as an anchor, i.e., an immobile fraction of the lubricant film. The addition of an alcohol (–OH) end group to a lubricant molecule adds an interaction energy of the order of $20\,\mathrm{kJmol^{-1}}$, even if no chemical reaction occurs with the surface. The attachment of lubricant molecules with or without functional groups is enhanced after sliding as long as the lubricant chains are exposed to the disk surface (Zhao *et al.* 1999).

The PFPE backbone mainly interacts with surfaces through van der Waals forces. The van der Waals interaction energy of PFPE molecules with a DLC surface is of the order of $2\,\mathrm{kJmol^{-1}}$ or less. This energy is sufficiently high so that molecules lie flat on the surface when the lubricant film thickness is comparable to the polymer chain diameter of 0.7 nm.

There are two approaches for chemisorption that have been shown to be successful in chemical bonding of the liquid monolayer to the overcoat. The first relies on exposure of the disk lubricated with neutral PFPE to various forms of radiation, such as low-energy x rays, electron or ion beam, nitrogen plasma, or far UV. The improved affinity of the lubricant for the surface by obtained by UV radiation is believed to result from enhanced bonding by photochemical alteration of the lubricant, the substrate, or the air-deposited organics. The PFPEs undergo dissociative electron attachment caused by photoelectrons that are generated by the interaction of the UV light with the substrate. This dissociative electron attachment results in the formation of a negative ion and a radical. It is suggested that subsequent radical propagation and termination steps cross-link the PFPE and bond it to the substrate. Another approach uses chemically active PFPE molecules through either the above-mentioned treatments or a post-thermal treatment, in which the various functional end groups offer the opportunity of strong attachments to a specific interface if a high enough temperature is applied to overcome the activity barrier (Zhao and Bhushan 1996, Zhao *et al.* 2000). The activation energy of the thermal attachment of Z-Dol to a carbon surface is of the order of $30\,\mathrm{kJmol^{-1}}$. Surface cleanliness and chemical activity of the overcoat affect the degree of bonding. The length of the thermal treatment and the temperature for PFPE lubricants with polar end groups are important factors in determining the adsorption level of lubricants to the disk surface (Zhao and Bhushan 1996).

The lubricant film thickness ($h$) and composite roughness ($\sigma$) are generally known to have an opposite effect on static and kinetic friction and durability in terms of desirability, i.e., an increase in $h$ or a decrease in $\sigma$ results in an increase in the values of $F_s/W$, $F_k/W$, and durability. $F_s/W$, $F_k/W$, and durability data obtained on various disks with a lubricant C (Z-Dol) as a function of $h/\sigma$ is shown in Fig. 12 (Bhushan and Zhao 1999). In Fig. 12, $h$ represents a mobile fraction of the total lubricant film thickness in static and kinetic friction because only the mobile fraction forms menisci; $h$ is a total film thickness in durability because both mobile and immobile fractions affect wear life. The Z-Dol lubricants used are untreated, partially bonded, and fully bonded. The normalized static friction force ($F_s/W$) and normalized kinetic friction force ($F_k/W$) increase rapidly above a critical value of $h/\sigma$ ($\sim 0.7$) and durability decreases above the critical film thickness. Trends in experimental results for static friction force are comparable with the results of the numerical contact model presented earlier (see Fig. 6(b)). A rapid decrease in durability above a critical film thickness occurs because of a large meniscus being formed around slider edges and the presence of the stick/slip phenomena (Bhushan and Zhao 1999).

Zhao *et al.* (2000) and Kajdas and Bhushan (1999) have presented detailed discussion of various degradation mechanisms of Z-Dol lubricant which include thermal decomposition, catalytic degradation, electron-mediated degradation, and mechanical degradation processes. Comparing various degradation mechanisms it is believed that the catalytic degradation mechanism proposed in the literature is not relevant because kinetics is slow at asperity temperatures. Based on a wide variety of experimental data it is reasonable to emphasize that anionic intermediates (negative ions and/or negative-ion/radical species) produced by low-energy electrons play an important part in both (i) the electron-mediated degradation process of PFPE lubricants, and (ii) chemical bonding of PFPE lubricant films with DLC surfaces under sliding conditions.

## *3. Microtribology of Magnetic Storage Devices*

At most interfaces of technological relevance, contact occurs at multiple asperity contacts. Consequently, the importance of investigating single-asperity contacts in studies of the fundamental micromechanical and tribological properties of surfaces and interfaces has long been recognized. The emergence and proliferation of proximal probes, in particular tip-based microscopy (the atomic force microscope/friction

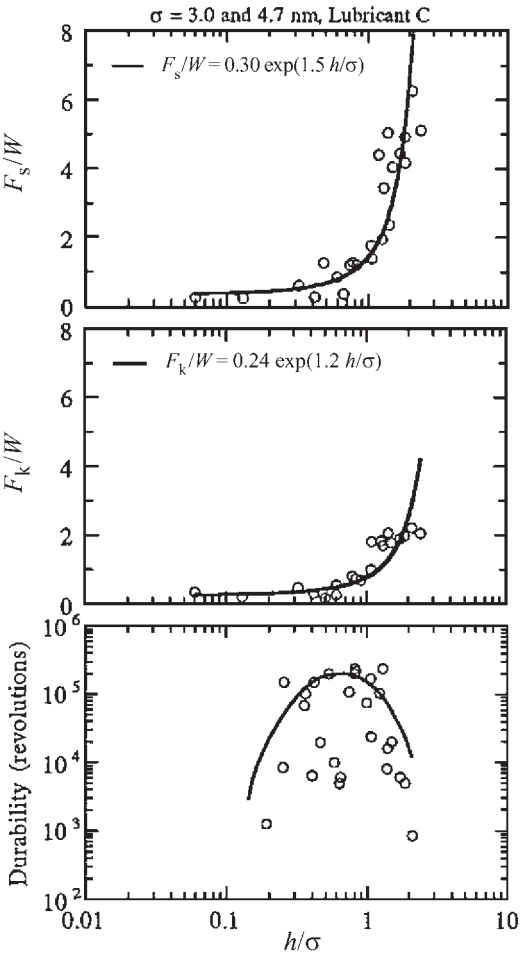

***Figure 12***
Normalized static and kinetic friction forces and durability in revolutions as a function of the ratio of the lubricant film thickness to composite roughness ($h/\sigma$). Data on untreated, partially bonded, and fully bonded Z-Dol lubricants are presented. For static and kinetic friction data, $h$ used is a mobile fraction; for durability, $h$ used is a total film thickness (after Bhushan and Zhao 1999).

microscope (AFM/FFM)), and of computer simulations of tip/surface interactions and interfacial properties, provide nanoscale realizations of single-asperity contacts, and allow systematic investigations of interfacial problems of materials with high resolution as well as ways and means for modifications and manipulations of nanoscale structures. These advances provide the impetus for intensive research endeavors aimed at fundamental understanding of the nature and consequences of the interactions between materials on the atomic scale, and guide the "rational" design of material for technological applications. The advent of these techniques and methodologies has led to the development of the field of micro/nanotribology and micro/nanomechanics (Bhushan 1999a, Bhushan *et al*. 1995). This field pertains to experimental and theoretical investigations of processes ranging from the atomic and molecular scales to the microscale, that arise as a consequence of interfacial interactions.

### *3.1 Friction*

Friction has been measured on a microscale (Bhushan 1999a), and it has been reported that the coefficient of friction on a microscale is lower than the macrofriction. Table 1 gives typical values of coefficients of friction of metal-particle (MP) and metal-evaporated (ME) tapes, poly(ethylene terephthalate) (PET) tape substrate, and thin-film rigid disks. Friction values on the microscale are much lower than those on the macroscale, which is believed to be because of a lower plowing contribution (almost no damage on the disk surface as measured). When measured for the small contact areas and very low loads used in microscale studies, mechanical properties are higher than at the macroscale, this reduces the degree of wear. In addition, the apparent area of contact reduces the number of particles trapped at the interface, and thus minimizes the plowing contribution to the friction.

Gray-scale plots of coefficients of local friction of a thin-film disk as the FFM tip is scanned in either direction are shown in Fig. 13. Corresponding gray-scale plots of slope of roughness profiles are also shown in Fig. 13. Since the sign of the friction and the slope reverses with the change in the scanning direction, the sign of one set of images needs to be reversed before data can be compared. The left-hand sections correspond to the sample sliding from the left towards the right, the center sections correspond to the sample sliding from the right toward the left, and the right-hand sections correspond to the first set with the sign of slope and friction values reversed. We note a general correlation between the slope and friction profiles. We note that generally the points that have high friction in the left to right scan also have high friction as the sliding direction is reversed (after sign change). This relationship is not true at some locations. We observe some differences in the friction profiles that may result from the asymmetrical asperities and/or asymmetrical transfer of wipe material during manufacturing of the disk. The directionality effect in friction on a macroscale has been observed in some magnetic tapes (Bhushan 1999a).

### *3.2 Scratching and Wear*

Microscratches made on MP tape and on an unlubricated thin-film rigid disk at various loads are

***Table 1***
Surface roughness (r.m.s.), microscale and macroscale friction, and nanohardness data of thin-film magnetic rigid disk, magnetic tape, and magnetic tape substrate (PET) samples.

| | Roughness (r.m.s.) (nm) | | | Coefficient of microscale friction | | Coefficient of macroscale friction | | |
|---|---|---|---|---|---|---|---|---|
| | NOP[a] | AFM[b] | | | | | | |
| Sample | 250 μm × 250 μm[c] | 1 μm × 1 μm[c] | 10 μm × 10 μm[c] | 1 μm × 1 μm[c] | 10 μm × 10 μm[c] | Mn–Zn ferrite | $Al_2O_3$–TiC | Nanohardness/normal load (GPa)/(μN) |
| Unlubricated disk | 2.2 | 3.3 | 4.5 | 0.05 | 0.06 | | 0.26 | 21/100 |
| Lubricated disk | 2.3 | 2.3 | 4.1 | 0.04 | 0.05 | | 0.19 | |
| Metal-particle tape | 6.0 | 5.1 | 12.5 | 0.08 | 0.06 | 0.19 | | 0.30/50 |

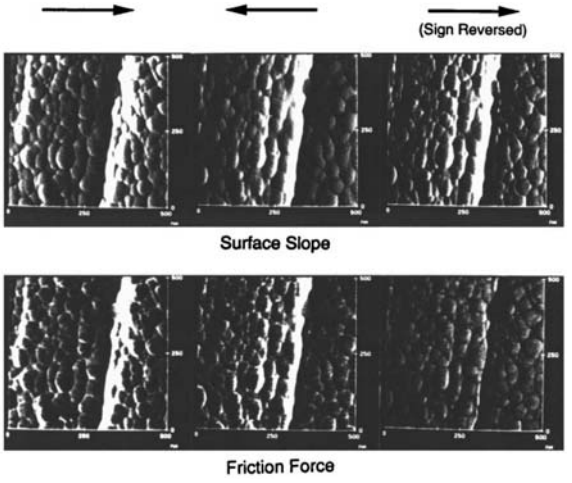

***Figure 13***
Gray-scale plots of the slope of the surface roughness and the friction force profiles for a lubricated disk with FFM tip sliding in different directions. Higher points are shown by lighter color (after Bhushan 1999a).

shown in Fig. 14. All scratches are made with 10 cycles. We notice that the scratch depth increases with an increase in the normal load. Figure 15 shows the microwear profiles at 20 μN load and at various cycles of an unlubricated thin-film disk. We note that wear is not uniform and is largely initiated at the texture marks present on the disk surface. This suggests that surface defects act as initiated sites for wear. Figure 16(a) shows the wear depth as a function of the number of cycles for unlubricated and lubricated thin-film disks at 10 μN and 20 μN loads. Wear

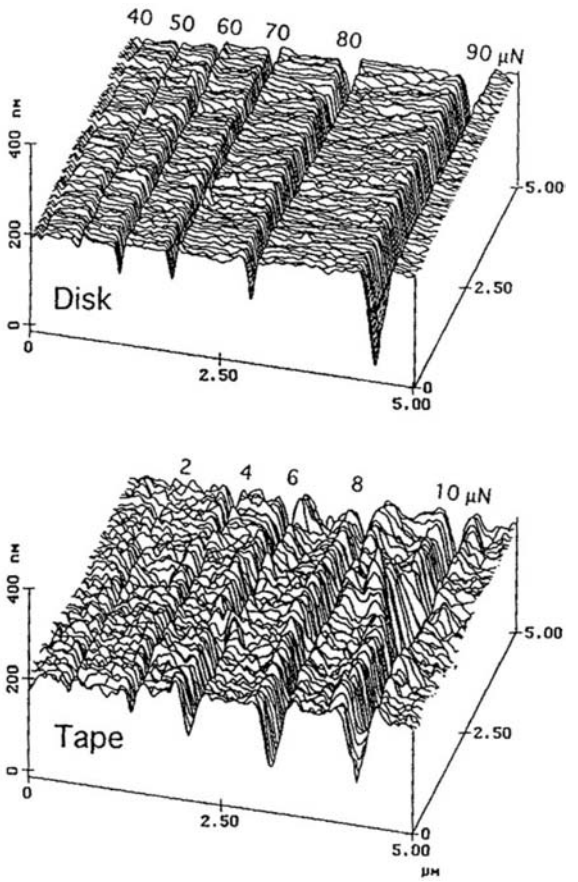

***Figure 14***
Surface profiles for scratched, unlubricated thin-film rigid disk and MP tape (after Bhushan 1999a).

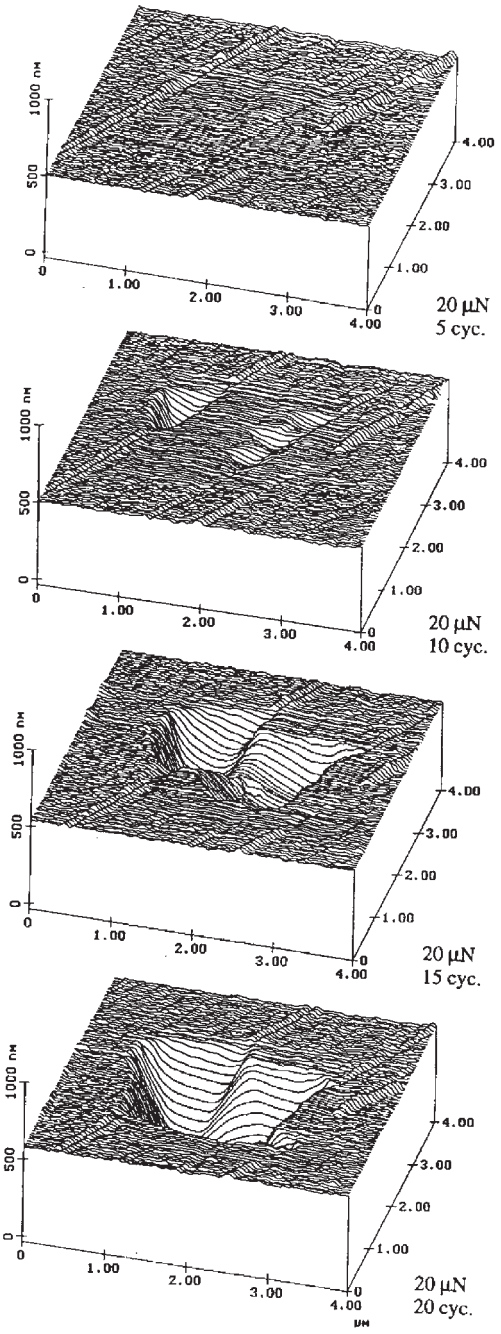

*Figure 15*
Surface profiles of unlubricated thin-film rigid disk showing the worn region (center 2 μm × 2 μm). The normal load and the number of test cycles are indicated (after Bhushan 1999a).

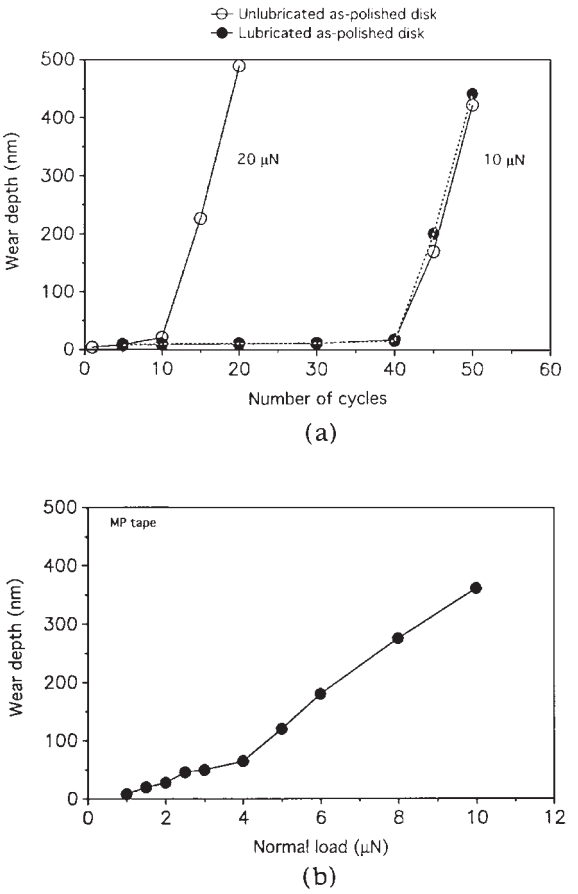

*Figure 16*
Wear depth as a function of number of cycles for (a) unlubricated and lubricated thin-film rigid disks at 10 μN and 20 μN loads, and (b) MP tape at a normal load of 2 μN (after Bhushan 1999a).

initially takes place slowly with a sudden increase after about 40 cycles at 10 μN and after about 10 cycles at 20 μN. The rapid increase is associated with the breakdown of the carbon coating. Similar behavior has been reported for ME tapes. Wear rates for particulate tapes (Fig. 16(b)) and PET tape substrates are approximately constant for various loads and number of cycles (Bhushan 1999a).

We note that scratches and wear profiles can be produced with very shallow depths, thus the AFM technique can be used to measure scratch resistance and wear resistance of ultrathin films.

### *3.3 Lubrication*

To study lubricant depletion during microscale measurements, the microscale friction as a function of

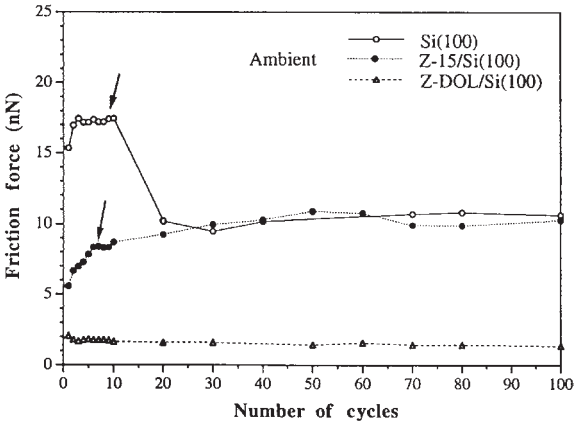

*Figure 17*
Friction force as a function of number of cycles for unlubricated and lubricated silicon samples (after Bhushan 1999a).

number of cycles of a virgin Si(100) surface and a silicon surface lubricated with about 2 nm thick Z-15 and Z-Dol PFPE lubricants are shown in Fig. 17. These experiments were conducted in an AFM/FFM by sliding a $Si_3N_4$ tip against the samples. Z-Dol is a PFPE lubricant with hydroxyl end groups. Its lubricant film was thermally bonded at 150 °C for 30 minutes and washed off with a solvent to provide a chemically bonded layer of the lubricant film. We note from Fig. 17 that the friction force in a virgin silicon surface decreases after a few cycles after the natural oxide and other contaminant film present on the silicon surface gets removed. In the case of the Z-15-coated silicon sample, the friction force is initially low and then approaches that of an unlubricated silicon surface after a few cycles. The increase in friction of the lubricated sample suggests that the lubricant film gets worn and the silicon underneath is exposed.

In the case of the Z-Dol-coated silicon sample, the friction force starts out low and remains low during the 100 cycles of the test. It suggests that Z-Dol does not get displaced/depleted as readily as Z-15. Furthermore, the initial friction value for Z-Dol is low as compared to that of Z-15. Z-15 gets displaced locally by condensed water molecules permeated through the lubricant film or condensed over exposed areas, whereas Z-Dol does not get displaced as readily by water because it is chemically bonded to the substrate. The absence of mobile lubricant and lack of water molecules minimize the possibility of formation of meniscus bridges, which is responsible for low friction in the case of Z-Dol. From this example, it is clear that AFM methods can be used to study the performance of lubricants in simulated single-asperity contacts.

## 4. Closure

The magnetic recording process involves relative motion between a magnetic medium and a stationary or rotating read/write magnetic head. Under steady operating conditions, a load-carrying air film is formed. There is a physical contact between the medium and the head during starting and stopping. In modern high-end computer tape and disk drives, the surfaces have roughness of the order of 2–5 nm r.m.s. and the head-to-medium separation is of the order of 25–50 nm. The need for higher recording densities requires the surfaces be as smooth as possible and the flying height be as small as possible. The very smooth surfaces and ultralow flying heights required present challenges and opportunities unparalleled in any other industry.

Analytical models and experimental data available of the tribology of the head/medium interface are plentiful. Understanding of tribology on nanoscales is beginning to emerge. Understanding of micro/nanotribology of ultrasmooth surfaces and small components in future head/medium interfaces is lacking. AFM/FFM studies are expected to play a major role in computer tribology.

# Magnetic Recording Devices: Inductive Heads, Properties

Modern magnetic recording heads are made using the techniques of integrated circuit fabrication technology: photolithographic pattern transfer, selective thin film deposition and selective thin film etching. The use of these methods has allowed dramatic miniaturization of components and increases in recording densities and operating frequencies. The first magnetic recording heads had magnetic cores machined from ferrite and did not use thin film technology. This approach was used in both magnetic tape and disk recording until the end of the 1970s, and was the focus of much invention and miniaturization in its own right.

Then, in 1970, researchers at IBM published a description of thin film processes that could be used to fabricate recording heads (Romankiw *et al*. 1970). Further refinements led to several patented designs by IBM (Church and Jones 1980, Jones 1980) and a transition to thin film technology for head fabrication in the disk industry, allowing greater degrees of manufacturing automation and integration. Tape recording heads followed suit approximately 10 years later. While begun over two decades ago, this trend toward greater degrees of integration continues today, as merged inductive and magnetoresistive (MR) heads are integrated with secondary mechanical actuators and trace suspension assemblies. These trends in head manufacturing are likely to continue for the foreseeable future, and will be detailed in the ensuing sections of this article.

The progress in shrinking magnetic recording heads through advances in fabrication technology can be seen in Fig. 1, which shows an outline, to scale, of the various disk head sliders over the last several decades. As can be seen the technology has been shrunk by a factor of three times (in each linear dimension) since the 1970s. The dimensions given are industry standards, and are available in Hoyt (1997; see also *Magnetic Recording Heads: Historical Perspective and Background*).

## 1. Pre-1990s Head Fabrication Technology

### 1.1 Ferrite Heads

Prior to the advent of thin film head technology, magnetic recording heads for rigid disk applications were fabricated using precision machining techniques from bulk materials, typically magnetic ferrites. Ferrites are insulators, and, therefore, can be operated at high frequencies without eddy current damping. Ferrite heads were the workhorse recording heads for many years in both tape and disk drives, serving both the magnetic writing function and the inductive readback function. MnZn–ferrite and NiZn–ferrite were the main materials used.

Slider bodies were made of a nonmagnetic ceramic body to provide mechanical durability. A variation on this was a 'monolithic' head design, introduced by IBM. This name signified that the entire slider was machined and assembled from ferrite, reducing the part count and the number of assembly steps in the head fabrication. This was made possible by advances in ferrite technology which permitted them to have

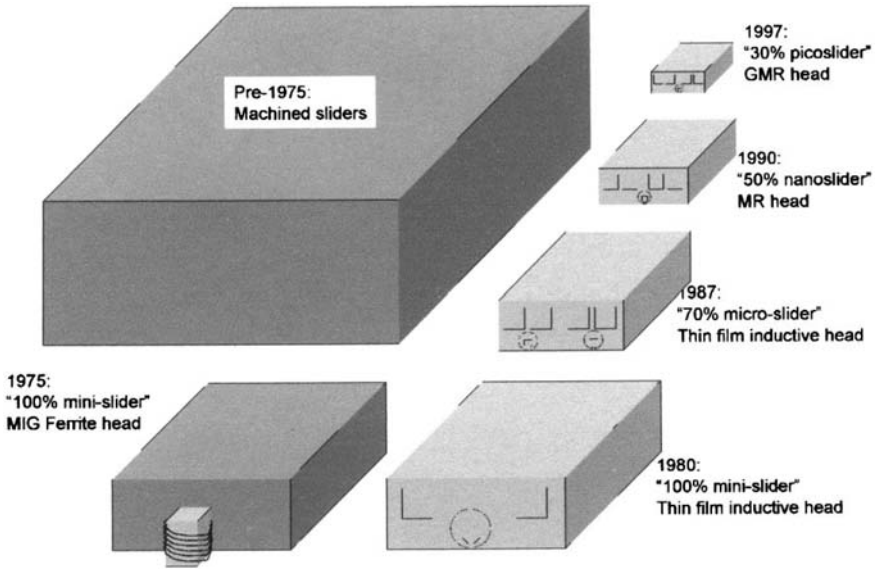

***Figure 1***
Progress in shrinking recording head fabrication over the last 50 years. Parts are drawn approximately to scale.

sufficient mechanical toughness to serve both a mechanical (the slider) and a magnetic function (the core). This summary is drawn from an excellent discussion of the ferrite head process in (Ashar 1997, Chap. 4).

As the demands on the recording heads became more stringent, it became difficult for ferrite to meet both the frequency requirements and the magnetic field levels required by the system. Ferrites, while conveniently insulating, have relatively low values of magnetization compared to most magnetic metals, and therefore cannot generate a very large write field. This situation gave rise to the metal-in-gap (MIG) head. The MIG design inserts a metal layer (typically sputter deposited) in the gap of the ferrite core. This allowed the use of higher induction metals, like NiFe or Sendust (FeSiAl) for generating higher writing fields, while continuing to suppress eddy currents in the large part of the magnetic yoke by continuing to make them out of ferrite.

The features of these major types of magnetic heads are illustrated in Fig. 2, which compares a composite-body head, a monolithic head, and a thin film head, which represents current (2001) technology (Ashar 1997). Also shown as an inset in Fig. 2 is a schematic cross-section of a gap of a MIG head, in which the additional metal layers are indicated. All three of these fabrication methods are compared in Table 1.

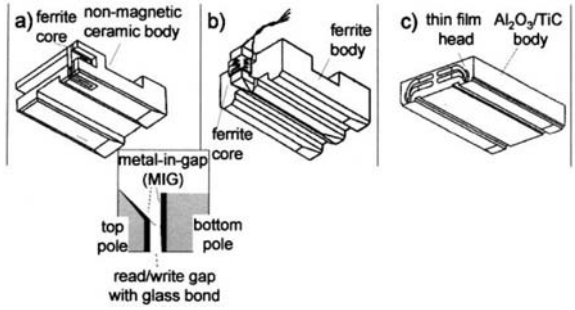

***Figure 2***
Types of recording head architectures: (a) monolithic, (b) composite, (c) thin film (adapted from Ashar 1997).

### *1.2 Thin Film Inductive Heads*

While MIG heads offered ways to obtain both high frequency performance and reasonably high writing fields, they had some serious drawbacks. Chief among these was manufacturing costs. Most designs had some degree of hand assembly, which introduced expense and variability in device parameters. Additionally, shrinking sizes were harder to produce with traditional precision machining technology, and the allowed geometries and materials were limited. Thus, thin film technology became the preferred method of device fabrication after the first devices were introduced by IBM in 1970 (Romankiw 1970) and patented in 1978 (Church and Jones 1980, Jones 1980).

The original patented thin film head design from 1978 is shown in Fig. 3 (Church and Jones 1980). Like monolithic and composite heads, the first thin film heads were used both for writing and inductive

***Table 1***
Features of heads fabricated using the major fabrication techniques.

| Feature | Composite | Monolithic | Thin film |
|---|---|---|---|
| Magnetic core | Machined ferrite (metal in gap) | Machined ferrite (metal in gap) | Electroplated or sputter deposited |
| Coil | Hand-wound or machine-wound | Hand-wound or machine-wound | Electroplated |
| Coil insulation | Coated wire | Coated wire | Photoresist or dielectric films |
| Slider body | Machined ceramic (nonmagnetic) | Machined ferrite | Alumina-TiC |
| Airbearing | Sawed slots | Sawed slots | Sawed slots or ion milled patterns |

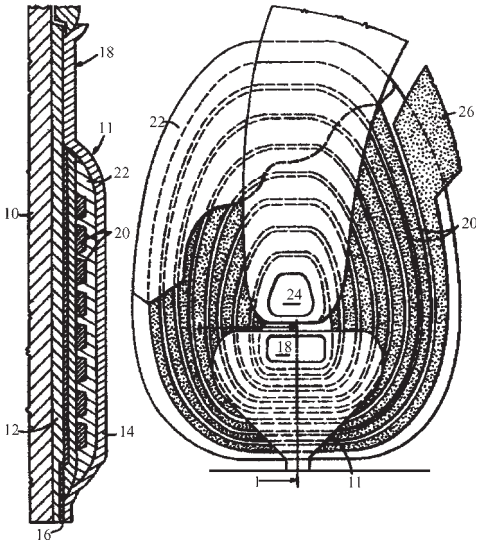

***Figure 3***
Original thin film inductive head from the IBM patent (Church and Jones 1980).

readback. This part of thin film write heads has not changed substantially since its inception, although dramatic shrinking has taken place. However, inductive writers have been combined with MR readback sensors in modern devices, as demonstrated first in Bajorek *et al*. (1974). These MR heads will be discussed in an ensuing section, with detail being given about the fabrication of both the read and write parts of the head. The basic structure of the thin film write head will be summarized here.

Scrutiny of Fig. 3 reveals that there are six essential layers in the fabrication of an inductive thin film head: Pole 1, Underpass, Insulator 1, Coil, Insulator 2, and Pole 2. These are labeled and shown more clearly in Fig. 4, which indicates how these layers are oriented relative to the substrate and the final device. In addition to the six layers that form the device, there are a number of packaging and interconnect layers also indicated in Fig. 4. These include Cu studs, $Al_2O_3$ overcoat, and Au bond pads. All of these layers will be discussed further in the next section on merged inductive/MR heads.

While thin film inductive heads enjoyed a number of years of high volume production as the head of choice, they were eventually supplanted by heads in which MR elements were used for readback. There were a number of limitations to the inductive-only designs that eventually led to this transition.

The main driver for the obsolescence of inductive heads was the fact that one head had to serve both the write and read function. Inevitably this led to design compromises in which both read and write functions performed by the inductive core were suboptimal. For example, in deciding the number of turns within a thin film inductive design, writing speed considerations favored a small number of turns for low inductance. However, readback sensitivity favors a large number of turns for large inductance and larger readback voltage. Increasing the data rate makes this situation worse, and limits the sensitivity of an inductive readback head, such that the more sensitive MR heads eventually become necessary. A summary of the main design tradeoffs in optimizing an inductive head for both reading and writing are listed in Table 2.

The transition from inductive read/write heads to merged MR/inductive heads was delayed by a number of design and fabrication innovations with the inductive heads. These innovations mainly focused on increasing readback sensitivity, without increasing inductance. Typical of these innovations was the use of multilevel coils first reported in Tamura *et al*. (1990) and eventually extended up to a total of four levels (Daniel *et al*. 1999). This approach allowed more compact coil designs with a lower inductance and higher efficiency as compared to a design with the same number of turns, but in a single layer. New planar yoke designs have also been demonstrated, for example, the so-called *omega-head*, with as many as 120 turns (Tang *et al*. 1994).

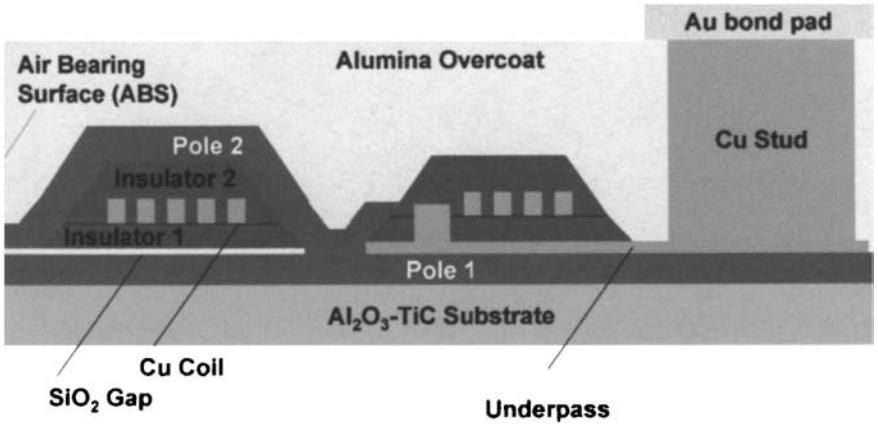

***Figure 4***
Basic structure of layers in early thin film inductive heads.

***Table 2***
Design tradeoffs in an inductive read/write head.

| Wafer fabrication | | Postwafer fabrication | |
|---|---|---|---|
| Major steps | Description | Major steps | Description |
| Bottom shield | Photolithographic patterning and electrodeposition | Rowbar slice | Precision sawing |
| Bottom read gap | Vapor deposition and patterning | Throat lap | Lapping with electrical feedback |
| MR sensor and MR thin leads | Sputter deposition and patterning with biasing elements | Airbearing pattern | Patterning and ion milling |
| Top MR shield/ Bottom write pole | Vapor deposition and patterning | Slider dice | Precision sawing |
| Thick MR leads | Vapor deposition and patterning | HGA assembly | Precision assembly and wire bonding |
| Write coil and insulation | Patterning and electrodeposition | | |
| Top pole | Patterning and electrodeposition | | |
| Leads and studs | Patterning and electrodeposition | | |
| Alumina overcoat | Sputter deposition | | |
| Planar lap | Lapping/polishing | | |
| Bond pads | Patterning and electrodeposition | | |

To further increase efficiency, a recessed cavity design was developed. In this design, the bottom pole is deposited into a cavity, such that the same separation between the two poles can be achieved with less steep slopes in each layer (Zak *et al*. 1996). An even more novel design was proposed by Mallary and co-workers, the so-called *diamond head*, in which all the flux threads in each coil turn twice for greater output (Mallary *et al*. 1994, Mallary and Ramaswamy 1993).

## 2. 1990s Technology: Integrated MR Heads

### 2.1 Overview of the Head Fabrication Process

Since the late 1980s, the canonical recording head configuration has been an inductive writer coupled with a MR reader. As with the original thin film inductive heads, these heads are constructed using thin film fabrication techniques. MR heads are used because they give much better signal to noise performance than inductive readers, and the separation of

the two functions allows greater optimization of each one.

These types of heads are typically referred to as "*merged heads*" because the reader and writer actually share one magnetic element. This can be seen in Fig. 5, which shows a schematic of the active region a state-of-the-art magnetic head circa 2001. The magnetic film that forms both the bottom pole of the writer and the top shield of the reader is shown. The hierarchy of the steps in fabricating a merged MR head are shown in Fig. 6. Each of the following subprocesses will be discussed below: reader fabrication, writer fabrication, mechanical encapsulation, and postwafer fabrication. A tabulation of the major steps in a typical head process flow is given in Table 2.

While the merged back-of-slider architecture (e.g., Hannon 1994) represents the vast majority of commercial heads (c. 2001), a number of other inductive write/MR read head designs have been proposed and occasionally commercialized on a smaller scale. Preceding the merged head, a "piggy-back" design was commercialized in which the top MR shield

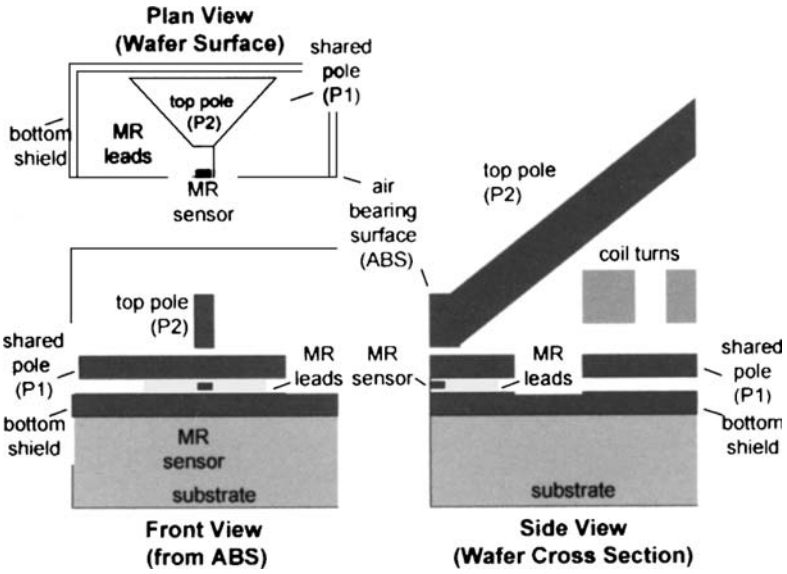

*Figure 5*
Structure of merged MR head (ca. 2001).

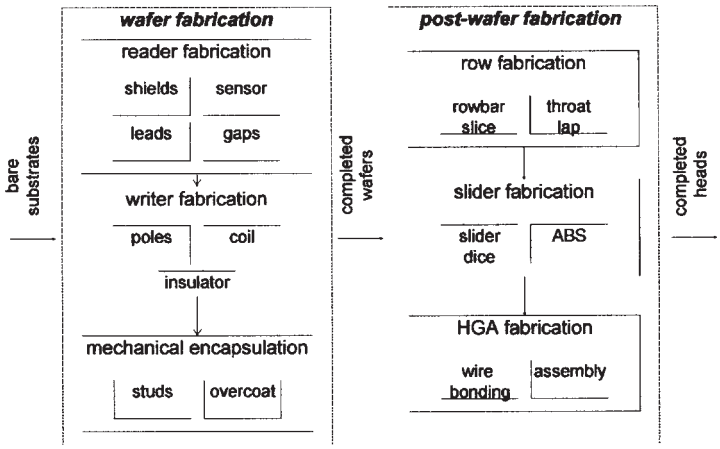

*Figure 6*
Hierarchy of fabrication steps in the construction of a merged MR thin film recording head.

and the bottom pole were separate layers (Bajorek *et al*. 1974, Tsang *et al*. 1990a, 1990b). Yoke heads, in which the MR head is separated from the medium surface by a flux conductor and forms part of a magnetic circuit have been commercialized. The most notable was that of the Digital Compact Cassette (DCC) tape recording system architected by Philips (Zieren 1993). Silmag, in France commercialized the planar head on a Si substrate (Lazzari 1974, 1996, 1997), and MR heads in which the current flows perpendicular to the MR sensor film plane have been proposed due to their higher giant MR (GMR) ratio in this geometry (Zhu and O'Connor 1995). All of these innovations in design required somewhat different fabrication sequences, but all were built out of the same basic set of thin film processes. The details of each of these heads will not be discussed here; rather a detailed discussion of the fabrication steps of a merged MR head will be given as representative of head fabrication in general.

An important concept in the discussion of thin film device fabrication is that of the critical dimension. This is the smallest feature that can be reliably fabricated on the wafer using a particular process. Recording heads, like semiconductor devices, have several critical dimension per device, with typically 10000 devices per wafer. Si device wafers can have billions of critical dimensions per wafer. This will have important consequences for the feasibility of certain types of high-resolution fabrication techniques that have a serial nature to them, like electron beam lithography or focused ion beam etching. These processes have some application in head fabrication, while they are expensive to implement in the semiconductor industry.

There are at least seven critical physical dimensions in a merged MR recording head. Control of these dimensions is required to get reliable performance from the fabricated device. This is accomplished though careful process design. The seven critical dimensions are as listed here, and the fabrication processes used to control them are discussed below. The read trackwidth and the write trackwidth are the only two critical dimensions controlled exclusively by lithography. The MR sensor stripe height, the write head throat height, and the head medium separation are controlled by a combination of lithography and precision mechanical machining. Finally the MR sensor thickness, MR gap thickness, write gap thickness, and the pole thicknesses are controlled by film deposition, and are not influenced by lithography.

In addition to critical dimensions in head manufacturing, there are also critical alignments. These include the read to write track alignment and the alignment of the magnetic to the electrical trackwidths of the MR sensor. Some important processing advances have been made in addressing the need to control these alignments.

Finally, in addition to mechanical dimensions and positions, the material properties of the thin films from which the heads have been fabricated must be carefully controlled. These include the sensitivity, bias point and the stability of the reader, and the permeability and switching speed of the writer core. The materials used in these devices are listed in Table 4.

### 2.2 *MR Read Sensors*

#### *(a) Sensor materials*

MR heads utilize materials whose resistance changes with applied field. These may be anisotropic magnetoresistive (AMR) materials in which the resistance versus field is given by:

$$R(\theta_{\mathrm{AMR}}) = R_{\perp,\mathrm{AMR}} + \Delta R_{\mathrm{AMR}} \cos^2\theta_{\mathrm{AMR}} \qquad (1)$$

***Table 3***
Major steps in the fabrication of modern magnetic recording heads.

| | Desirable properties for … | | |
|---|---|---|---|
| Design feature | Inductive writing | Inductive reading | Comment |
| Pole materials | High magnetization for high field | High permeability for sensitivity | Features are not mutually exclusive but dual optimization is restrictive |
| Pole thickness | Small for speed large for efficiency | Large for sensitivity | Fundamental write speed vs. read sensitivity trade-off |
| Number of turns | Small for speed large for high field | Small for resonance large for sensitivity | Fundamental write speed versus read sensitivity trade-off |
| Fly height | Small for resolution | Small for resolution | Smaller fly height is always better |
| Write gap | Large for overwrite small for sidewriting | Small for resolution | Fundamental overwrite versus resolution trade-off |

***Table 4***
Thin film materials used in the fabrication of magnetic recording heads.

| Component | Materials |
|---|---|
| Substrate | $Al_2O_3$/TiC |
| Poles and shields | $Ni_{80}Fe_{20}$ (permalloy) $Ni_{45}Fe_{55}$ FeXN (X = Al, Ta, Zr) (iron nitride) FeCoN (iron cobalt nitride) |
| Read and write gaps | $SiO_2$ (silicon dioxide) SiN (silicon nitride) $Al_2O_3$ (aluminum oxide or 'alumina') AlN (aluminum nitride) |
| MR sensors | $Ni_{80}Fe_{20}$ (permalloy) Spin valve stacks (e.g., NiFe/Cu/NiFe; CoFe/Cu/CoFe) Antiferromagnets (e.g., FeMn, NiMn, IrMn, PtMn, NiO, CoO) |
| Coil insulators | Photoresist (hardbaked) $SiO_2$ |
| Leads | AlCu Cu |
| Studs | Cu |
| Bondpads | Au |

where $R(\theta_{AMR})$ is the resistance of the device as a function of $\theta_{AMR}$, the angle between the current in the device and the magnetization. $R_{\perp,AMR}$ is the resistance of the device when the current and field are perpendicular to one another and $\Delta R_{AMR}$ is the amount of change in the resistance in going from a parallel configuration of magnetization to a perpendicular one. Thin films of NiFe show this effect ($\Delta R_{AMR} \sim 2\%$) and have been widely used as sensors.

The sensor materials may also be GMR materials, in which the resistance of the sensor is given by:

$$R(\theta_{GMR}) = R_{\parallel,GMR} + \Delta R_{GMR} \sin\theta_{GMR} \qquad (2)$$

where $R(\theta_{GMR})$ is the resistance of the device as a function of $\theta_{GMR}$, the angle between the magnetization in one ferromagnetic layer and the magnetization in the other. $R_{\parallel,GMR}$ is the resistance of the device when the two magnetizations are parallel and $\Delta R_{GMR}$ is the change in resistance of the device when the two layers change from being parallel to antiparallel.

Examples of typical transfer functions for these devices are shown in Fig. 7 (Brug *et al.* 1996). It can be seen that the amplitude of the GMR effect is typically much larger than the AMR effect (hence the term 'giant'), which is the reason for the appeal of these materials. It can also be seen from this figure and from the functional forms of Eqns. (1) and (2), that the transfer functions have very different shapes, and therefore require different biasing schemes to achieve linear operation.

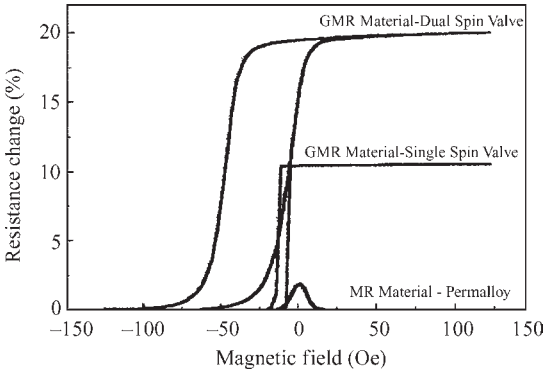

***Figure 7***
Comparison of different MR sensor responses on the same scale (from Brug *et al.* 1996).

This biasing process is typically accomplished using soft adjacent layers (SALs) or exchange pinning with antiferomagnets. These layers are typically incorporated within the so-called *MR stack*, such that the construction of the sensor and the biasing scheme can be thought of as a single manufacturing step. This article will not dissect the stack structure and function in detail as several excellent references exist on the AMR effect (McGuire and Potter 1975), the GMR effect (White 1992), and MR head materials and technologies (Mallinson 1996, Jones *et al.* 1995). An excellent review of antiferromagnetic metallic exchange materials is also available (Lederman 1999), and developments in synthetic antiferromagnets (trilayers of Co/Ru/Co patented by IBM, Coffey *et al.* 1994) have added enormous flexibility to the MR fabrication process by eliminating most of the demagnetizing fields from the biasing layer.

While the deposition of the MR sensor layer (sensing layer plus biasing layers) can be treated like a single manufacturing step, consisting of the deposition and patterning of a composite structure, the complexity of this step and the associated tooling should not be underestimated. A typical stack of modest complexity is shown in Fig. 8. Note that this structure consists of nine layers and six different materials, and the complexity can grow to twice this for dual spin valves. Deposition tools with 1.5 m diameter chambers containing six or more 30 cm diameter targets and costing several million US dollars are needed for this process.

### *(b) Shields and gaps*

When an acceptable sensor material candidate is identified, it must be patterned into a sensor and placed between two insulating shields, to provide resolution during the readback process. Without shields, the sensor will pick up magnetic flux from many bits and not be able to resolve single bits easily.

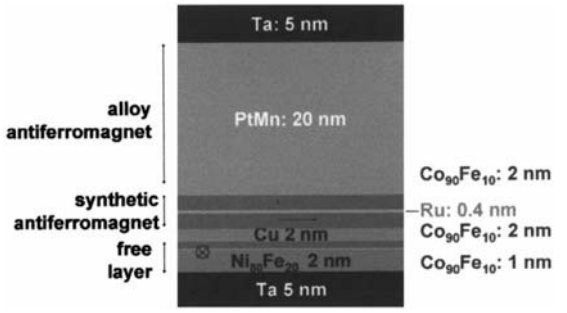

*Figure 8*
A typical MR stack consisting of a spin valve of modest complexity. All nine of these layers, consisting of six different materials, must be deposited in a single pumpdown.

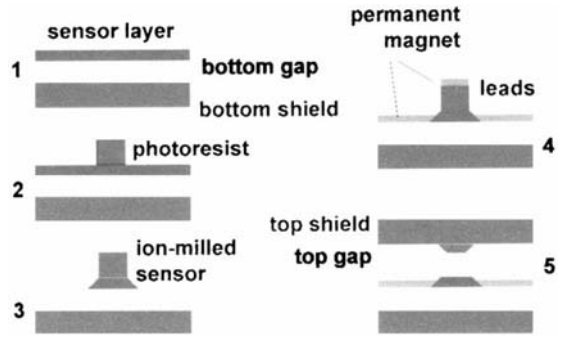

*Figure 9*
The self-aligned lift-off process typically used for the definition of read sensor magnetic width, electrical width, and for accomplishing the alignment of these two features.

Shields are constructed of electroplated or sputter deposited thin films, typically 1–2 μm thick, consisting of materials similar to pole materials. High permeability and magnetic stability is a higher priority in these materials than is high saturation magnetization, as the shields conduct signal flux during readback. Ductility of the shields is undesirable to prevent smearing of these layers during the mechanical lapping process (see discussion below under stripe height definition). This can cause shorting of the shields to the sensor, rendering it nonfunctional.

A functional sensor is electrically isolated from the magnetic shields (which are usually electrically conductive) by a thin insulating gap. Controling the dimension of this gap, of the order of 100 nm in thickness, is relatively straightforward, since it is set by a film thickness. This dimension determines, to a large degree, the resolution of the head. However, ensuring that no electrical shorting takes place across this gap is more challenging. While chemical vapor deposition of these layers would produce denser films with better insulation properties, these films are typically sputtered because this approach can be done at a lower substrate temperature. GMR films are particularly temperature sensitive and cannot typically survive above 250 °C.

*(c) Stripe height definition*
The definition of the stripe height in an MR head is accomplished not through optical lithography, but through a mechanical lapping or polishing process. Optically defined structures (lapping guides) are used, indirectly, to control this process, but the physically polished interface determines the final stripe height. This process is discussed below in the context of postwafer fabrication.

*(d) Trackwidth definition*
The definition of the reader trackwidth involves two critical dimensions and a critical alignment. Since the head conducts electrical current and magnetic flux, it actually has two widths: a magnetic width and an electrical width. These are the two critical dimensions. Additionally, these two segments need to be aligned, which constitutes the critical alignment. The standard way of accomplishing this task that has emerged is the self-aligned lift-off process. This method allows two layers to be patterned with the same photoresist, making the process ''self-aligning.'' The two layers are the sensor stripe and the electrical leads. An example of how this is accomplished is shown in Fig. 9. The permanent magnets used for longitudinal stabilization are also shown.

*(e) Longitudinal stabilization*
Longitudinal stabilization of MR sensors is done to prevent random, nonrepeatable domain activity in the sensor, which introduces noise into the readback channel. In today's devices it is accomplished with permanent magnet abutted junctions. These permanent magnets are typically incorporated into the self-aligned lift-off as noted in Fig. 9. This procedure was patented by IBM in 1991 (Krounbi *et al.* 1991). These magnets provide a longitudinal field that helps to keep the device in a single domain, and prevent domain wall jumps. The abutted junction is usually not ideal, and is frequently represented as trapezoidal, (as shown in Fig. 9) due to the etching profile of the sensor stripe before the permanent magnet and lead deposition step.

While a close placement of the magnetic material is good for achieving large fields, it is important to decouple (in terms of magnetic exchange) the permanent magnetic from the sensor. If they are strongly coupled, this introduces noise in the sensor, due to the nucleation of domain walls by the permanent magnet grains (Zhu and O'Connor 1996). Permanent magnet stabilization has also been implemented using

overlay techniques, in which an abutted junction is not formed. Both designs have been analyzed for performance (Shen *et al.* 1996) and produced commercially.

One other widely used longitudinal biasing scheme was the exchange tab. In this design, material in the wings of the sensor (outside the trackwidth) was tightly coupled to an antiferromagnetic layer in this region (Tsang and Fontana 1982). This rendered this region like a permanent magnet with the same magnetization as the active region of the sensor. This approach has at least two drawbacks. First, the wing region is not pinned rigidly, so some side reading occurred due to flux sensing in the tab region. Second, an exactly matched permanent magnet was not optimal. In fact typically, permanent magnets used for longitudinal stabilization have a greater thickness-magnetization product than the sensor they stabilize.

### 2.3 Inductive Write Transducer

#### (a) Pole materials

The thin film materials used for write head poles need to satisfy several criteria. First, they need to have sufficient saturation magnetization, as this sets the ultimate field they can generate. Second, they need to be magnetically soft, such that they produce a linear field response with current, and maintain this permeability up to high frequencies of operation. Current systems operate in the hundreds of MHz range with GHz operation frequencies on the horizon. Third, they need to be compatible with head fabrication techniques. For example, they cannot require processing temperatures above 250 °C. Finally, they need to be magnetically and chemically stable for a long period of reliable operation.

A list of the main candidates for thin film pole materials is given in Table 5. These materials are sorted in order of saturation magnetization, $M_s$, ranging from 800 $kAm^{-1}$ in permalloy to 1900 $kAm^{-1}$ in FeCoN. Steady increases in pole magnetization have made writing on higher coercivity media possible. In the right most column of Table 5 is listed the maximum coercivity of the media that a head with the given pole composition could write on. This ratio between the magnetization and the maximum longitudinal media coercivity (measured at room temperature and at long time scales) is about 4:1.

All of the materials in this list have been made in highly permeable forms. Maintaining high magnetic permeability at high frequency requires two things. First, eddy currents must be suppressed. Eddy currents occur when the skin depth of the material, $\delta$ becomes less than half the film thickness. At this point, the center of the film (most distant from the surface) is shielded from the applied current and ceases to switch. Pole permeability consequently falls off. The skin depth, $\delta$ is given by:

$$\delta = \sqrt{\frac{\rho}{2\pi f \mu_r \mu_0}} \tag{3}$$

where $\rho$ is the material electrical resistivity, $f$ is the operation frequency, $\mu_r$ is the relative permeability of the material (unitless) and $\mu_0$ is the permeability of free space ($H/m$). The above equation suggests that high resistivity materials are the only practical solution, as frequency is a given and a reduction of permeability is generally undesirable for magnetic functionality.

Increasing film resistivity is accomplished in one of two ways: adding elemental constituents or laminating. In either case, a reduction of the saturation magnetization, $M_s$, generally occurs because of the introduction of nonmagnetic material. Lamination with insulating layers (by analogy to power transformers and other 60 Hz devices) is more predicable in its effects on high frequency permeability than alloying, and generally improves the magnetic domain configuration of the layers. However, it is much less compatible with electrodeposition (the preferred method of pole fabrication from a cost perspective) than alloying.

A second requirement at high frequencies is the rapid damping of magnetic precession. This ensures

***Table 5***
Pole materials.

| Material | | | Media | |
|---|---|---|---|---|
| Composition | Name | Deposition method | Ms ($kAm^{-1}$) | Hc Max ($kAm^{-1}$) |
| $Ni_{80}Fe_{20}$ | Permalloy | Plating, sputtering | 796 | 199 |
| FeAlSi | Sendust | Sputtering | 955 | 239 |
| $Ni_{45}Fe_{55}$ | | Plating, sputtering | 1114 | 279 |
| CoZrX | | Sputtering | 1194 | 298 |
| FeXN | Fe-Nitride | Reactive sputtering | 1592 | 398 |
| FeCo | | Plating, sputtering | 1910 | 477 |

that the magnetization actually switches, rather than simply precessing at the frequency of interest. While the actual ferromagnetic resonance frequency, $\varpi_{FMR}$, can be pushed to higher values by proper design, increasing the damping is presently not a well-understood process. The FMR resonance frequency, $\varpi_{FMR}$, is given approximately by:

$$\varpi_{FMR} \approx \gamma \sqrt{\frac{M_s^2}{\mu_r}} \tag{4}$$

where $\gamma$ is the gyromagnetic constant ($HzmA^{-1}$), $M_s$ is the saturation magnetization of the film, and $\mu_r$ is the relative permeability of the film (unitless). From this relationship, it can be seen that resonant frequency can be increased by raising $M_s$ (desirable) or decreasing $\mu_r$, (undesirable).

The above considerations are relevant to choices made in the head fabrication process. As seen in Table 5, the two main options for pole deposition are electroplating and sputter deposition. Plating has the advantages that it tends to have higher throughput, require lower cost tools, produce films with lower stresses, and facilitates finer line patterns, since it is an additive rather than a subtractive process. Sputtered materials have the big advantage that laminating with insulators is simple within a sputter deposition system. Until now, there has been very little commercialization of sputtered materials in disk heads. (Tape heads use them regularly for their superior wear resistance.) This is because the cost of processing and the ability to cheaply fabricate narrow tracks have dominated the tooling decisions.

*(b) Trackwidth definition*

Definition of the write trackwidth is perhaps the single greatest challenge of the modern writer process. This is because of the large aspect ratios of these devices. In some cases a submicron lateral dimension is needed on a 2–3 μm thick feature. As a general rule, aspect ratios of this type are difficult in planar lithographic processes. Typically, the top pole is electroplated into a photoresist mask to give a high aspect ratio, then "trimmed" after photoresist removal, to give a top and bottom pole that are close to the same width, and well-aligned. This is another self-aligning process, and is shown schematically in Fig. 10.

*(c) Coil formation*

The fabrication of coils in heads is typically through electrodeposition (or "plating") of Cu into photoresist dams. An electrically conductive seedlayer (50–100 nm thick) is needed, as in the electrodeposition of poles, in order to preferentially plate where the coil needs to be formed. After plating 1–2 μm of Cu into the photoresist dams, all of the turns of the coil are shorted together by the seedlayer. Thus it is removed by ion milling. An insignificant amount of the coil themselves is removed in this process as well. In high performance inductive writers, there is a push toward fewer turns, short yokes, and coils that are less complicated than those used in inductive read heads. This trend allows a very low inductance head to be constructed, which has good high-speed performance.

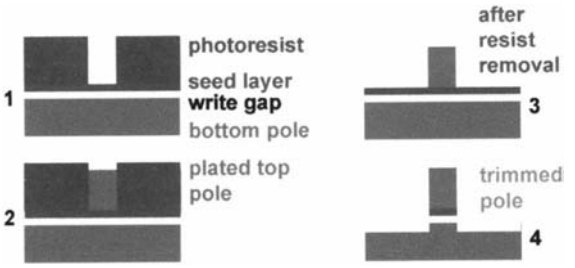

***Figure 10***
Electrodeposition of the top pole followed by pole trimming at the wafer level.

## 2.4 *Electrical Connection and Mechanical Encapsulation*

After a head is electrically complete, it must be mechanically processed to expose the sensor at the edge of the slider. This requires that the head be encapsulated in a thick layer of electrically insulating, mechanically robust material. Typically, sputtered alumina is used, because it can be made thick with low stress and, therefore, low propensity for delamination. It is, however, a somewhat time consuming process, taking typically several hours to deposit the required 20 μm thick films.

Electrical connection through the encapsulation is necessary to contact the devices, and this is typically done with a composite stud-bond pad structure. The studs are 20 μm thick posts of Cu that are electroplated before the deposition of the alumina. A mechanical planarization process, like lapping or chemical-mechanical polishing (CMP) is used to expose the Cu after the alumina deposition. Finally, the exposed Cu contact regions are covered with Au bond pads to facilitate the connection of the head leads and to prevent Cu corrosion.

## 2.5 *HGA Construction: Postwafer Fabrication*

After the wafer is complete, it is diced into rows, and these are lapped to create the correct stripe height in the MR head and the correct throat height in the inductive writer. Since this is a single operation that sets two critical dimensions, the alignment of the zero

stripe height point of the reader to the zero throat height point of the writer is extremely critical, as only one of the layers can be used as the reference layer for lapping.

Control of the lapping process is done with some lithographically defined feature that changes in a systematic way with lap depth. In early generations of thin film head technology, optical lapping guides (OLGs) were used. These were patterned structures thick enough to be seen in cross-section from the airbearing surface during lapping. They were typically triangular in shape such that their visible width changed in a systematic way with lapping depth. Lapping was stopped when a particular dimension was reached in the visible structure.

Since this process did not lend itself easily to automation, electronic lapping guides (ELGs) became the standard. These structures were made from the same layer as the MR stripe, and were similar in shape. Their resistance increased as their stripe height was reduced in a predictable fashion and could be used as an endpoint detection for lapping. Once this process was automated, it was possible to sense variations across the row by monitoring a number of lapping sensors and to actually flex the row slightly, increasing the pressure in slow lapping points to obtain maximum uniformity during the lapping process. Absolute resistance is typically not used as a stopping criterion, as it is too susceptible to process variation. Typically a differential or ratio technique is used to make the sensors as insensitive as possible to process variations in film thickness, stripe height, etc.

Once the rows have lapped to stripe height, an airbearing contour is formed on the airbearing surface of each slider in the row. Older-style air bearings were simply machined rails, which allowed the head to be near the disk while allowing a lot of air to rush through a channel between the head and medium. Air bearings have become patterns that cannot be formed with rectilinear batch machining, and are formed through one or more steps of ion milling. This requires photolithography on the airbearing surface, allowing air bearings of arbitrary shape. Some of these are quite complicated with negative and positive pressure regions, fly heights that are insensitive to speed, and excellent stability. State-of-the-art commercial air bearings (ca. 2001) allow head to medium spacings of $<25$ nm, with further reductions of at least a factor of three under development. A good review of ABS technology is given in Hoyt (1997).

Once the air bearings are complete, the rows are diced or parted into sliders, again with precision sawing. Individual sliders are then mounted on stainless steel suspensions, using adhesive between the gimbal mounting point and the slider. In some advanced designs, these suspensions are active devices, incorporating secondary fine actuators that use piezoelectric, electrostatic (Kim *et al.* 1999), or electromagnetic (Lin and Ong 1999) forces to provide fine tracking. It is widely assumed that secondary actuation is required for very high track densities (Fan *et al.* 1995).

## 3. *The Future of Recording Head Fabrication*

The future of magnetic recording likely holds at least four major paradigm shifts in the coming years. Some of these will have a profound impact on head fabrication. Not all of these will become a reality, but it is almost certain that at least one that will have major effect on head architecture and fabrication will reach commercialization. These four trends are (in order of increasingly radical departure from today's head manufacturing paradigm);

- patterned media
- perpendicular or vertical recording
- thermally assisted (or hybrid) recording
- micro-array based storage

Patterned media do not in themselves require any changes in the head, although it will certainly change the system architecture, especially the channel (Nair and New 1998, Hughes 1999). It may change the head, if the required field magnitudes or rise times become radically different than they are today. If (and/or when) patterned media do become commercialized, the head changes to support it will be mainly evolutionary.

Perpendicular recording will almost certainly change the write head design, although similar steps will be used in fabrication. It is possible to record on and read from perpendicular media with a standard head for longitudinal recording, but more optimum designs are possible (Khizroev *et al.* 1997). Some kind of probe head with a relatively large gap is likely for writing. Soft underlayers in the media will be used to increase the head field. Long magnetic circuits with distant return paths must be avoided to avoid stray field sensitivity (Cain *et al.* 1996). Reading will be magnetoresistive, but whether the sensor will be at the airbearing or recessed, and the exact type of sensor, is still to be determined.

Thermally assisted recording will precipitate a radical change in the head geometry. Some source of heat, most likely light will need to be conducted to the medium by the head. At the densities where this will become necessary due to thermal stability considerations (Ruigrok *et al.* 2000), near-field optics will be necessary. This will require optical coupling and focusing elements on the head, and many new fabrication techniques.

Several research groups are currently working on microarray-based storage, including IBM and Hewlett Packard (described in Toigo and Hayashi 2000), Kionix and Carnegie Mellon (Carley *et al.* 2000). If these devices become widely commercialized, they will represent radical departures in head

fabrication technology. Heads will be tightly integrated with Si electronics, on Si substrates. They will be massively parallel, and they may employ any number of physical mechanisms to read and write including magnetic. Whether such radical architectural changes will completely replace standard disk drives is an open question. It almost certain, though, that they will at least find some niche market, and introduce some radically different designs to the data storage head.

## Magnetic Recording Heads: Historical Perspective and Background

Magnetic recording heads are a key enabling technology for the recording of information on magnetic media since they both write and read the magnetic transitions. The first recording heads were inductive, composed of a bulk ferromagnetic material such as iron and a coil to both magnetize the iron and to provide a means to detect the magnetic flux from a magnetic transition.

The inductive head served to both read and write in the same structure. Figure 1 shows a simplified diagram of an inductive recording head. As current flows through the coil a magnetic field flows in a circular path through the core and gap of the device. Some of the flux in the gap fringes outside of the core. It is this flux that writes the transition on the media. By a principle known as reciprocity the flux from a transition beneath the head will be picked up by the coil and sensed as voltage proportional to the change in flux under the gap; i.e., the signal is proportional to the product of the velocity of the head over the media and strength of the flux emanating from the transition.

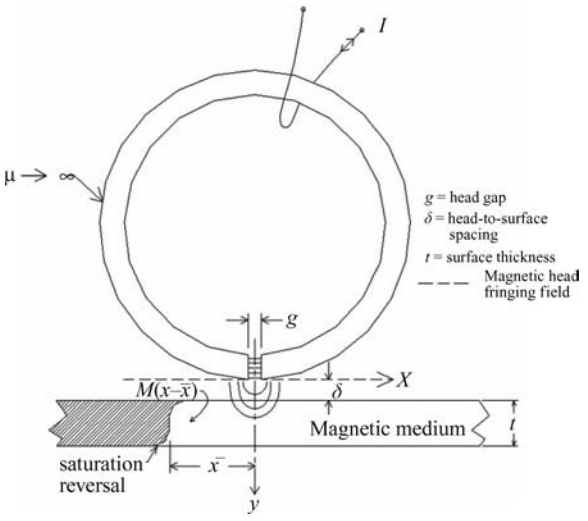

***Figure 1***
Inductive ring head.

Oberlin Smith, an American, suggested the first magnetic recording head in 1888. It featured a wire recording medium with an electromagnet consisting of a coil wound around a rod of iron as shown in Fig. 2. Valdemar Poulsen of Denmark built the first functioning recorder using this head in 1898.

The wire was replaced by a steel tape in the 1930s. In Germany, the Stabltone-Bandmachine was first offered for sale in 1935. In England, the Blattnerphone was first offered for lease in 1931 and in 1933 the rights to the Blattnerphone were sold to Marconi's Wireless Telegraph Company, Ltd.

Marconi, in cooperation with Stille, one of the developers of Stabltone-Bandmachine, developed a second-generation machine. The head on this machine consisted of a dual pole head, one on each side of the tape. The flux was concentrated by tapering the tips of each pole. In 1935, Marconi modified the head design to single-pole design. It is interesting to note the pole head is favored for perpendicular recording, which has attracted a lot of attention lately in the push to higher areal densities.

In 1933, Eduard Schuller of AEG in Germany took out a patent on the ring head. At AEG, tape recorders were built using ring heads for recording, playback, and erasure. They are still used today for virtually all writing on magnetic recording media.

For five decades ring heads were used for reading and writing in most recording applications. The basic

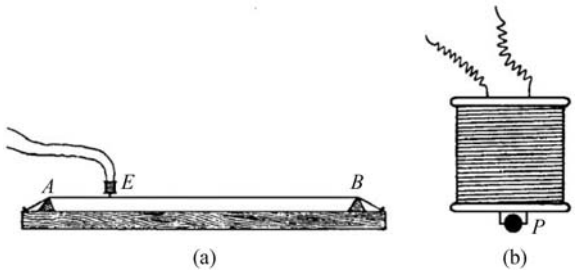

***Figure 2***
(a) The apparatus used by Poulsen for his first experiments. A steel wire is stretched between A and B. The electromagnet E was moved along the wire by hand to record or replay sound. In (b), the wire is shown partially surrounded by the pole piece of the electromagnet.

design remained the same but improvements in materials and the manufacture of smaller heads with tighter tolerances extended them to more advanced application. The original steel heads were replaced by mu metal and laminated mu metal. This was followed by NiZn and then MnZn ferrite. Manufacturing technology improved to allow for batch fabrication of many cores together which were then sliced up like loaves of bread to yield individual cores.

Core winding moved overseas. Epoxy and then glass was used to bond together the cores and to bond the cores into the sliders. The last evolution in this batch-fabricated technology was the MIG (metal in gap) head, which featured a ferrite core with high-moment material such as Sendust deposited in the gap.

The first commercial thin-film single-turn heads were made by Burroughs in 1975 on the B9470 head/track disk file. In 1979, IBM introduced thin film heads. These heads were made by a semiconductor-type process with hundreds and then thousands of heads fabricated on a single wafer. The wafers were then sliced up, made into sliders, and mounted on head gimbal assemblies (HGA) as shown in Fig. 3. This batch process eventually reduced the cost and improved the performance of the magnetic recording heads until MIG ferrite heads were driven from the market place for disk drives around 1995. Ferrite heads continue to find application in floppy disks, video, and other tape recorders.

As the areal density increased in the 1980s the smaller tracks required more and more turns be put on the heads to make up for the signal lost as the track width was decreased. This was not entirely without cost since the inductance increased with the square of the number of turns and the increasing turns reduced the frequency response of the heads by increasing the resonant frequency of the coil. The thin-film heads had an advantage in this respect over the ferrite heads since their smaller size resulted in lower inductance than the larger ferrite heads.

The first IBM thin-film heads had a single-layer eight-turn coil. Two-layer coils followed these. In the early 1990s, three-layer and four-layer coils were developed. Inductive thin-film heads reached their limit with heads manufactured by Dastek Corporation consisting of four layers and 54 coil turns. The last read/write inductive head drive was shipped by Western Digital Corporation in 1995.

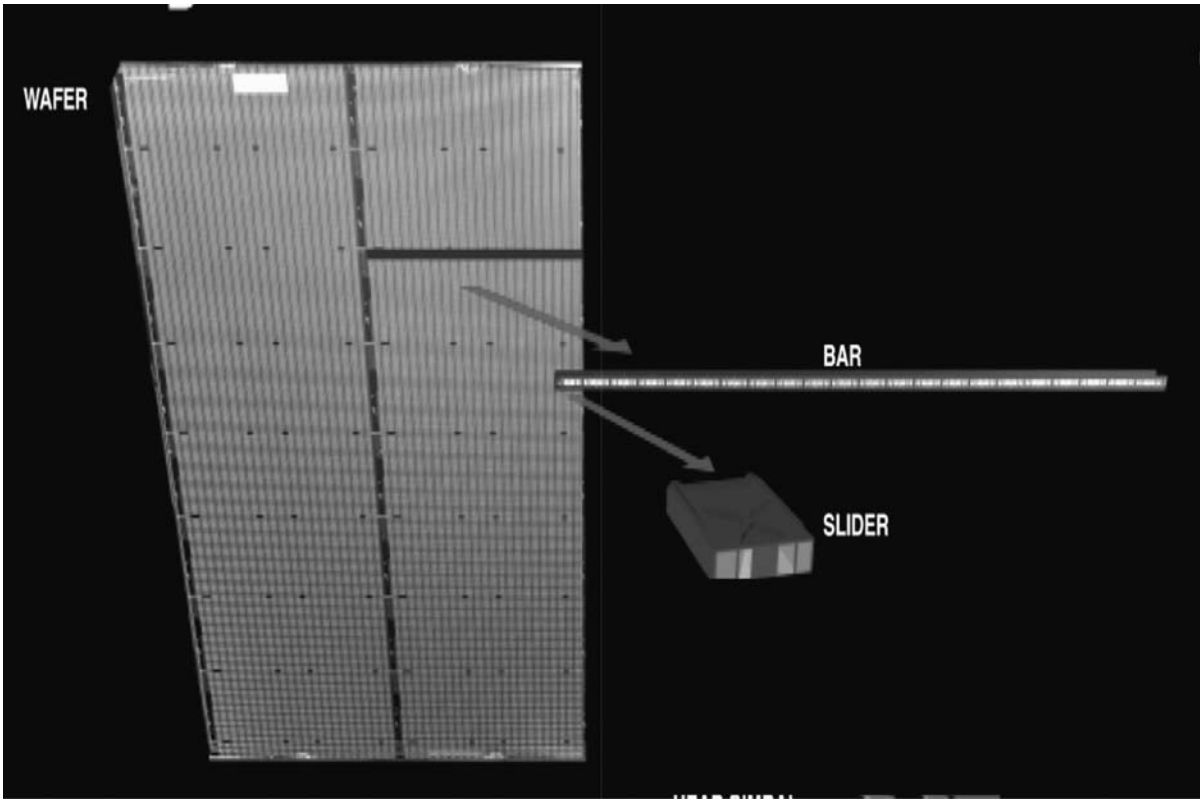

***Figure 3***

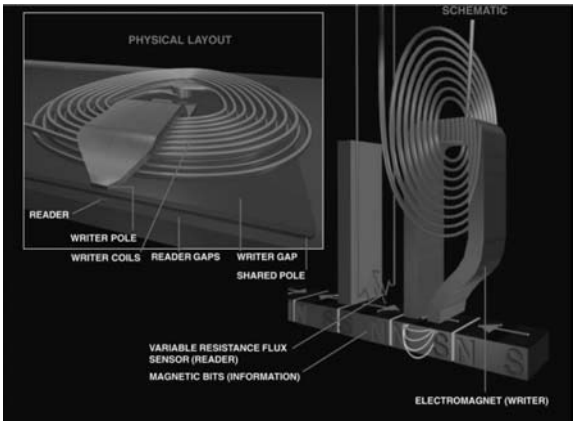

***Figure 4***
Merged MR head (courtesy of Seagate Technology, LLC).

In 1991 IBM introduced the MR (magneto-resistive) read head using the AMR (anisotropic magnetoresistive) effect in which the resistance of the element was determined by the angle between the sense current and the magnetization. This AMR device was coupled with an inductive write head (see Fig. 4). From this point MR and GMR heads proceeded to dominate the disk storage business within the next five years.

***Figure 5***

### *1. Air Bearings*

Hand-in-hand with the improvements in transducers, the increases in areal density of the previous four decades were enabled by the decrease in head-to-media spacing (HMS), usual referred to as "fly height" (FH). In 1953, Bill Goddard of IBM designed and flew a hydrostatic air bearing as part of the development of the IBM RAMAC disk drive. This was an externally pressurized air bearing where the air cushion was supplied by air piped into the head assembly as shown in Fig. 5.

The heads were mounted on a gimbal spring that allowed the head to pitch and roll so that it could align with the surface of the rotating disk underneath. All subsequent flying heads used a gimbal assembly to allow alignment of the head and disk surfaces. This is referred to as a head gimbal assembly (HGA).

The first self-acting air bearing for magnetic recording was developed at IBM beginning in 1955. Jake Hagopian developed the first concept and Bill Gross, Ken Haughton, and Russ Brunner refined it. The self-acting air bearing was introduced in the IBM 1301 disk drive in 1962. This air bearing and the following ones had a cylindrical or spherical crown and featured a large mass and load pressure (several hundred grams force). The use of these cylindrical self-acting air bearings reduced the fly height from 800 μm on the RAMAC to 50 μm on the IBM 3330. They were of the load/unload type, which means they were lifted from the disk surface before the disk stopped rotating and loaded when the disk was up to speed.

In the early 1970s, IBM developed and shipped the 3340 "Winchester" disk drive which featured a two-rail taper flat air bearing with a low-low mass slider flying over a lubricated ferric oxide disk in a contact start–stop mode. The head flew at about 20 micro-inch when the disk was rotating but was in contact when the disk was stopped. At about the same time Digital Equipment Corporation designed and shipped the RS04 disk drive featuring a taper-flat, contact/start–stop, air bearing flying on a lubricated thin-film plated disk.

These taper-flat, contact/start–stop sliders were used on many drives until the introduction of the negative-pressure air bearings in 1991 by IBM in the Corsair Drive. In 1995, Read-Rite Corporation introduced the Tri-Pad air bearing featuring a pseudo-contact air bearing where the head and disk were almost in contact. This approach only worked with inductive heads due to the sensitivity of the MR and

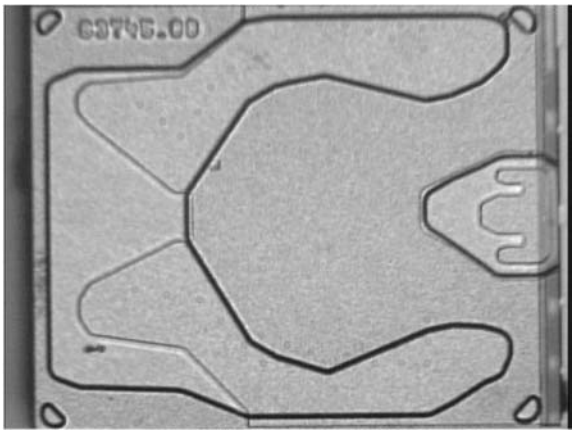

*Figure 6*
Negative-pressure air bearing (courtesy of Seagate Technology, LLC).

GMR heads to contact problems such as electrostatic discharge (ESD) and thermal noise due to the contact with asperities on the disk surface.

Current air bearings are of the negative-pressure type and fly below 1 microinch (25 nm). A negative-pressure air bearing has regions of both above- and below-ambient pressure as shown in Fig. 6. The resultant pressure is positive and is balanced by the head load; however the negative-pressure air bearing has the advantage of being stiffer for the same load and being amenable to designs that are insensitive to changes in pressure (altitude) and velocity (radius). The increasingly smooth surfaces needed to facilitate these low flying heights have led to a resurgence of the load/unload concept due to the wear and stiction problems associated with two very flat surfaces in contact.

The complex shapes required for negative-pressure designs are created by photopatterning after the bar is cut from the slider. The cavities are formed by ion etching of the air-bearing surface.

To be useful in a disk drive, the slider must be mounted on a HGA and assembled into a positioner in the drive as shown in Fig. 7. Basic flexure design has not fundamentally changed since the early days of disk storage. They have become less stiff and apply smaller loads as the sliders have become smaller. The discrete wires of the early heads have given way to miniature flex circuits for connecting the head to the electronics.

The higher performance of tomorrow's drives has given rise to consideration of moving the critical front end electronics closer to the head itself and even integrating the electronics with the head on the slider. The ever-increasing number of tracks per inch (tpi) has resulted in much development on microactuator designs. These are structures which move the head a very small distance very quickly and significantly enhance the servo performance of the heads.

*Figure 7*
HGA head assembly (courtesy of Seagate Technology, LLC).

## 2. The Longitudinal Write Head

The simplest approximation to the write field from a ring head is the Karlqvist head equation published in 1954 (Karlqvist 1954) as shown in Fig. 8. It ignores the bulk of the head and concentrates on the gap area where a very high (infinite) permeability is assumed. The head is assumed to be infinitely wide, reducing the problem to two dimensions and the magnetic field in the gap region is assumed to be uniform.

In the limit of a very small gap, the equation reduces to

$$H_x = (H_g g/\pi)(y/x^2 + y^2)$$

$$H_y = (H_g g/\pi)(x/x^2 + y^2)$$

The field in the gap can be approximated by

$$H_g = (NI/g)E$$

where $E$ is the head efficiency and $I$ is the current in the coil. The head efficiency is a measure of how difficult it is to pass flux through the core of the head. The efficiency is dependent on the head material, head geometry and, if there is saturation, the right

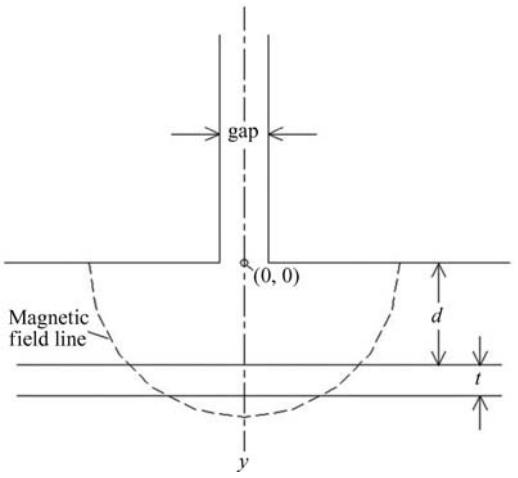

***Figure 8***
Karlqvist head.

current. In a good modern design, the write efficiency can vary from 40% to 80%.

The Karlqvist equation predicts that when the wavelength of the written signal, $\lambda = g/n$, where $n = 1, 2, 3, \ldots$, then the readback will be zero. This is called the gap null. It must be considered when using the inductive head to readback but no null is created when writing at gap null wavelengths. The Karlqvist equation is an approximation and more exact calculations show that the first gap null is at 1.136 g.

In a real inductive head the magnetic fields produced by the head are complex and difficult to model because of several factors including the complicated head geometry, the nonlinear magnetic materials, and the size of the calculation to do a full micromagnetic calculation.

The important parameters that a write head designer will consider are:

- The strength of the field at the media,
- The write-field gradient at the point where the transition is written,
- The off-track writing or fringing,
- The frequency response of the head.

The head designer using a standard thin film ring head has the following parameters to work with:

(i) The gap length can be adjusted and write field and gradient traded off against fringing.

(ii) The number of turns can be adjusted and inductance traded off against write current.

(iii) The yoke can be made shorter to gain better NLTS (nonlinear transition shift) and frequency response.

(iv) The frequency response can be increased by laminations, thinner poles, higher resistivity pole material, and materials with high-frequency permeability.

(v) The field and field gradient can be increased in the head by increasing the deep gap field using higher moment materials.

The design improvements in the head show a trend to heads moving to fewer turns, shorter yokes, and a tendency to run closer to the saturation of the pole tips. Actual saturation of the pole tips can lead to very undesirable nonlinear effects.

High-resistivity materials such as CoZrTa and CoZrNb have been used in poles or in the part of the pole close to the gap. Although these materials reduce eddy currents, they have a $B_s$ of only about 1.3 T so they can not produce the high fields of alternative materials. $B_s$ is the saturation magnification and is the highest magnetization that can be induced in a material. Laminated materials have been used to suppress eddy currents in the yokes of heads; however, they have not been widely used.

The materials used in head poles are moving to higher saturation moments with a common composition now being $Ni_{45}Fe_{55}$ ($B_s = 1.6$ T). These alloys are in common use and are deposited by electroplating. Sputtered alloys with higher moments such as FeNX (X = tantalum, aluminum, zirconium, etc.) ($B_s = 2.0$ T) and other alloys such as FeCoX (X = zirconium, niobium, boron) ($B_s = 2.2$ T), and FeCoNi ($B_s = 2.0$ T) are also known. High-moment materials are often used with other lower-moment materials in the pole tips as shown in Fig. 9. The high-moment material is placed closed to the gap where the high flux is needed. Lower-moment material guides the flux to the gap. Generally, the lower-moment materials such as Permalloy have superior soft properties to the higher-moment materials.

The maximum $B_s$ obtained in a bulk alloy is 2.4 T in $Fe_{65}Co_{35}$. Some materials have been reported with higher $B_s$ such as $Fe_{16}N_2$ but never in stable phases of

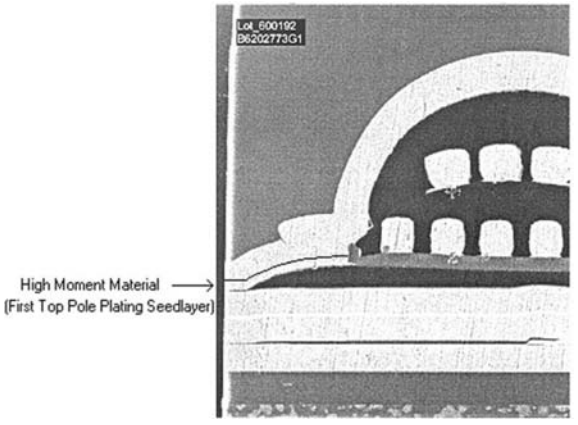

***Figure 9***
Dual-layer write head (courtesy of Seagate Technology, LLC).

enough material to make a pole. This lack of a soft material of high $B_s$ places a fundamental limit on how high a coercivity can be written. The coercivity, in turn, is directly related to the stability of the grains in the media and thus the $B_s$ of the pole material is one of the key factors in limiting the size of the grains in magnetic media.

Since smaller grains are required for higher signal-to-noise, the $B_s$ of the pole material limits the density of magnetic recording. Researchers continue to search for higher-moment materials that have adequate soft properties, are stable over the operating temperatures of the disk drive and the processing temperatures of head manufacture, and can be made in large enough pieces for pole fabrication.

## 3. *Perpendicular Write Heads*

The longitudinal heads discussed above are limited to a field of less than $2\pi\ M_s$ ($<1.2$ T for known materials) at the media. Perpendicular recording, on the other hand, can produce fields of almost $4\pi\ M_s$ (2.4 T) due to the more favorable geometry utilizing a soft underlayer (SUL) beneath the recording layer in the media. This is one of the main attractions of perpendicular magnetic recording.

Perpendicular recording utilizes a so-called pole head to write on the media as shown in Fig. 10. In this process, the vertical field from the head is used to write the media. In perpendicular recording, the SUL in the media is really part of the head flux path providing the return path for the flux from the head. As we approach the "superparamagnetic limit," taking into account thermal stability and SNR in a model with a number of simplifications, Bertram (1994) has shown that perpendicular recording can have a 4–5 times advantage in areal density over longitudinal.

While there are factors other than SNR and thermal stability that may affect the relative densities of perpendicular and longitudinal recording, there has been a reawakening of interest in perpendicular recording for high densities.

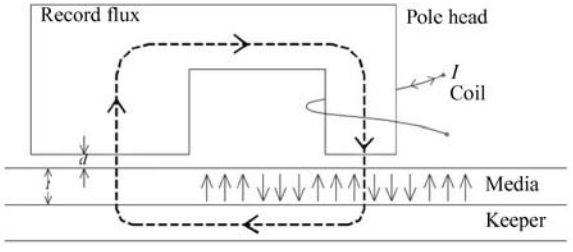

***Figure 10***
Perpendicular write head.

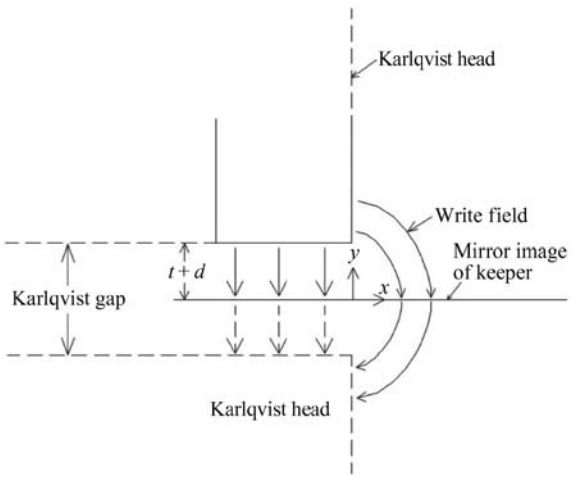

***Figure 11***
Karlqvist model for perpendicular.

The perpendicular recording head can be modeled by a Karlqvist head turned on its side as shown in Fig. 11. In this case, the field is given by

$$H_{\text{head}} = \frac{H_g}{\pi}\left[\tan^{-1}\left(\frac{d+t/2}{x}\right) + \tan^{-1}\left(\frac{d+3t/2}{x}\right)\right]$$

where $H_g$ is the deep gap field.

The considerations for designing a perpendicular write head are similar to those for a longitudinal. Frequency response can be improved by using lamination or using high-resistivity materials and by making the structure smaller. The write efficiency is generally higher in perpendicular heads so lower currents can be used for the same number of turns. Off-track writing is not affected by the gap and can be less than longitudinal in the ideal case. The fringing will, however, increase with increasing skew angle and this may be a problem for heads with finite-length pole tips. The SUL causes some unique problems since it provides the return path for the head flux and is part of the media.

Its orientation, permeability, and saturation magnetization are important. The SUL also extends far beyond the normal extent of a normal ring head and this requires careful treatment in models. The shape of the pole is important in preventing the pole from becoming magnetized when not being driven by the coil. Work in the past has also shown perpendicular heads to be more susceptible to the pick up of stray flux. Whether perpendicular recording will replace longitudinal at densities above 100 Gb/in$^2$ depends on overcoming these and other problems to realize the potential density increases promised by thermal stability and SNR considerations.

## *4. The Read Head*

In 1988, the giant magnetoresistive (GMR) effect was discovered by Baibich *et al*. (1988) in Fe/Cr multilayers (see *Giant Magnetoresistance*). In this effect layers, of ferromagnetic (FM) material alternate with layers of nonmagnetic metals. These structures exhibit a large change in resistance when switched from the low-resistance state, where the FM layers are parallel to each other, to a high-resistance state, where the layers are antiparallel.

There are two types of architecture of potential use in read-head geometry, the CIP (current in plane) and CPP (current perpendicular to the plane) as shown in Fig. 12. The vast majority of today's heads are in a simple two-layer CIP configuration referred to as a spin valve.

Spin valve heads (see *Magnetic Recording Systems: Spin Valves*) have separate read and write elements as shown in Fig. 4, which allows separate optimization of the read and write function as compared to the inductive only head. These heads are also much more sensitive to flux than inductive or the MR readers. An inductive-style writer is usually built on top of a magnetoresistive reader. As shown in Figs. 13 and 14 the GMR sensor consists of several layers.

In the bottom spin valve shown here there is a seed layer, an antiferromagnetic (AF) pinning layer that holds the pinned layer magnetization in a constant direction through exchange coupling with the pinning layer which has no net moment. Between the pinned layer and the free layer is a thin layer of copper. The free layer is free to rotate under an applied field as shown in Fig. 15. The structure is protected with a capping layer.

The change in voltage of the spin valve is given by

$$\Delta V = -\tfrac{1}{2} I \Delta R \sin\Theta$$

where $I$ is the bias current flowing through the sensor, $\Theta$ is the angle of rotation of the free layer wrt in its quiescent state and $\Delta R$ is the maximum change in resistance when the two layers change from parallel to antiparallel. The response of a spin valve to a transition on the disk is shown in Fig. 16.

In a real spin valve the magnetization is not uniform and the $\sin\Theta$ must be averaged over the active area of the spin valve.

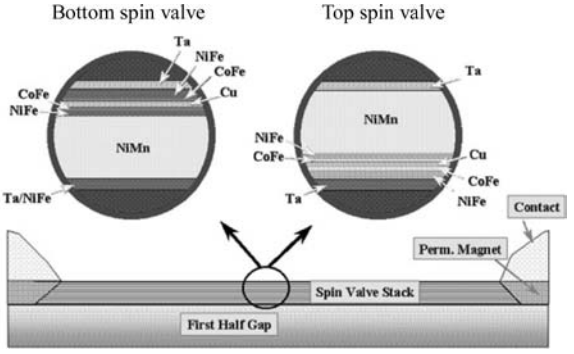

***Figure 13***
GMR spin valve sensor stack.

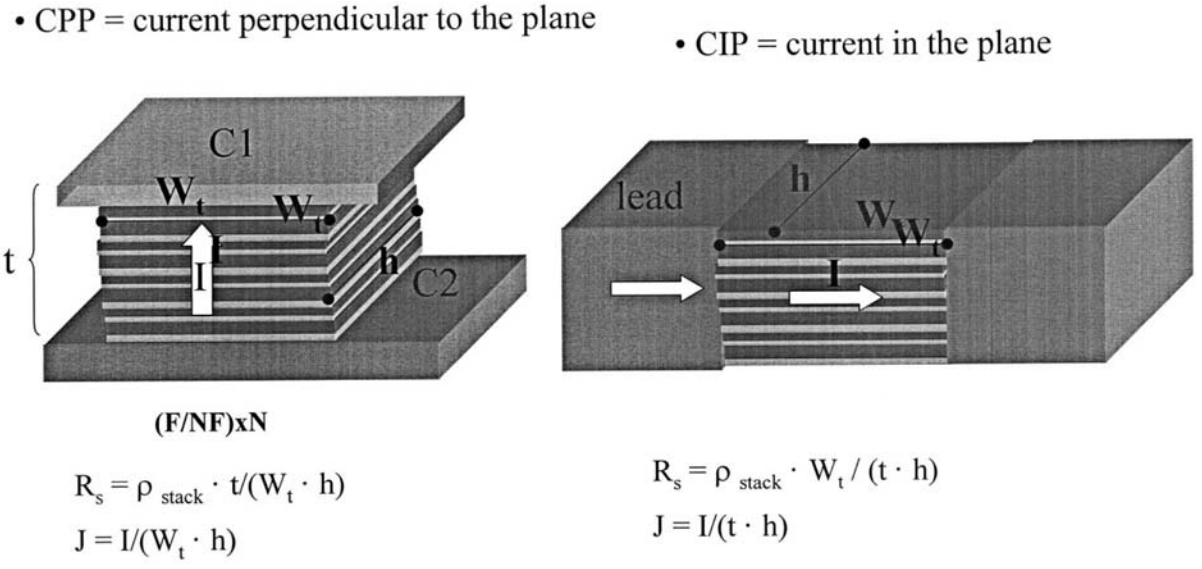

***Figure 12***
CPP and CIP geometries.

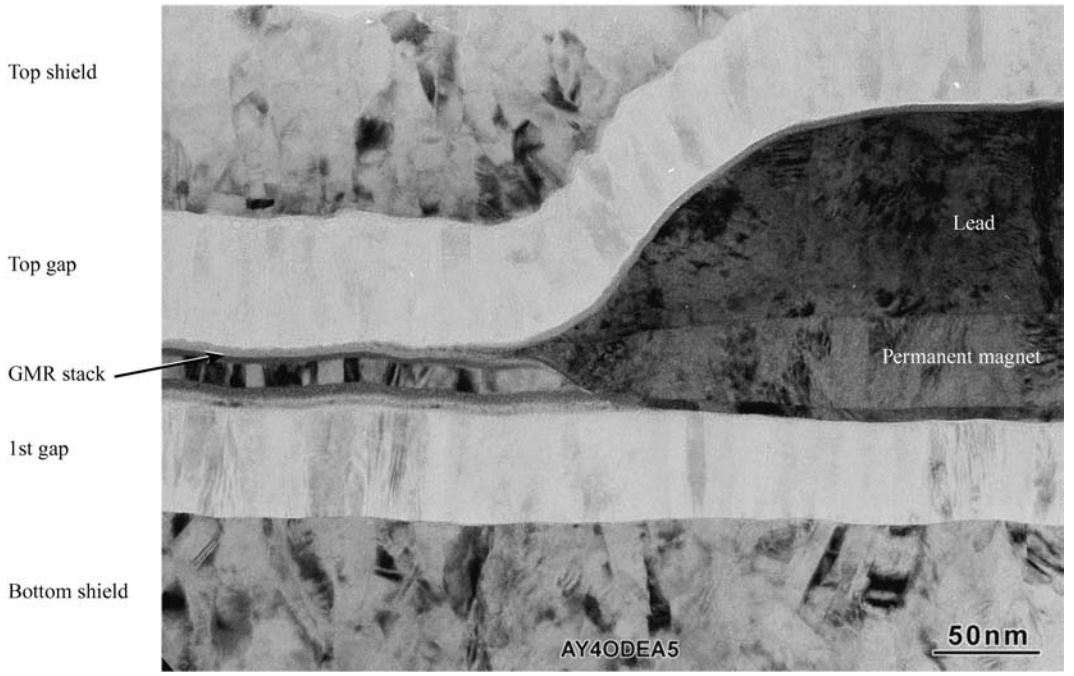

***Figure 14***
Cross section of a GMR reader (courtesy of Seagate Technology, LLC).

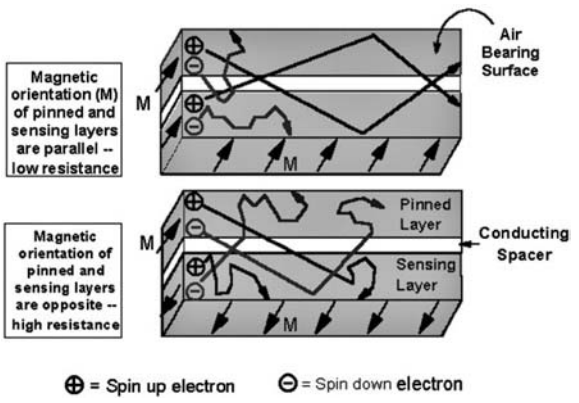

***Figure 15***
GMR sensor basics (courtesy of IBM Corporation).

$\Delta R/R$ values of over 20% have been observed in spin valves but values of 7–12% are typical of today's production. Typical sensor resistances are 40–50 Ω. Bias currents are typically about 5 mA. Output voltages of over 1 mV/μm have been achieved.

This spin valve structure is sandwiched between two insulating layers so that the device will not short. This structure is then placed between two soft magnetic layers called shields as shown in Fig. 14. These shields prevent the sensor from picking up flux from bits both down-track and up-track from the sensor and limit the pickup to the flux immediately under the device.

In order to remain stable under the operating conditions of disk drives, these heads require longitudinal stabilization, which keeps the magnetization in these devices more coherent and prevents the breakup into smaller domains. This function is served by attaching a permanent magnet structure (PM) to the sides of the GMR sensor and magnetizing it in a direction across the track. The PM is combined with a lead structure to bring the sense current to the device. The change in resistance is then typically read out as a change in voltage with a constant sense current.

In addition to the gap and track width, the height of the sensor is important. This is referred to as the stripe height and is accomplished by precision lapping of the sensor after it is cut from the wafer in the form of a bar. In order to precisely determine the stripe height, electronic lapping guides are formed simultaneously with the sensor and provide an exact reference to the back of the stripe.

The modern spin valve head is made up of several layers of very thin films (10–200 Å commonly) and small feature sizes (submicron track widths) (see Fig. 13). These sensors require ultraclean vacuum processing and thickness control better than 1 atomic

layer in many cases. Special precautions must be taken because of ESD (electrostatic discharge). Precise photo-processing and etch techniques are needed. In spite of these exacting requirements, spin valve heads are manufactured by the million using advanced manufacturing techniques unavailable before the end of the 1990s. It is the dominant sensor in magnetic recording.

In 1995 the concept of a head architecture using the shields as leads on the top and bottom of a sensor in the CPP mode was proposed (Rottmayer 1994, Rottmayer and Zhu 1995). This configuration can be used with both a CPP GMR multilayer or MTJ (magnetic tunnel junction) sensor.

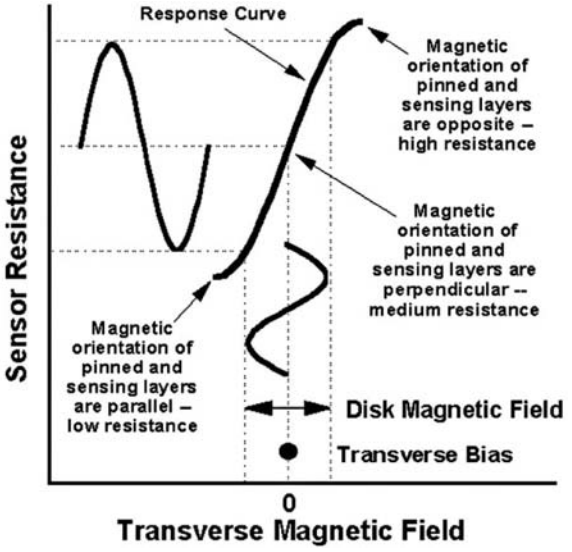

*Figure 16*
GMR sensor response to disk magnetic field (courtesy of IBM Corporation).

The CPP GMR head consists of a number of layer pairs of GMR material, e.g., copper/cobalt as shown in Fig. 17. The interlayer coupling across the copper is relatively small so that the coupling is primarily magnetostatic. The GMR $\Delta R/R$ is 2–4 times the $\Delta R/R$ in the CIP direction and can be as high as 100%. The device is placed between two shields, which also serve as leads. This confers a large degree of ESD protection since all parts of the device are at approximately the same potential.

A single bias magnet is placed behind the sensor. This is an advantage over the leads and magnets that must be attached to the sides of a spin valve head since it is much easier to fabricate and control track width. The CPP GMR is a low-impedance device having a resistance of only a few ohms even at densities of 100 Gb/in$^2$. This can result in a low signal amplitude. However, the CPP GMR has the advantages that its resistance increases with the square of the track width (TW) and so as densities increase, the resistance is in a more favorable range.

The MTJ device is made by sandwiching a thin insulating layer of alumina between two ferromagnetic metal layers, one of which is pinned as in a spin valve as shown in Fig. 18. Electrons can tunnel through the thin ($<2$ nm) barrier. Since they are spin-polarized, the current is larger when the magnetization of the two FM layers is parallel. $\Delta R/R$ ratios of more than 25% have been reported for MTJs.

In contrast to the CPP GMR head, the MTJ has a high resistance of about 1 k$\Omega$ at 100 Gb/in$^2$. The MTJ requires longitudinal stabilization with a magnetic field; however, this does not require that the magnet be in contact with the MTJ and so it enjoys the same advantages as the CPP GMR as far as ease of fabrication and track width definition. The thin barrier is

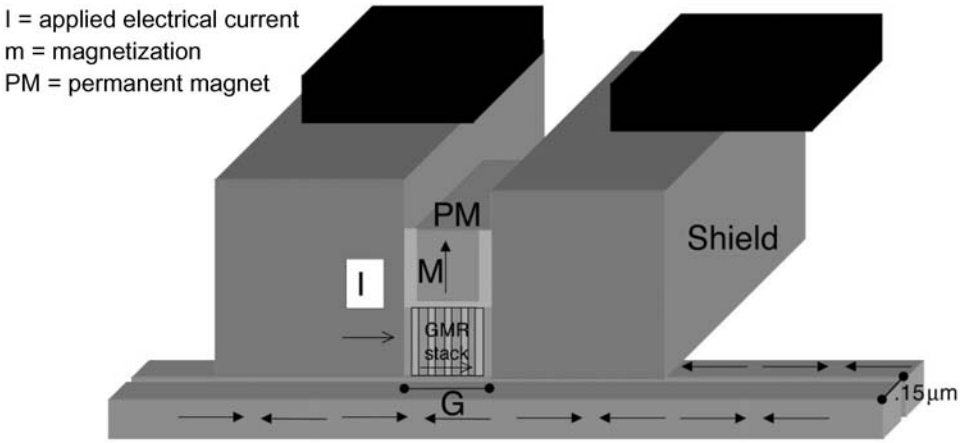

*Figure 17*
CPP GMR head (after Rottmayer and Zhu 1995).

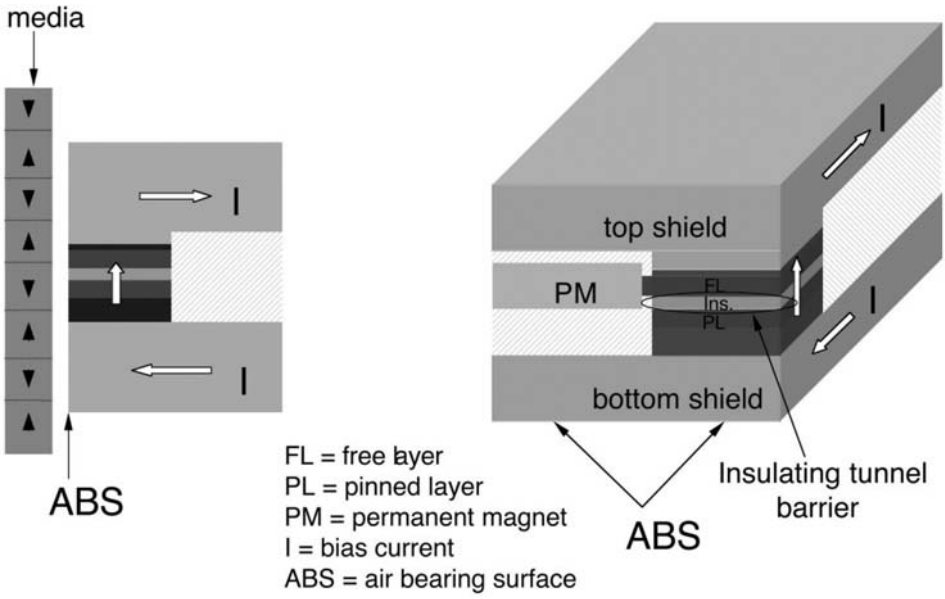

*Figure 18*

susceptible to ESD and this will be a challenge for use in disk drives.

## 5. *The Future of Magnetic Recording Heads*

Magnetic recording heads have answered the challenges of the data storage market place from the IBM Ramac (2.6 Kb/in.$^2$) to today's drives of approximately 20 Gb/in$^2$. This represents an increase in areal density of seven orders of magnitude in 45 years. This has been accomplished primarily by scaling—that is reducing the dimensions of the head, as the bits became smaller. The high leverage scaling parameters were the fly height, the gap length track width, and core size. In conjunction with this, scaling advances in materials also contributed. Most notable was the change from bulk-ferrite to thin-film magnetic materials and the development of GMR sensors for increased output. Semiconductor-like batch fabrication processes have reduced the costs while simultaneously improving performance. What does the future hold?

Head media spacing (HMS) continues to be a key parameter in increasing areal density. With today's fly heights close to 10 nm and an additional 5–7 nm of disk overcoat, head protection, and lubrication film, we are approaching a regime where we are getting close to the physical limits of the proximity of two materials. In addition, other considerations such as media thickness limit the advantage of lower fly height as we get into the nm region. So gains will be limited by HMS in the future.

In the area of head critical dimensions (CD), the acceleration of the areal density race has led to a convergence between the semiconductor line-width roadmap and the head-track-width roadmap. At the present rates of growth, the two curves will intersect early in the first decade of the twenty-first century. The head industry has traditionally relied on the semiconductor industry to develop the lithography equipment and processes.

If the track density of magnetic recording continues to outpace the line-width reduction of semiconductors then the head industry will no longer be able to depend solely on the semiconductor industry for its technology. However, there are lithographic technologies that can push track widths more than an order of magnitude from current production. There are also alternative architectures such as putting the transducer on the side of the slider and allowing the deposition thickness to determine the track width.

Gaps and sensor thicknesses are defined by deposition processes which can be extended to much higher areal densities. The most important problem at this time is thin insulating layers needed both for gap layers in SPV heads and for the tunnel barrier on MTJ heads. Both the rapid advances in deposition technology and the variety of alternative architectures mentioned above show great promise in extending head areal densities.

Sensor sensitivity can be extended by further improvement in SPV heads and the use of alternative technologies such as CPP GMR and MTJ heads. The frequency capability of the write head is now the

major problem in higher data rates. Improved materials, geometries, and architectures can extend frequency limits of the write head. The switching frequency of the head may be ultimately limited by ferromagnetic resonance in the head materials.

The biggest problem in recording-head design today is providing heads with the capability to write higher media coercivities and thus push back the superparamagnetic limit. Perpendicular recording with a soft underlayer can help overcome this problem. Also, thermally assisted magnetic recording can lower the coercivity of the media during writing thus enabling the writing of a pattern more stable at operating temperatures. Whatever the architecture used, the density can be extended by increasing the $B_s$ of the pole materials. Thus there is much active research on materials with $B_s > 2.4\,\mathrm{T}$. It is, however, not clear that such materials exist in a form suitable for head poles.

Even though magnetic recording is pushing some physical limits and certain fabrication limits mentioned above, there still exist many paths to increase areal density and data rates. Heads play a key role in both areas. With the many alternatives available to increase areal density and data rate, magnetic recording should continue to improve in performance with magnetic recording heads playing a key role.

## Magnetic Recording Materials: Tape Particles, Magnetic Properties

The basic principles of magnetic recording and information storage have remained unchanged for more than a century. The initial machines used steel wire as the recording medium, but in 1928 Pfleumer patented a paper tape coated with iron filings and a magnetophone using this tape was demonstrated in the 1935 Berlin exhibition. During the World War II, plastic tapes coated with magnetic particles were developed in Germany and since then the basic structure of the modern magnetic storage tape has remained unchanged. Certainly there have been innovations, improvements in performance and properties of the media, and a range of different formats and methods of storing the information, but the basic structure of magnetic particles embedded in a nonmagnetic matrix on a plastic substrate has remained the same.

When considering analog recording, it is not obvious what the fundamental properties of the magnetic medium should be. In all analog systems a linear relationship is required between the signal and the magnetization and this is usually achieved by a.c. bias to use the anhysteretic remanence properties of the magnetic components. The a.c. bias is superimposed on the signal in the case of analog audio systems, but is self biasing when frequency modulation is used in analog video recording.

The fundamental properties of the magnetic medium becomes more obvious when digital storage is considered. Here, information is stored as one of two states (in simple terms corresponding to the binary states of digital bits) and it is clear that the components used to make up the magnetic medium must also have two discrete magnetic states. If the medium is composed of particles, then these particles should be capable of being switched between two states with an easy axis which can be magnetized in either of two directions. These particles are single domain and ideally should have a square hysteresis loop. In addition, since the information must be stored indefinitely or until erased, the energy barrier between these two

states should be of sufficient height to prevent thermal decay of the information or accidental erasure.

Modern data systems require very high aerial densities of information to be written at very high rates. In order to accommodate the higher densities, there is a continual move towards thinner magnetic layers and to higher coercivitiy particles. For analog audio and video formats, magnetic layer thickness of several microns consisting of ferrite particles were adequate. For the latest advanced data storage tapes metal particles have replaced the earlier ferrites allowing coercivity to be pushed up to in excess of 2 kOe and magnetic layer thickness down to hundreds of nanometers.

Magnetic properties are also dependent on the time scale so that writing at high frequencies confronts the dynamic switching time of particles resulting in much higher coercivities than those involved in the long-term storage. This is becoming more of a problem as data rates increase. Time dependence of magnetization is, therefore, crucial to magnetic information storage properties at both ends of the time scale—at high frequencies the time to switch a particle is a limiting factor whereas for long-term archival of information, thermally activated decay of magnetization presents a problem. All these properties will be considered in this article.

## 1. Magnetization Reversal (the Origin of Coercivity)

### 1.1 Single Domain Particles

Bulk magnetic materials will divide up into domains. This has the effect of reducing the total magnetic energy contribution. However, because energy is associated with a domain wall, for small particles it is energetically preferable for the particle to remain as a single domain and, with the associated anisotropy resulting from the shape and the intrinsic crystal properties of the material, the single domain magnetization will lie in preferred directions. In the case of hexagonal or uniaxial anisotropy, there are two easy directions and the particle is said to have an easy axis. (See also *Magnets, Soft and Hard: Domains*, *Coercivity Mechanisms*.)

### 1.2 Coherent Reversal

The Stoner Wohlfarth model (Stoner and Wohlfarth 1948) was the first successful attempt to describe the hysteresis behavior of a particle. Although the predicted coercivity was much larger than that observed in experimental systems, the simplicity of the model allowed a mathematical description of the reversal and the model is still used as a means of describing particulate systems and is a good model for visualizing the reversal process. Stoner and Wohlfarth (1948) and Cullity (1972) provide a full description of the model. In the model, reversal is regarded as a coherent process where all the individual spins rotate in unison.

The particle moment is, therefore, single valued and can rotate relative to the particle axis. Crystal and shape anisotropy of the particle will determine the energy associated with different orientations of the particle moment and result in an energy barrier between minimum energy positions. For a uniaxial system, these energy minima are opposite each other and the system has a particle easy axis and, in the absence of an external magnetic field, the energy is a minimum when the moment is pointing along the axis or in the opposite direction. At an angle $\theta$, then the energy can be written approximately as

$$E = K_1 V \sin^2\theta \tag{1}$$

where $K_1$ is the anisotropy constant, $V$ is the particle volume, and $KV$ is the height of the energy barrier. Given the potential energy of interaction of the particle moment with an external field and expressing the anisotropy constant in terms of the anisotropy field as

$$K_1 = H_K M_s/2 \tag{2}$$

where $H_K$ is the anisotropy field and $M_s$ is the saturation magnetization of the particle, then the energy associated with the magnetic moment of the particle, $\mu$, in an applied field $H$ at an angle $\phi$ to the particle axis can be written as a 2D expression as

$$E = \mu[H_K \sin^2\theta/2 - H\cos(\theta-\phi)] \tag{3}$$

Visualizing the reversal process for different orientations of the particle is straightforward and a number of examples are shown in Fig. 1. Figure 1(a) shows the energy of a moment as a function of angle for various fields applied in the direction of the particle easy axis. Consider the moment at $\theta = 0$ in a field $H_K$. The moment will be in the energy minimum at A. As the field is reduced the moment will remain at $\theta = 0$ until $H = -H_K$ when the equilibrium position becomes unstable and thermal fluctuations will switch the moment direction to 180° at position B. It will remain in that direction until the field is increased to $+H_K$. Thus, the particles will exhibit a square hysteresis loop (Fig. 2). Figure 1(b) shows the case where the applied field is at 45° to the particle easy axis. At high positive fields the particle moment will lie along the field direction.

However, note that when the field has been reduced to $H_K$, the energy minimum at A has moved towards the easy axis direction. As the field is reduced further, the energy minimum becomes shallower and moves towards $\theta = 0$ and at $H \sim -0.5\,H_K$ it disappears so that the moment will switch to position B and then move towards the field direction as the field becomes

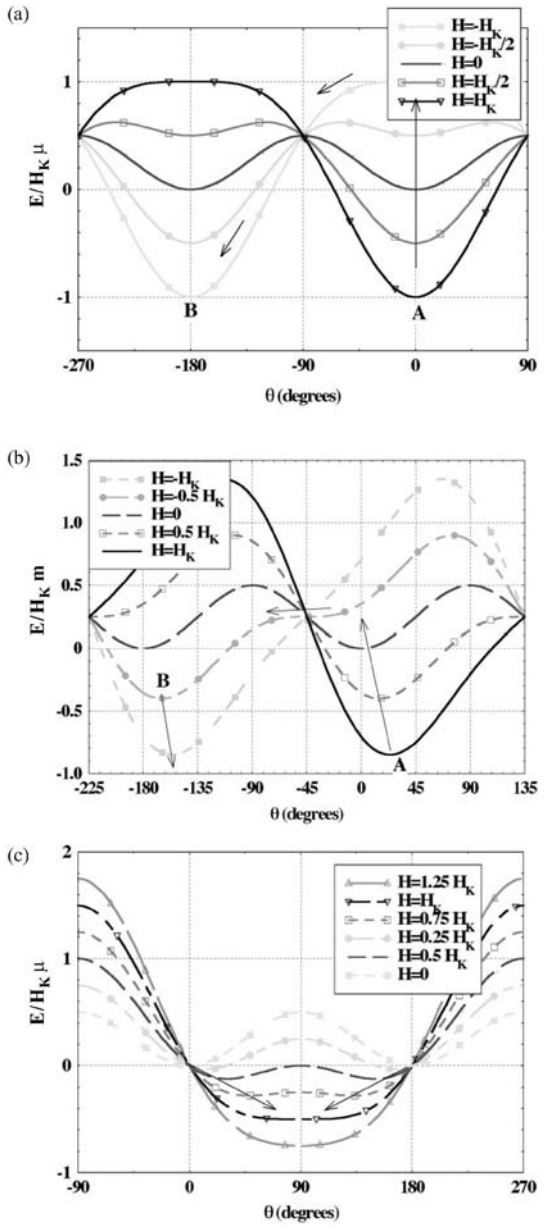

***Figure 1***
Energy of a particle moment as a function of angle to the easy axis direction when the magnetic field is applied in different directions: (a) along the easy axis, (b) at 45° to the easy axis, and (c) at right angles to the easy axis.

more negative. The whole process is reversed when the field change is in the positive direction and this produces a hysteresis loop with reversible, but field-dependent, magnetization at fields in excess of the

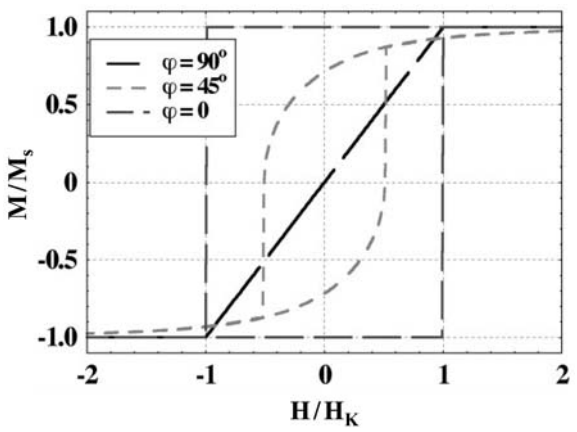

***Figure 2***
Hysteresis loops for a Stoner Wohlfarth particle for applied field directions of 0°, 45°, and 90° to the easy axis.

coercivity. Figure 1(c) shows the case when the field direction is at rights angles to the easy axis. In this case no switching occurs but the two energy minima merge to produce a single flat bottomed minimum at $H = H_K$. Hysteresis loops for all three conditions are shown in Fig. 2 obtained by a numerical solution of the Stoner Wohlfarth model.

### *1.3 Superparamagnetism*

The energy barrier to reversal is proportional to the particle volume so that as the size of the particle is reduced, the height of the barrier moves into the thermal regime when the particle moment can be switched by thermal energy alone and the time for reversal, $\tau$, is given by the Néel-Arrhenius law (Néel 1949):

$$T^{-1} = f_o \exp(-E_b/kT) \tag{4}$$

where $f_o$ is a frequency factor usually taken as $\sim 1 \times 10^9$, $k$ is Boltzmann's constant, and $E_b$ is the height of the energy barrier. The particle is then said to be superparamagnetic. The onset of superparamagnetism is not only dependent on the shape and size of the particle but is also related to saturation magnetization and the anisotropy constant.

### *1.4 Incoherent Reversal*

In practice, coherent reversal is only observed for very small particles and recording tape particles are sufficiently large that the normal reversal mode is incoherent. In this case, the energy is minimized during reversal by reducing the magneto-static energy

between individual spins through their misalignment. There are various simple models for this incoherent reversal and the two most commonly referred to are fanning and curling whose names graphically describe the particle motion during the reversal process.

### *1.5 Interaction Effects in Particle Systems*

In recording media, magnetic properties are determined by the mean behavior of all the particles in the system. Particles will have a range of volumes and shapes which will produce a distribution of switching properties. In addition, particle orientation will be spread around an axis determined by magnetic orientation along the tape during manufacture. These will produce a switching field distribution which is further modified by the magneto-static interactions between particles due to their close proximity and the long range of the dipole–dipole interaction. A study of single particle properties from optical observation of magnetic reversal of single particles and comparison of simulated magnetic tape properties with measured properties indicated a very large shift in the switching field distribution (McConochie *et al.* 1996). Figure 3 shows results for such a system in which the displacement of the switching field distribution due to interactions can be seen.

Because of interaction effects, the switching field distribution of a system varies between processes. In Fig. 4 switching field distributions for the isothermal remanent magnetization and the d.c. demagnetization processes are shown for a cobalt modified $\gamma$-$Fe_2O_3$ video tape. These curves are also referred to as the *irreversible susceptibility* curves because they are measured in the remanent state so that changes are only due to irreversible switching properties. These susceptibility distributions have been normalized so

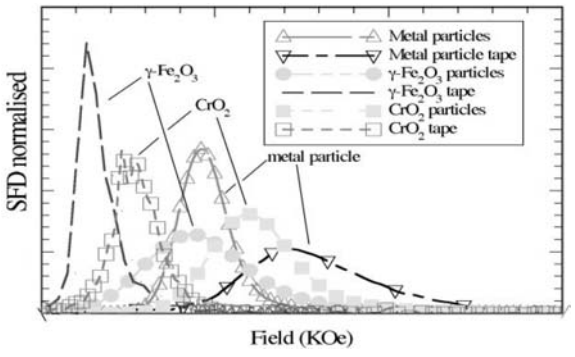

***Figure 3***
Switching field distributions simulated for an ensemble of tape particles and the measured switching field distribution showing the shift in properties produced by the interaction effects.

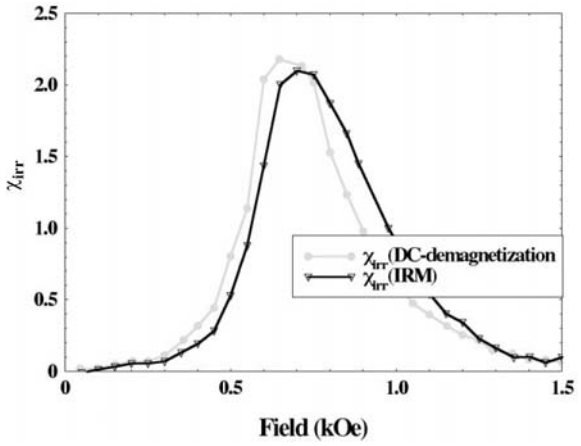

***Figure 4***
Switching field distributions for a cobalt-modified $\gamma$-$Fe_2O_3$ video tape measured for isothermal remanent magnetization and d.c.-demagnetization processes.

that the area under the curve is unity. Any magnetization state can then be represented by an integral of these distributions as

$$M(H) = \frac{\int_0^H \chi(H)\mathrm{d}H}{\int_0^\infty \chi(H)\mathrm{d}H} \tag{5}$$

where $\chi(H)$ is the susceptibility.

## *2. Time Dependence*

The previous discussion has been in terms of static properties of media. However, thermal activation can cause moments to switch over energy barriers and will produce time-dependent changes in magnetization. This was first investigated by Street and Woolley (1949) who observed a logarithmic decay as:

$$M = \text{const} - S\ln(t) \tag{6}$$

where $S$ is the magnetic viscosity coefficient and is dependent in the applied magnetic field (see *Magnetic Viscosity*). Although this relationship does not hold over very short and very long time scales, it is found to be applicable over several decades of time and gives a reasonable description of time-dependent behavior in most cases. The magnetic viscosity coefficient is field dependent and is related to the number of moments which are in an energy minimum within the thermal range.

Intuitively it would be expected that the maximum $S$ would occur close to the center of the switching field distribution (i.e., near to the coercive field) and that the variation of the viscosity coefficient would be closely related to the switching field distribution. This

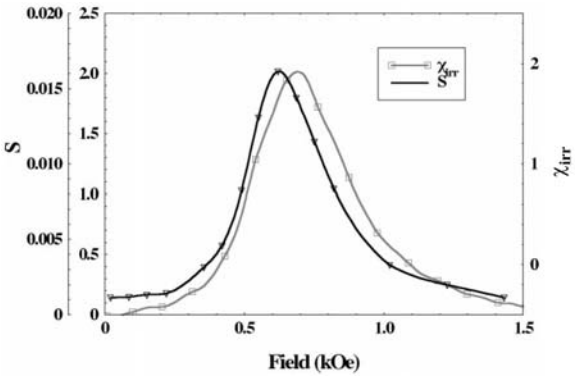

***Figure 5***
Variation of the magnetic viscosity coefficient for a cobalt-modified $\gamma$-$Fe_2O_3$ video tape showing the peak close to the coercive field value.

is indeed found to be the case and Fig. 5 shows the variation of $S$ with field along with $\chi_{irr}$ obtained from the d.c.-demagnetization curve for the cobalt $\gamma$-$Fe_2O_3$ video tape. Because of the intuitive link between $S$ and $\chi_{irr}$, Street and Woolley proposed a parameter called the *fluctuation field*, $H_f$ defined by:

$$S = \chi_{irr} H_f \tag{7}$$

The fluctuation field was associated with the concept of an activation volume, $V_{ac}$ by Wohlfarth (1984) where

$$H_f = \frac{kT}{V_{ac} I_s} \tag{8}$$

and $I_s$ is the saturation magnetization of the bulk material. The interpretation of the fluctuation field and activation volume is difficult as they do not relate to any physical media properties. However, the activation volume is often taken to represent the volume of the particle which is involved in the initial reversal process. This does seem to have some basis as activation volumes are generally smaller than the particle volume and can be considered as the volume of the region in which reversal is first propagated during an incoherent process. However, this is not always the case, and sometimes activation volume can exceed the particle volume which seems physically unreal.

### 3. Concluding Remarks

Intrinsic magnetic properties of tape particles and the recording process have remained unchanged throughout the history of magnetic recording. However, to accommodate the need for higher data densities and faster switching there has been a move to thinner magnetic layers and higher coercivity particles. The earlier ferrite particles are now being replaced by metal particles in the high density advanced data storage systems.

## Magnetic Recording Measurements

Magnetic recording devices use materials that exhibit spontaneous magnetization in their operating temperature range: ferromagnets and ferrimagnets (see *Magnetic Recording Technologies: Overview*). The magnetic properties of these materials can be classed into two categories: properties that are determined by composition and crystal structure, denoted intrinsic; and properties that depend on microstructural factors such as grain size and shape in a polycrystal, or particle shape and orientation in a composite, denoted extrinsic. Both intrinsic and extrinsic magnetic properties are functions of environmental factors such as electric and magnetic fields, temperature, pressure, and atmosphere.

The measurements described below depend on the scale on which they view the magnetic property to be measured. The microscopic scale focuses on a magnetic material as an arrangement of interacting atoms and interprets magnetic properties in terms of spin and orbital moments, energy levels, binding energies, spin–orbit, exchange, and superexchange

interactions, etc. The mesoscopic scale averages these microscopic interactions over small homogeneous regions (grains, particles) comprising many atoms. Averages over many such (interacting) regions constitute the macroscopic properties of the magnetic material.

An important consideration in measuring the magnetic properties of a material is its uniformity. Inhomogeneities may occur on the microscopic scale (point defects such as vacancies and interstitials, line and planar defects such as dislocations, or composition fluctuations in disordered alloys), on the mesoscopic scale (grain or particle clusters, voids, and segregations), and on the macroscopic scale, given the limits on quality control in fabrication.

## 1. General Measurements

In most instances, magnetic measurements described below are *extrinsic* measurements made by measuring a sample's response to an externally applied magnetic field. The measurements can depend on the sample's shape: the inhomogeneities and discontinuities of the magnetization in the sample's interior and on its surface are sources of a magnetostatic demagnetizing field that depends on the sample's shape and that affects the internal field. As the internal magnetization changes in response to applied fields, temperature, or time, the internal field will also change due to the changing demagnetizing fields. These fields can also be microstructure dependent because typical polycrystalline or particulate materials exhibit effects due to grain boundaries and particulate or grain orientation.

These measurements are also affected by the rate at which the magnetic field is changing (viscosity and eddy current effects) and how long it takes to make the measurements. Indeed, the magnetization of all materials will eventually seek the lowest energy state, if we wait long enough at any nonzero temperature. In the absence of an applied field this is always a state of demagnetization with zero net magnetization when summed over the whole sample volume, because such a demagnetized state minimizes the magnetostatic or dipolar self-energy. We conclude that the sample's coercivity, defined as the field that must be applied to a magnetized sample to reduce its magnetization to zero, is zero for infinite-time measurements! At the other end of the time scale we might try to coerce the spins in a magnetic material to change directions with a short field pulse.

We are concerned here with the magnetic properties of electron spins but, as the word implies, spins are associated with angular momentum, and exhibit the (quantum mechanical) inertial effects of angular momentum. Moreover, spins are usually coupled to each other and to their surroundings, and thus spin dynamics exhibits spring-like inertial and damping effects. Put another way, spins do not change instantaneously but take time to alter their direction. In general, if the magnetization is to be changed a given amount (say from a magnetized to a demagnetized state) in a shorter time, this will require a larger externally applied field. Measured coercivities are larger for shorter applied field times.

Measurements then need to be described by the applied field rates of change and are generally grouped in three regimes: slowly varying fields, quickly varying fields, and pulsed fields. The fields may be localized, uniform over large areas, or changing in space (field *gradients*). The measurements can interrogate a small region of a whole or an entire large sample. (See also *Magnetic Measurements: Quasistatic and ac*.)

### 1.1 Vibrating Sample Magnetometry

Developed in the late 1950s by S. Foner, the vibrating sample magnetometer (VSM) continues in widespread use for measuring magnetic properties of materials including thin films and particulate media. The basic technique involves a large-scale applied field, using an electromagnet to immerse an entire small sample in a nearly uniform field (Fig. 1). The field is swept *slowly* (usually less than $\mathrm{mTs}^{-1}$) and the sample is moved (vibrated) in the applied field. As described previously, the magnetic sources associated with a sample's geometry and magnetization cause internal magnetostatic fields and of course external fringing fields. Inductive pick-up coils are placed in close proximity to the sample, inside the applied field, and sensed synchronously with the motion of the sample. The assumption is made that the external fields are proportional to the net internal magnetization (modified only by the geometry of the sample, i.e., its demagnetizing factor) but since this is a large-scale measurement, internal domain structure may affect the measurement.

### 1.2 AGFM

Another approach to generating macroscopic magnetic parameters is the alternating gradient force magnetometer (AGFM). Its salient feature is the ability to trace a major hysteresis loop in seconds rather than minutes as with a VSM.

### 1.3 a.c. Hysteresis Loop Measurement

If the interrogating magnetic field is applied rapidly and repetitively, usually at 60 Hz or 1 kHz, the sample's major hysteresis loop can be detected and traced synchronously. In this method, the sample is stationary and the field changes rapidly causing the magnetization and its resulting fringing field to change at the rate of the applied field. Differential inductive pickup coils are typically employed to sense these

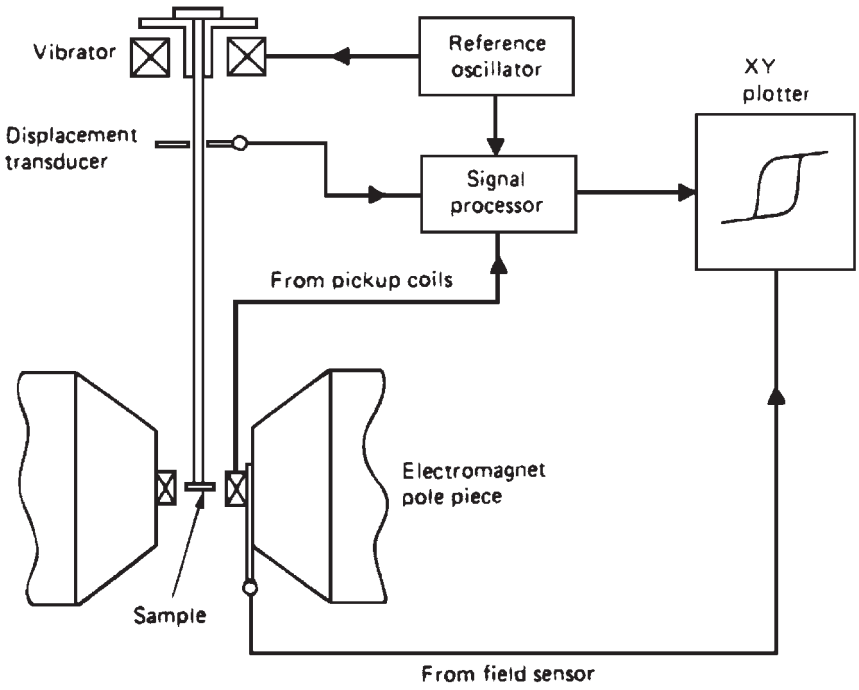

*Figure 1*
VSM illustration (schematic).

fringing fields and the average magnetization is assumed to be proportional to them. Measurements are made considerably faster than with a VSM. As discussed previously, these faster measurements can produce measured values of coercivity larger (by tens of percent) than those obtained from a more slowly varying VSM measurement.

### 1.4 Torque Magnetometry

If a sample's average magnetization is not aligned with an applied uniform magnetic field, a torque will be created on the sample through its magnetostatic energy (as described above) and its magnetocrystalline energy, the energy associated with the orientation of the spins relative to the material's crystal lattice. A material may have a preferred easy axis of magnetization, through a macroscopic shape, mesoscopic particulate or granular alignment, magnetocrystalline anisotropy, or other phenomena. To examine internal anisotropies, a large, static magnetic field is applied to a sample with uniform demagnetizing factors (ideally an ellipsoid of revolution). As the sample is rotated in this field, the magnetization does not completely align with the applied field because of its internal anisotropy. The resulting torque on the sample is measured and recorded as a function of sample rotation angle. A typical method includes suspending the sample on a torsional wire or glass fiber, and small torsional angles are measured optically using a reflecting mirror attached to the suspension and optical lever enhancement. These data can be used to determine the form (uniaxial, cubic, or other) of the anisotropy and its magnitude as a function of applied field.

### 1.5 Magneto-optical Measurement

Instead of measuring the external fringing fields and inferring the average magnetization from them, the samples may be probed optically. The Faraday or Kerr effects are incorporated into these systems and very small samples or small sample areas of larger samples can be examined. These magneto-optical methods utilize the interaction of light with a magnetic material (see *Magneto-optics: Inter- and Intraband Transitions, Microscopic Models of* ). The customary system measures the rotation of the plane of polarization or induced ellipticity of a light beam (often from a HeNe laser) as the linearly polarized light ray passes through (Faraday) or reflects off (Kerr) the sample. For the former, linearly polarized light passes through samples and the electric field of the light interacts with the transverse magnetization and induces an electric field orthogonal to both the planes of polarization and magnetization. This is

particularly effective for samples whose magnetization is collinear with the applied light. The rotation for magnetization parallel to the direction of propagation is opposite that for magnetization antiparallel to the propagation direction. To overcome the reduction in amplitude from material absorption, transparent materials or thin magnetic films need to be used for the Faraday measurement to be practical.

The Kerr effect employs a similar phenomenon associated with the interaction of the electric field with the sample's magnetization. The interaction induces a secondary electrical field that alters the light's initial polarization. In this technique, linearly polarized light is reflected from a magnetic material's surface. Since the angle of incidence is usually not normal, the *s*- and *p*-polarizations interact differently with the magnetization and by examining the rotation and ellipticity, in-plane and perpendicular (polar) magnetizations can be measured.

These magneto-optical measurements can be made at any speed with which the magnetization can be changed, from subnanoseconds to hours. The light can be spread to average large sample areas or focused to subdiffraction limited spots using near-field optics. Since microscopic measurements can be made rapidly, this technique is often employed to determine a sample's degree of uniformity.

### 1.6 Magnetoresistance Measurement

Transport properties of films used in magnetic recording for transducer applications are measured to predict device performance. Typically, the resistivity of unpatterned films of magnetoresistive materials is measured using a four-point probe technique. Typical four-point probes use an in-line geometry but magnetoresistance measurements are best done with a rectangular configuration with the current applied along the long side of the rectangle and the voltage measured along the other long side of the configuration. The measurements are made in a varying applied magnetic field. The output is normally expressed as the ratio of the difference of the resistivities measured with the magnetization along the current direction ($\rho_{\parallel}$) and transverse to it ($\rho_{\perp}$), to the average resistivity; i.e.,

$$\rho_{\text{ave}} = \frac{\rho_{\parallel} - \rho_{\perp}}{\frac{1}{3}\rho_{\parallel} + \frac{2}{3}\rho_{\perp}}$$

The field that saturates the film or device, the anisotropy field $H_k$, together with the magnetoresistance ratio, forms the figure of merit, or usefulness. The amount of resistance change *per applied field* is often the quantity of interest. A device having a 50% change in resistance at several tesla may not be as useful to a system as one that has a 2% resistance change at less than a millitesla.

### 1.7 Magnetostriction Measurement

As a sample's magnetization is changed the material may deform and similarly as a material is stressed the magnetization may be affected. This phenomenon of magnetostriction is important for magnetic recording media and transducer fabrication, since stresses developed in these materials during deposition or patterning, or temperature-induced stresses due to thermal expansion mismatches between materials including the substrate, can dramatically affect the properties and performance of the materials and devices. To measure these effects on films for magnetic recording applications, film samples are typically prepared on substrates that are not perfectly rigid. The sample is placed in uniform applied magnetic fields that cause the sample to bend due to differential strains of the film and substrate. These small bends can be measured effectively using optical reflection: the position of a light spot specularly reflected off the sample's surface is monitored as a function of applied field (see *Magnetoelasticity in Nanoscale Heterogeneous Materials*).

### 1.8 Electron Microscopy

Since the introduction of magnetic force microscopy (MFM, see below) using an electron beam for imaging magnetic structure has been rendered largely obsolete because of the difficult sample preparation necessitated by electron microscopy. To the extent that it is still used, magnetic contrast in the electron microscope can be classified into three categories: scanning electron microscope (SEM), Lorentz deflection microscopy in the transmission electron microscope (TEM), and electron holography.

There are two basic modes of magnetic contrast in the SEM, denoted as type I and type II magnetic contrast. In these modes, the electron beam interacts with the sample and the fringing magnetic field. Type I contrast comes from polar magnetization through Lorentz force effects on the secondary electrons. In one orientation, the Lorentz force will cause more electrons to drift toward the detector while the opposite magnetization will force the secondary electrons away from the detector. Type II contrast images in-plane magnetization when the sample is rotated along an axis collinear with the magnetization. This technique involves number contrast with the backscattered electrons. As the electrons come near the sample the Lorentz force due to the magnetization will cause more electrons go toward the sample for one orientation while the other magnetization direction will force the electrons out, away from the sample. For these electron beam techniques, samples need to be clean and conductive (to reduce charging) and are placed in a vacuum. Spatial resolution of 50 nm is readily achieved but a quantitative measure of magnetization is impossible to obtain.

Transmission imaging in the TEM uses Lorentz forces as the electron beam passes through the sample. This diffraction contrast method is sensitive to in-plane magnetization and uses a defocused electron beam image. Imaging domains and domain ripple are the premier application for TEM Lorentz microscopy. Since the beam needs to pass through the material, samples must be thin and conductive, and usual techniques for vacuum sample preparation need to be observed. Submicron spatial resolution for this method can be achieved but higher resolution imaging can be very difficult.

Electron holography uses the interference effects as some of the electrons pass through a perturbing fringing field. These fields may even be from a magnetized sample of an energized device such as a recording head. The Lorentz force causes the electron path, integrated along the field, to deflect it from its nominal path. (See also *Magnetic Materials: Transmission Electron Microscopy*.)

### *1.9 Magnetic Force Microscopy*

Developed from the 1986 Physics Nobel Prize winning development of the scanning tunneling microscope (STM), magnetic force microscopy (MFM) uses a small magnetic probe tip that scans over an area of a sample's surface. The tip first measures the sample's mechanical surface detail, then retraces the surface measuring the interaction between the magnetized tip and the fringing fields emanating from the sample's surface. In contrast with the original STM that requires a vacuum, MFM is typically performed in ambient conditions. As with most of the techniques described the measurement only senses the external fields. This necessarily means that the magnetization within the sample is not known directly and can only be inferred.

In a typical measurement, a micromachined cantilever with a pyramidal tip coated with a ferromagnetic film is vibrated at resonance (Fig. 2(a)). The fringing fields from the medium interact with the ferromagnetic tip shifting the tip's resonance. This frequency change is related to the strength and direction of the fringing field and the resolution is limited by the gradient of the magnetic field and the geometry of the tip. Quantitative MFM output is still being developed. The spatial resolution of this technique is currently about 30 nm. Images take several minutes to produce and are typically less than 100 micrometers square. The images are usually taken in remanence but techniques for making measurements at applied fields have been developed and are becoming widely used.

A striking example of the power of the method is shown in the image (Fig. 2(b)) of a track written on a longitudinal medium. The image displays not only the written bits and the transitions between them; it also shows the contrast between the d.c.-erased region on which the track was written, a region which is at remanence with its relatively uniform magnetization, and the surrounding demagnetized region, with its randomly magnetized and hence noisier grain structure. (See also *Magnetic Force Microscopy*.)

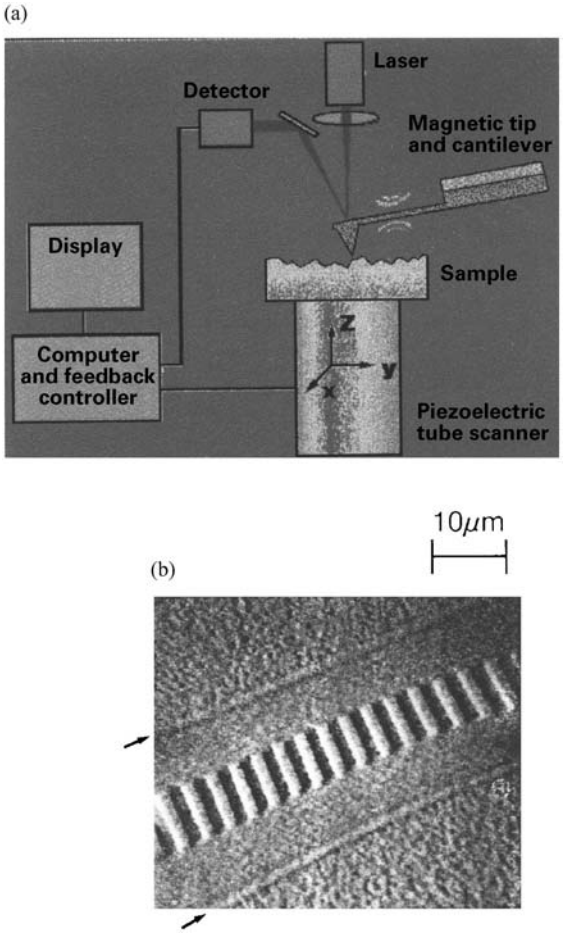

***Figure 2***
MFM illustration (schematic and typical output). (a) Schematic of a scanning probe microscope (MultiMode design). For magnetic imaging, the probe has a magnetic tip. The sample is moved in a raster pattern by the piezoelectric scanner, and the sample's stray fields cause shifts in the resonance of the cantilevered probe that are measured by laser detection. Phys.*, 1990, **68**, 1169).

## 2. General Recording

As a context for the application of magnetic measurement techniques to recording measurements, we begin with a brief outline of the various forms of the magnetic recording process. This context is necessary for an understanding of the relation between the measured macroscopic magnetic properties and the recorded signals. This includes such obvious relations as that between the amplitude of the signal and the remanence of the recording medium, or the medium coercivity and the demands on the saturation magnetization of the head, the less obvious effect of medium coercivity and saturation magnetization on the transition width in digital recording setting a bound on the bit cell size, and such subtle effects as the degree of intergrain exchange interaction on the noise properties of polycrystalline films.

### 2.1 Analog and Digital Recording

Analog recording still dominates consumer audio and video apparatus. In the standard audiotape cassette system, a carrier (called the a.c. bias) is amplitude modulated at the audio frequency and partially magnetizes a thick magnetic coating of the tape. The portion of the coating magnetized is linearly proportional to the audio signal. In the various video recording schemes, a frequency-modulated carrier saturates the tape, and the signal is recorded and detected in the zero crossings.

Digital magnetic recording is the standard in data storage and instrumentation recorders, is becoming so in professional audio and video recording, and has begun making inroads in consumer audio and video. In digital systems, the information is quantized and represented as a sequence of binary bits. The bits are recorded and sensed as transitions between saturated regions, usually along narrow tracks of magnetic tape or disk.

### 2.2 Anhysteretic Remanence

The media bearing magnetically recorded information are stored under ambient conditions. This means that their magnetic state is a remanent state from whatever magnetic history they have been subjected to, ordinarily not a state linearly related to the most recently experienced magnetic field. In saturation recording, the state is the conventional remanence, which is independent of the most recently experienced field, if that field was large enough. When linearity is required, as in analog audio recording, the linearity is provided by the a.c. bias field. In the presence of the bias field, the remanent magnetization is a function of the modulating field known as the anhysteretic remanence. The anhysteretic remanence curve is a linear function of the modulating field for small values of that field, and the linear range is largest for bias fields near the medium coercivity.

### 2.3 Erasure

The virtually universal practice in saturation recording is direct overwriting. The write head field is designed to have a value several times the medium coercivity, so that any previously written information is wiped out. Incomplete erasure of track edges does present some problems, which are addressed by methods (servo, coding) discussed elsewhere.

Erasure is an essential requirement in linear audio recording, where any existing recorded signal would not be completely overwritten by the new information. The standard practice is to provide the transducer with a separate erase head. This head has a wider gap than the write or read heads, so that its field is assured of penetrating through the full thickness of the medium. The erase can be either d.c. or a.c. In d.c. erase, a large steady head field leaves the medium saturated, obliterating any existing information. In a.c. erase, a large oscillating field is gradually reduced to zero, leaving the medium demagnetized. In practice, a.c. erasure is achieved with an oscillating field of constant amplitude; the decrease of the field occurs as the tape leaves the head region.

### 2.4 Tape and Disk

Tape and disk storage have kept pace with increases in density and speed. Magnetic tape is polyethylene tape coated with a magnetic particulate or film medium. Signals are recorded on tape in linear, helical, or transverse tracks. The tape is stored on reels or cassettes. Magnetic disks are flexible (diskettes) or rigid. Flexible disks are made of polyethylene, usually coated with a particulate magnetic medium, and enclosed in a protective package. Rigid disks are aluminum alloy or glass, now universally coated with continuous magnetic films. Information is recorded in circular tracks.

Tape has the advantage of low cost and small volume per stored bit; disk the advantage of rapid direct access. These properties—and the scope of the competing optical storage technologies—affect the application areas of tape and disk. Tape dominates archival digital storage, and audio and video magnetic recording. Disks—including such developments as redundant arrays of inexpensive disks (RAID) are ubiquitous in storage for computers.

### 2.5 Particulate Recording Media

The original (and long since obsolete) recording medium was a magnetized wire. This was replaced by a plastic tape or disk coated with a medium consisting of submicron size magnetic particles in an organic

binder. The commonly used particles are iron oxide or chromium oxide or a magnetic metal or alloy; they are too small to sustain domain walls and each particle therefore is approximately uniformly magnetized. The particles typically are of elongated shape, giving each particle a preferential magnetization axis; an alternative class of particulate media use submicron barium ferrite platelets that have a very large magnetocrystalline anisotropy that aligns their magnetization along the platelet normal. In all these media the particles are spatially distributed randomly, and they can be geometrically oriented during fabrication.

In operation, each magnetized region of a particulate medium must contain a large enough number of particles to keep the noise due to number fluctuations and anisotropy distribution in bounds.

### 2.6 *Film Media*

A disadvantage of particulate media is the presence of the binder which constitutes wasted nonmagnetic volume, and the difficulty of fabricating media with magnetic volume fractions exceeding 60–70%. The disadvantage is overcome by using polycrystalline oxide, ferrite, and especially metallic alloy films whose grains can occupy very nearly the entire film volume. This also means that the medium can effectively be a single layer of grains, thus considerably thinner than a typical particulate medium. Very thin media are ideally suited for high-density longitudinal recording.

A generally undesirable consequence of close proximity is the resulting exchange coupling of the grains that leads to magnetic clustering and results in increased noise. Various metallurgical procedures have been found capable of inducing grain boundary compositional segregation that reduces the coupling and improves noise performance.

### 2.7 *Longitudinal and Perpendicular Recording*

Information is recorded by magnetizing regions of the recording medium in opposite directions either in the plane of the planar medium (longitudinal recording) or normal to the plane (perpendicular recording) (see Fig. 3). The dominant recording technology is longitudinal, but it has been argued for several decades that perpendicular recording offers advantages that will lead to its widespread adoption as recording densities increase. Longitudinal recording is favored by circumstances of history and inertia; in-plane magnetization is favored by shape anisotropy in thin planar media; longitudinal write heads are simpler; and the information is stored in the form of magnetic poles with large fringing fields. This last advantage is also a central problem of the technology, because the demagnetizing fields associated with the poles become destabilizing at high recording densities. In perpendicular recording the magnetization direction is determined by the chosen magnetocrystalline anisotropy of the material. Its greatest advantage is that oppositely magnetized adjacent regions give rise to magnetic dipoles instead of poles, and the resulting demagnetizing fields are stabilizing.

### 2.8 *Keepered Media*

Keepered media are films in which a magnetically soft film (the keeper) is deposited under the recording medium, on the side opposite the head, or on top of the recording layer (in which case the recording is done through the keeper layer) (see Fig. 4). This device addresses two of the issues raised in Sect. 2.7. In a longitudinal medium the adjacent soft magnetic film provides a low reluctance path for the demagnetizing flux, shunting it out of the medium itself. In a perpendicular medium it provides a low reluctance

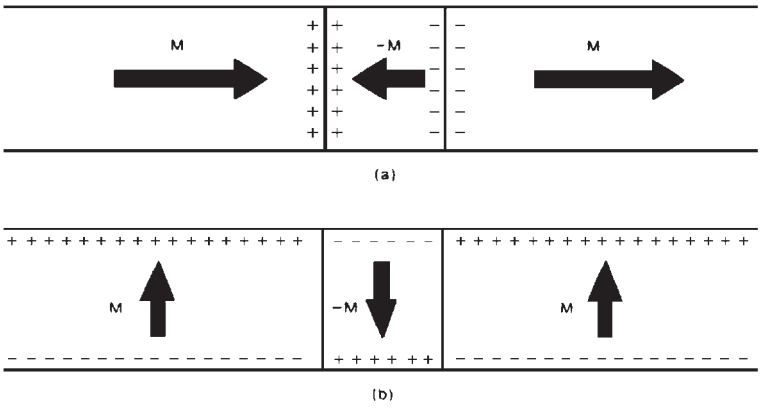

***Figure 3***
Longitudinal and perpendicular recording schematics (after Mee and Daniel 1990).

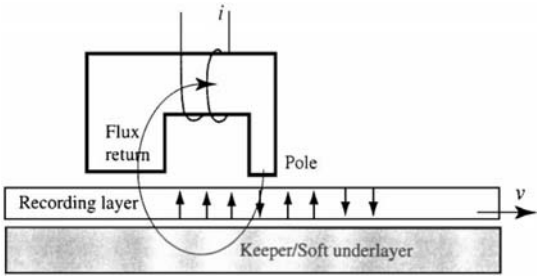

***Figure 4***

return path for the perpendicular component of the write head flux, effectively increasing the recording layer thickness.

## 3. Medium Measurements

### 3.1 Definitions and Measurements

*Magnetization* **M**: magnetic moment per unit volume, a vector quantity of magnitude $M$.

*Hysteresis loop*: a plot of magnetization $M$ as a function of magnetic field $H$ (Fig. 5). This is a multiple-valued function, depending on the sequence in which the time-varying field is applied. In the figure it is assumed that the measurement is made starting from a very large field in either direction.

*Saturation magnetization* $M_s$: strictly, the magnetization of a uniformly magnetized region (domain) in a homogeneous magnetic medium. This is an intrinsic property, a function of temperature, and weakly dependent on magnetic field and stress. In practice, $M_s$ is also used for the magnetization $M$ of any (not necessarily homogeneous) magnetic material in a large applied field.

*Remanence (or remanent magnetization)* $M_r$: the magnetization of a magnetic object that remains after it has been magnetized in a large applied field that is subsequently removed. Remanence is an extrinsic quantity that depends on microstructure, shape, and the phase of the moon (this last factor is meant to indicate the experimentalist's frustration with the sometimes apparently random fluctuations in the results of very carefully controlled measurements). A related quantity most meaningful for magnetic recording, especially with thin media, is the product of remanent magnetization and thickness $M_r t$. This quantity determines the magnetic moment associated with a bit cell of a given size, and thus the ability to detect it. $M_r t$ of a specimen of known area can be accurately measured in a VSM even if $M_r$ and $t$ are poorly determined.

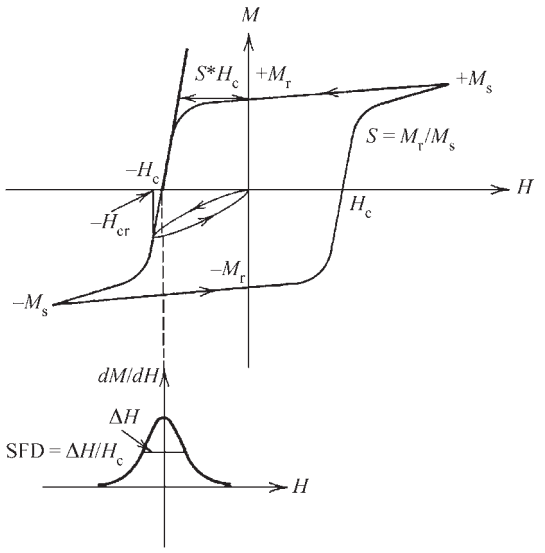

***Figure 5***
Schematic hysteresis loop (after Hoagland and Monson 1991).

*Remanence curve* $M_r(H)$: a plot of the sequence of final values of $M$ reached when a specimen is cycled as follows: saturation by a large applied field; application of a reversing field $H$ which is then reduced to zero; resaturation; and repetition with a different reversing field. On this curve, the remanence as defined above is $M_r(0)$.

The remanence curve of a specimen can be measured directly, for example in a VSM, by following this procedure, a time-consuming process. A fair approximation can be constructed from the hysteresis loop by drawing lines, with the slope of the loop at remanence, from the loop at several values of reversing field to the $M$-axis, and associating with each field value the value of $M$ at the intersection with the axis.

The remanence curve of a recording medium can also be measured nondestructively on a spin stand by measuring the output voltage from nonsaturating transitions.

*Coercivity* $H_c$: the value of reverse applied magnetic field required to reduce the magnetization from remanence to zero in the presence of the reversing field.

*Remanence coercivity* $H_{cr}$: the value of reverse applied magnetic field required to reduce the magnetization from remanence to zero after the reversing field has been turned off.

*Squareness*: a measure of the degree to which the shape of a hysteresis loop is approximated by a rectangle. Two measures of squareness are in common use: the remanence squareness $S = M_r/M_s$ which measures how close the top and bottom traces of

the loop are to a horizontal; and the coercive squareness $S^*$ (see Fig. 5) which measures how close the tangent to the loop at $H_c$ is to a vertical.

*Anisotropy energy*: energy associated with the direction of the vector magnetization **M** relative to a given set of axes. The energy is associated with the shape of the magnet and with its crystal structure. In an ellipsoidal body the shape anisotropy energy (extrinsic) is minimum when **M** lies along the longest principal axis, and higher when it lies along any other direction (for example, the magnetization of a magnetic needle tends to align along the needle, not across it). The magnetocrystalline anisotropy energy (intrinsic) $K_a$ is the energy per unit volume associated with the direction of **M** relative to the crystal axes. For example, in a uniaxial crystal such as cobalt, $K_a = K\sin^2\varphi$, where $K$ is the anisotropy constant and $\varphi$ is the angle relative to the c-axis.

*Anisotropy field* $H_k$: a magnetic field that represents the magnetocrystalline anisotropy in the form $\mathbf{K_a} = -\mathrm{M} \cdot \mathbf{H_k}$. In a uniaxial crystal, the magnitude of $H_k$ is $(2K/M_s)\sin 2\varphi$.

*Magnetostriction*: the deformation of a magnetic specimen when its magnetization **M** is varied and, conversely, the effect of a strain on **M**. The exchange and dipolar interaction energy of the atomic magnets on a crystal lattice depends on their orientation and on the bond lengths and bond angles. This energy can be represented as a magnetoelastic constant, an intrinsic property of the material, times the product of the strain tensor and the direction cosines of **M**. The equilibrium orientation and strain minimize the sum of the magnetoelastic energy, which is linear, and the elastic energy, which is quadratic in the strain (see also *Magnetoelastic Phenomena*).

*Magnetic viscosity S*: a measure of the thermally activated decay rate of the magnetization $M$. It is found experimentally that the magnetization of a magnetized body decays logarithmically over a wide range of time: $M(t) = M(0) - S\log t$. This behavior has been accounted for as being a summation of exponential Arrhenius type decays over a typical range of energy barriers. The viscosity $S$ is a property of the magnetic material that is a function of temperature and of the applied reversing field and it is generally maximum when the reversing field is equal to the coercivity (see *Magnetic Viscosity*).

*Grain size and size distribution*: the most widely used media in rigid disk recording are polycrystalline films thin enough to consist of a single layer of grains. Individual grains of these films are too small to support magnetic domain walls, and therefore are approximately homogeneously magnetized. Measurements of grain size can use transmission or scanning electron microscopy. The distribution of grain sizes can affect the switching field distribution and the thermal stability.

*Intergranular interactions, Henkel plots, and* $\delta M$: the grain size sets the ultimate limit on the switching unit and hence on storage density. However, intergranular interactions can couple the switching behavior of neighboring grains, and contribute to medium noise. Intergranular exchange coupling can lead to the formation of grain clusters; dipolar interactions can favor parallelism (in longitudinal media) and antiparallelism (in perpendicular media) of neighboring grains.

A measure of intergranular coupling can be obtained by the use of a Henkel plot or the equivalent $\delta M$ curve. The Henkel plot is generated by obtaining a curve named the isothermal remanent magnetization $M_{ri}(H)$. This curve is measured by the same procedure as $M_r(H)$ described above (in this context sometimes denoted $M_{rd}(H)$), except now the starting point of each cycle is a.c. demagnetization, with $M_{ri}(0) = 0$. It is easy to see that now, since initially half the switching units are already in the direction favored by the reversing field, only half as many will reverse with each field step. Thus one expects that $M_{rd}(H) = M_{ri}(\infty) - 2M_{ri}(H)$. This relation, however, only holds for non-interacting switching units, and deviations indicate the presence of intergranular coupling. The conventional form of representing the deviations is the Henkel plot, $M_{rd}(H)/M_{ri}(\infty) = 1 - 2M_{ri}(H)/M_{ri}(\infty) + \delta M(H)$, with $\delta M$ positive for interactions favoring parallelism, negative for antiparallelism.

The measurement can be carried out on a coupon of the medium in a VSM, or nondestructively on a spin stand by measuring the output voltages from transitions written on the medium in saturated and a.c. demagnetized states.

*Switching field distribution (SFD)*: the fraction of medium magnetization reversed per increment of reversing field range $\delta M/\delta H$. This is a function of $H$, peaking at or near $H_c$. SFD is also sometimes defined as the reversing field range required to reduce the magnetization of an initially saturated medium from $M_r/2$ to $-M_r/2$. SFD can be inferred from the remanence curve. It has also been measured by differencing MFM images and counting switching events.

*Time dependence of measurements*: the result of a measurement may depend on the time scale on which the measurement is carried out. The hysteresis loop of a specimen is usually measured on a VSM, on a time scale of minutes or hours, or on a *B–H* loop tracer, on a time scale of typically tens of milliseconds. Magnetization reversals in writing recording transitions take place in nanoseconds. As mentioned earlier, the medium response to a magnetic field is not instantaneous. Specifically, the coercivity of a medium depends on the time scale of the measurement, leading to the concept of a dynamic coercivity, which increases with the rate of field application. A phenomenological theory has been developed which is quite successful in accounting for such effects (Sharrock and Flanders 1990).

*Orientation ratio*: it is desirable in several media to have the magnetic properties along the track different from those across the track. For tape, the coercivity along the tape can be greater than that across it and for disks, the circumferential (recording direction) coercivity may be larger that the radial coercivity by tens of percent. This phenomenon is built into the material at the time of manufacture and can be controlled by the deposition conditions, especially angle of incidence and applied magnetic fields, or from anisotropy in the substrate, especially microscratching. The conventional measure of this is the ratio of the macroscopically measured recording to cross-track coercivities.

### 3.2 Head Measurements

The write head must generate enough flux to saturate the recording medium and must be able to operate at high enough frequency and/or with fast enough pulse response to satisfy the system requirements, and it must do these things with reasonable head efficiency and at low cost.

The earliest write heads were small electromagnets with high permeability ferromagnetic metal cores. They were satisfactory for low-frequency applications. The frequency response is limited by eddy current effects, which can be reduced by laminating the cores and pole pieces. This makes metal heads usable at high audio frequencies. Better performance at megahertz frequencies could be obtained by using high-resistivity ferrite cores. This sacrificed permeability and flux density for frequency and pulse response, but was satisfactory for writing on recording media whose coercivity was no higher than about a third of the ferrite's saturation magnetization, in the range of 1000 Oe. Ferrite heads continue to be used in video recording; these are typically single crystal structures fabricated by precision grinding, a relatively costly procedure.

Write heads for modern high-coercivity media are again fabricated from ferromagnetic metals and alloys, now in the form of high-moment, high-resistivity films thin enough to be resistant to eddy current losses. These heads, and the coils driving them, are fabricated as integrated structures by lithographic, deposition, and etching techniques similar to those used in the fabrication of integrated semiconductor circuits.

### 3.3 Write Head Fields

Most recording heads are inductive in nature: a soft ferromagnetic core is coupled to a conductive write coil (Figs. 6, 7). The current in the coil creates flux that flows through the magnetic pole pieces. Some of the flux squirts out of a gap in the magnetic circuit. This flux is used to magnetize regions of the magnetic

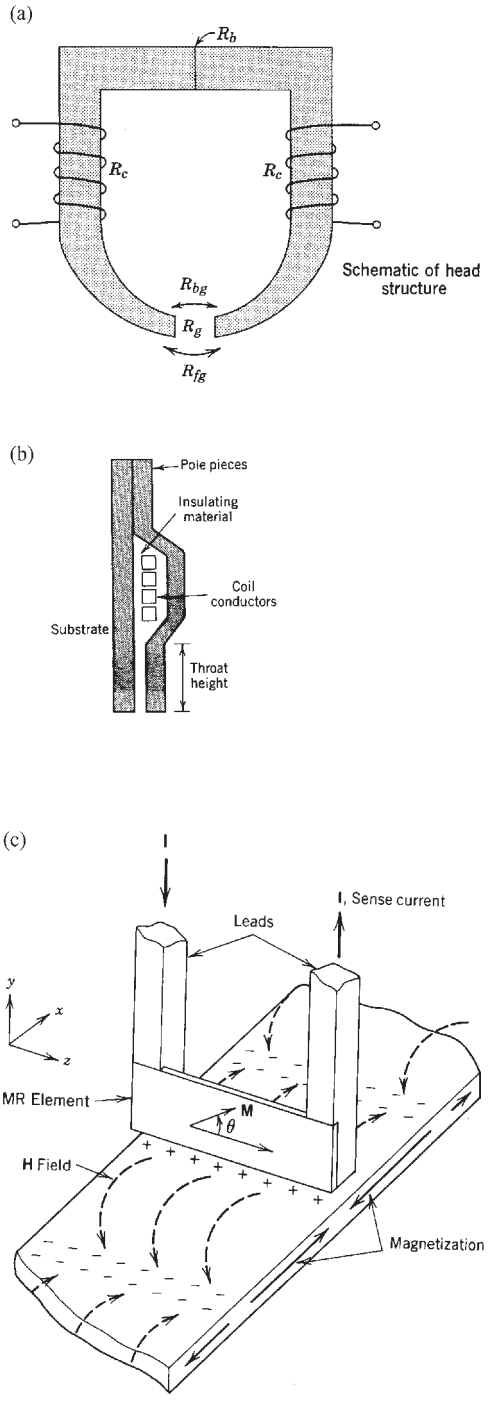

***Figure 6***
Recording head schematics: (a) ring-type head, (b) thin film-type head cross-section, (c) magnetoresistive (MR) head.

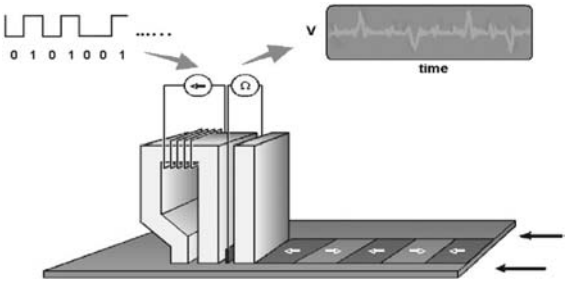

***Figure 7***
Recording schematic.

medium. The magnetic flux must be of sufficient strength to bring the magnetization to $M_r$. This field is typically much larger than the coercivity. A good rule of thumb is to supply a field about three to five times the medium's macroscopically quasistatically measured coercivity. To supply this large a field requires pole materials to have a very large effective permeability and saturation magnetization.

The pole piece saturation magnetization can be measured macroscopically in a variety of ways: VSM, a.c. hysteresis looper, etc. The effectiveness of the write field is verified easily through the saturation plot (see Sect. 4). The curve should reach and hold a maximum output, or even decrease slightly due to overwriting, for large currents. This indicates either that the medium is saturating or that the head pole material is saturating. If the head can write on higher coercivity media then saturation of the medium is differentiated from head saturation. Saturation of the pole material usually occurs first at the pole piece corners and where the coil couples with the poles. Once saturation is approached, the flux enhancement from the material's permeability is diminished.

The fabricated pole pieces typically have multi-domain structure. These domain structures can affect the writing process through speed, stability, and efficiency. Domains usually rotate faster than domain walls can move, so in multi-domain heads for high-speed applications it is desirable to have the walls pinned compelling the magnetization to rotate in response to applied fields. Domain wall jumps induce noise into the readback channel, even microseconds after writing. The direction and number of the domains also control the flux guiding property of the core.

The geometry of the writing field is controlled in large part by the geometry of the head pole pieces. The gap length controls the depth of the recording (of importance to particulate media but not for film media), the angle at which the medium sees the field, and the writing efficiency of the structure. During recording, the *gradient* of the write field is one of the most important metrics in defining good, sharply written transitions. Optimal head design attempts to have the maximum of the field gradient occur where the field equals the medium coercivity, which is where the transition is written. In addition, the gap defines the side writing; the field that fringes from the side, creating an effective erase band but potentially erasing previously written data.

The recording head in a rigid disk or high-end tape drive may be asked to switch at nanosecond rates to accommodate data transfer rates of hundreds of megabytes per second. As with media measurements (especially the dynamic coercivity) the high-frequency character of the switching of magnetization in magnetic head structures is critical to the success of the operation of the head. a.c. hysteresis looper measurements and conventional permeameters are not able to operate in the gigahertz range. The measurements of materials for use in heads are typically done with a pulsed frequency measurement. One method involves discharging a charged capacitive structure into a narrow stripline. The current through the line induces a magnetic field around it. The presence of a magnetic material will change the impedance of the pulsed stripline structure. Pulses can produce subnanosecond fields and reach fractions of a tesla. Sophisticated recording measurements can be carried out that can separate the write field rise time effects from other system effects.

An increasing number of read transducers are not inductive but flux-based sensors. The phenomenon used most often is magnetoresistivity. The material's magnetoresistance ratio, $\Delta R/R$, and the anisotropy, $H_k$, control the sensitivity and ultimately the figure of merit of these transducers.

These properties may be measured on the bulk films or in the patterned sensors as described above. Domain structures, demagnetizing fields, and stresses can have a tremendous effect on ultimate device performance so it is most meaningful, but usually more difficult, to measure the properties of the transducer itself.

An important issue with system performance of these devices is stability. The write field can affect the read transducer by changing the nominal state of the films and can induce noise through changing domain states of the write head long after the write current has ceased. A biasing field, from currents or magnetic materials, is used to assist in creating a known initial state and linearizing the output. The bias design point can be inferred from the magnetoresistance transfer character measured as described previously.

The read gap, the effective separation between the shields, is the dominant factor that controls the spatial resolution of a read head and, hence, its high-frequency performance. The physical gap is usually about 10% shorter than the gap inferred from magnetic recording measurements. Magnetically inactive inner surfaces account for this increase in effective gap.

The read width is largely controlled by the separation between the conductive leads, although some devices exhibit sensitivity to flux from the side, known as side reading. In general, a write-wide/read-narrow configuration is desired for overall device performance. This relaxes the tolerance for servoing during a read operation, but trades off some signal output.

Flying height, the distance between the head and the medium, is important to system performance since the output decreases exponentially with this separation. For rigid media, the head is designed with an air bearing to fly over the medium. The flying height may be measured optically, using a transparent head. As the separations are nominally less than the wavelength of visible light, broadband white light interferometry is used for this determination. Capacitive measurement can also provide the flying height if the medium is conductive and the head has some conductive contact area. Since the output varies exponentially, recording measurements can be made to infer the flying height as well. In most tape systems, contact between the head and medium is assumed but it is experimentally found that high-velocity tape drives have nonzero head–medium separations.

## 4. Recording Measurements

### 4.1 Introduction

The measurements discussed above concern properties and parameters that affect the performance of the recording system, and that are measured using a variety of instrumentation. Some parameters that impact performance are significant only in the context of recording, and can be carried out only in the recording system itself, on a spin stand or using the disk or tape drive itself. This section describes such measurements.

### 4.2 Saturation Plot

The measurement of the recording output (voltage amplitude) as a function of write current is the saturation plot. Initially the medium is demagnetized or in uniform remanence (from d.c. saturation). The recording head is used to apply the magnetic fields. The spatial field gradients are enormous and have a huge impact on the resulting magnetization in the medium. Very small amplitude applied fields will have no effect on whatever state the medium is in. As the applied field is increased through application of larger currents, more and more of the medium will respond, in part through the SFD. If a square wave signal is applied to the head as it moves relative to the medium, the magnetization will approximate this square wave remanence

### 4.3 Density Plot or Rolloff Curve

The rolloff curve is a measurement of the recording (voltage amplitude) output as a function of the recording density. For longitudinal recording, low densities have larger output amplitude than the higher densities. This is a consequence of demagnetizing effects and of the finite gap length. The internal demagnetizing field stresses the remanent magnetization for these densities more than in low-density recordings. This spreads transitions and reduces the magnetization, causing a reduction in the sensed output. The finite gap length also affects the output as a function of recording density. It was shown (Wallace 1951) that the output of a single-frequency sinusoidal recording varies as a sine function of density, with the ratio of wavelength to read head gap length as the argument of the sine. For digital recording, the output tracks this phenomenon as the fundamental of the square wave recorded signal. The nulls in the sine function (''gap-nulls'') correspond to an even number of transitions filling the length of the gap. $D_{70}$ or $D_{50}$, the density before the first gap null at which the readback output is 70% or 50% of the low density output, are typical design values for the maximum density in a system.

### 4.4 Read Head Linearity, Asymmetry, and Baseline Shift

Read head output, in particular MR transducers, are characterized by their linearity and asymmetry as well as their down-track and across-track spatial resolution. The head may respond differently to upward flux from a positive magnetic transition than from downward flux arising from a negative transition (asymmetry). The output may also not respond linearly to applied flux—a stronger flux may not produce a proportionately larger output. In addition, the level the output may reach after sensing a positive transition may be different from the level seen after a negative transition (baseline shift). These asymmetric and nonlinear effects may challenge the channel demodulation and degrade system BER (bit error rate, the fraction—before any error correction—of a misread zero or one) and performance.

### 4.5 Noise Spectrum

One measurement of the background system perturbations is the averaged noise power. This measurement may be taken with a spectrum analyzer providing measure of the noise power over a wide band of frequencies. The measurement can be made with the medium in d.c. remanence, a.c. demagnetized, or written with a very high-frequency signal that may approximate a.c. erasure. Note that this

measurement does not account for any signal dependence of the noise.

### *4.6 Signal-to-noise Ratio*

There are different ways of measuring a recording system's overall ability to reconstruct the written signal. In general, the system's ability to reproduce the written signal is proportional to the signal's amplitude with respect to the system's noise. It is assumed that the noise is independent of the signal and uniform over a broad frequency band (white Gaussian noise). A typical measurement of this metric is to record a single, moderate-valued frequency onto the medium, measure the signal's amplitude, and compare this output to the broadband noise. This noise may be measured from a medium that may have been erased with an a.c. or d.c. field, or may be written with a density beyond that which the system can reproduce. In a system characterized by Gaussian noise, the performance in detecting a signal is determined by the signal-to-noise ratio (SNR). Thus, the raw bit error rate is then determined by the SNR.

### *4.7 NLTS*

When the transitions close in on one another their signal pulses begin also to overlap and interact, changing their perceived shape. For moderate recording densities, the pulses can be represented as the linear superposition of two independent pulses. Such linear phenomena are usually easy to characterize and can be effectively removed through pre- and post-compensation techniques. As the transitions move closer together, their output can no longer be represented as the linear superposition of independent pulses. This phenomenon, usually referred to as nonlinear transition shift (NLTS), may be due to magnetic interactions of one transition with another and erasure of the magnetization between the transitions, and may be caused by a combination of the writing process of the transitions and of effects after the transitions have been written. The measurement of this effect can be done in several ways: writing and reading series of di-bits, using a pseudo-random binary sequence, or measuring noise as a function of recording density of a single tone.

### *4.8 Track Profile and Bathtub*

The ability to recover data is sensitive to the system's ability to remain on the data track during the time the transducer is reading the data. The measurement of track misalignment or track misregistration (TMR) is ever more challenging as the tracks become narrower. From a system viewpoint, the percentage of error allowed for TMR remains relatively constant. In general the head is not constantly being kept on track but servoed intermittently for a short time and then allowed to run freely. The track profile is generally plotted as the track averaged output amplitude as a function of the distance off track. If the source for the read signal were a very narrow track the curve would trace out the read sensitivity function of the head: insensitive to signals far off to either side; increasing as the source comes closer to the head; and uniform as the source moves across the read head's width (provided that the sensor's configuration is symmetric).

Such a "micro-track" can be approximated by writing a full width track and erasing all but a very narrow region of the track. If the bit error rate is measured and plotted as a function of distance off track, the error would increase as the head moves from the track center. When plotted with the vertical axis as the log of the BER and the abscissa as a linear function off-track, the resulting curve resembles a bathtub. The base of this curve with the lowest BER (lowest probability of error) will be relatively flat for a small distance and rise along the edges as the read transducer moves further from the track center. The upper edge of the curve (bathtub edge) will be reached when the signal can no longer be determined, when the read head is completely off the written track (and cannot even read the signals from its edge).

The measured track profile includes both the read sensitivity and its width as well as the write head's write width. Typical head configurations using a magnetoresistive head for read along with an inductive writer are designed so that the written track is wider than the reader's sense width. This "write-wide/read-narrow" configuration trades off some read signal (since not all of the written magnetization's flux enters the head) for more robust tracking—the head can wander from the track-center and still be reading over the original track.

### *4.9 Squeeze and 747*

These measurements are aimed at measuring the system's ability to reproduce recorded data in the presence of other information in adjacent tracks. After a test track has been written, adjacent tracks are written on both sides of the test track. The head is returned to the test rack center and the original data are read. Squeeze is measured as the adjacent tracks are moved in from afar. Initially the tracks have no effect, but will increasingly perturb the readback signal as they are brought in contact with the test track and then overwrite it. Eventually the test track will not be recoverable. This curve has a form something like the right side of a v-shaped valley. Due to the symmetrical approach from both sides of the over-writing tracks, it makes sense to plot only positive values.

In a more elaborate and more closely recording-like test, *old information* data tracks are first laid

down so that they extend (beyond, underneath) to the right and left of the test track (which overwrites a portion of the old information tracks). This is the worst-case situation for direct overwriting. The ''747-curve'' is formed as this situation is further aggravated by squeezing overwritten tracks into this situation and the original signal is measured with the head moved back on-track. Initially, when the squeeze tracks are far from the test track, no changes in the output are observed. When the squeeze tracks approach the test track, just enough so the edge of the head's erase band erases the old information but does NOT erase any part of the test track, the test signal becomes *easier* to read since all of the old information has been erased and the newly written signal is at least an erase-band's distance away. The system's off-track capability (OTC), or track misregistration (TMR) allowed to obtain a fixed BER increases slightly, proportional to the erase band of the write head. As the tracks squeeze in further, they begin to overwrite the test track reducing the OTC. These data, when plotted, modify the v-shaped valley as seen with a simple squeeze test by adding a mound to the top edge of the valley. This shape resembles the side view of a Boeing 747 aircraft: the nose rises to the hump of the cockpit that rolls off and levels out well above nose-level.

### *4.10 Write Width, Read Width, Side Reading, Side Writing*

The physical, patterned dimensions of the head are usually not equal to the precise read and write widths as determined using recording measurements. The effects of all of these parameters are seen in any usual recording system. The read and write widths are typically wider than those measured optically. Most write elements produce fields along the edge of the head that tend to degrade or erase old information a fraction of a gap length. This effect may provide a system with a natural guardband. Likewise the reader senses flux arising from beyond the side of the head.

### *4.11 Pulse Shape*

The shape of the voltage output is the product of the read head sensitivity function and the fringing magnetic field. The medium's magnetization controls only a part of the output pulse shape and the head's spatial extent determines the rest. The write field gradient, the medium's switching field distribution, and the demagnetizing fields at the transitions determine the sharpness of the magnetization through the transition and hence the spatial distribution of the external flux. The read head gap and the flying height define the spatial sensitivity of the sensor, analogous to the determination of spot size and resolution by the aperture in a classical optical system. The pulse shape in space determines the resolvability of a signal consisting of a set of pulses arising from closely spaced magnetic transitions. If the pulse is broad, the pulses will need to be spaced farther apart if the system is to recover the signal, as compared to a pulse whose amplitude is the same but whose width is narrower. The measurement of an isolated pulse's width is usually denoted by the width at half the amplitude height and designated as $PW_{50}$.

### *4.12 Jitter*

The most critical effect in determining a digital, saturation recording system's ability to recover information is the timing of the transitions. The *mis*-placement of this timing is jitter. If the transitions could be placed and sensed with unlimited precision, the amount of information stored would be boundless. In real systems, a fraction of the bit cell, denoted as the timing window, is the interval when the transitions are allowed to occur in order to be counted. If a transition falls outside of this window a raw error will occur. The timing errors can come from electronics noise, magnetic noise in the head, or from the magnetic medium (in particular its microstructure), and can manifest itself during writing, reading, and in general both. A jitter measurement quantifies the statistics of this uncertainty. A simple measurement consists of writing a single frequency square wave onto the medium and building up the histogram of the timing errors of the readback signal.

### *4.13 Thermal Decay*

As areal recording densities steadily increase the size of the bit cells decrease proportionately. In order that the shrinking bit cells may contain sufficient grains to supply reasonable statistics, so that written signals can be easily recovered (conventionally at least hundreds of grains), grain size must shrink to accommodate these needs. The stability of the grain is a function of the volume of the grain. Thermal energy becomes comparable to the magnetic stabilization energy with grain sizes near the regime where the atoms are readily countable, roughly 100 Å on a side. In this superparamagnetic regime, the grain remains magnetized but the direction of its magnetization is changed by thermal agitation. In a recording system, this change in magnetization direction results in degradation of a recorded signal. Since this is a thermal effect, time as well as temperature is a determining factor of the amount of signal lost. Assuming Arrhenius behavior, an assembly of non-interacting particles, each having the same activation energy, displays an exponential decay of magnetization with time. A collection of non-interacting particles with a wide, uniform distribution of activation energies exhibits logarithmic time decay. Many conventional

recording media can be approximated by such a model. If a recording is stressed in time by heat or applied fields, this manifests itself as decay in the signal sensed. If the track averaged output is plotted against the logarithm of time, nearly linear decay may result and can be used to predict the signal that will remain after a given time, for a given temperature, at a given recording density (whose demagnetizing fields act to reduce the stability of the grain's magnetization).

### *4.14 Imaging Internal to the Drive*

The scale of the magnetic features in a magnetic recording system can range from smaller than a single bit to many thousands of bits down-track or thousands of tracks wide. A millimeter long scratch, a thousandth of a millimeter wide, on a surface containing a million bits per square millimeter recorded with a bit aspect ratio of ten, may affect as many as ten thousand bits. Such a defect may be difficult to observe without taking the recording system apart. A sophisticated measurement that uses the read head as a probe of the surface and then plots the output from several adjacent tracks to build up a spatial picture of the surface can assist in the determination of systemic problems without having to disassemble the recording system. This type of functional imaging of the medium's surface can have resolution comparable to that of MFM and can be nondestructive.

## Magnetic Recording Media: Advanced

The development of advanced metal particle (AMP) media was initially driven by the need to match the performance of metal evaporated (ME) media in terms of areal data density and recording performance (output, frequency response, etc.). In this article, the term 'advanced MP media' is taken to mean a magnetic recording system containing a thin magnetic layer, an underlayer, a substrate, and a back coat. A schematic representation of such a system is shown in Fig. 1. The primary role of the back coat is to act as a conductive layer to disperse any static charge that may build up on the tape. The back coat will not be addressed in this article other than to say it consists of carbon black (graphitic carbon) particles dispersed in a binder matrix with a typical layer thickness of 0.5 μm.

The technological advantage of AMP media, initially introduced by Fuji Photo Film in 1992 (Shibata *et al*. 1992) with their Advanced Thin Layer High Output Metal Media (ATOMM) and subsequently adopted by many other magnetic media companies producing advanced data recording products, is a tribute to the technical excellence of the media manufacturers. Details of the exact processes used by the media manufacturers to obtain such uniform thin magnetic coating layers remains very much proprietary information.

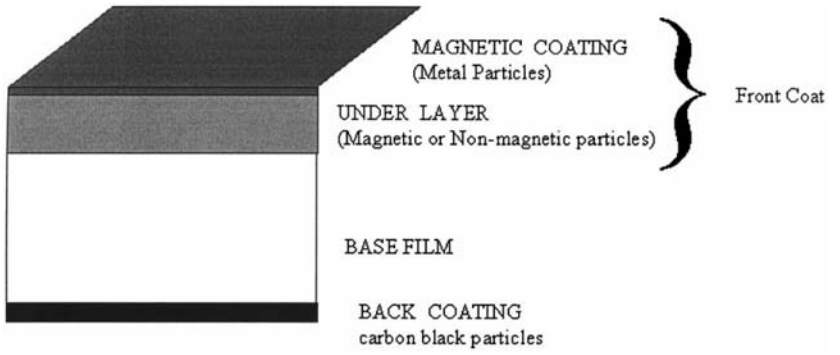

*Figure 1*
Schematic diagram of advanced MP media.

ATOMM technology is defined by the use of a dual layer front coating comprising a thin ($<0.25\,\mu m$) magnetic layer on top of a nonmagnetic underlayer ($<2.0\,\mu m$). The dual coat strategy confers the considerable advantages of reducing the surface roughness of the magnetic coating after post-coat calendering and improving the general durability of the media due to the design properties of the underlayer. Technological developments in the material science of metal particles, underlayer properties, and the substrate have contributed to the continued development of AMP media since the first introduction of a dual layer media product. The remainder of this article will address the development of each of these key areas, and address the impact of these developments on the recording performance of the system.

Schematic diagram of advanced metal particle.

## 1. Metal Particle Development

The manufacture of metal particles is highly proprietary within the very few companies that have large-scale production capability. The general technology trend for the particle manufacturers is to continually evolve and improve the properties of the metal particles to meet the requirements of a two-fold data capacity increase in AMP media every 2–3 years.

The first metal particles for digital data storage, developed in the mid-1980s, had a coercivity of approximately 1500 Oe ($119\,kAm^{-1}$), a particle length of 230 nm, aspect ratios of >10:1, and were based on a magnetic iron core protected by a passivating oxidation shell. Such a particle is shown schematically in Fig. 2. The corrosion resistance ($\Delta\sigma_s$) of these early metal particles, which measured the decrease in specific magnetization ($\sigma_s$), when subjected to 7 days storage at the environmental extremes of 60 °C and 90% relative humidity (RH), was typically around 20–25%. The loss of magnetic signal defined by $\Delta\sigma_s$ was initially a concern, as over time this corresponds to a reduction in the signal output from the tape. The early specialized surface treatments did manage to reduce this to <10%, but with a corresponding loss in $\sigma_s$ which compromised recording output of the media.

The incorporation of rare-earth elements in the protective oxidation shell improved the particle's corrosion resistance. The increased effectiveness of the outer shell in protecting the magnetic core from the degrading effects of oxidation allows a reduction in the average outer shell thickness. This reduction in the outer shell thickness increases the $\sigma_s$ value by allowing an increase in the ratio of the volume of the magnetic core to the volume of the oxidation shell. The use of magnetic alloys, using 10–30% weight ratio cobalt alloyed with iron as the magnetic core, has also allowed an increase in coercivity from 1500 Oe to 2400 Oe (119 to $191\,kAm^{-1}$) for large-scale production particles. Current AMP formats such as DDS-3 and DDS-4 media use metal particles with coercivities as high as 2300 Oe ($183\,kAm^{-1}$), particle lengths of <100 nm and aspect ratios from 4:1 to 5:1.

***Table 1***
Advanced media metal particle properties.

| Classification | Year | Particle length (nm) | Coercivity (Oe) | $\sigma_s$ (emu $g^{-1}$) | $\Delta\sigma_s$ | Particle volume ($nm^3$) |
|---|---|---|---|---|---|---|
| 1st MP data type particle | 1985 | 230 | 1500 | 122 | 20 | 49 000 |
| MP+ | 1989 | 170 | 1600 | 121 | 20 | 38 600 |
| MP++ AMP media | 1993 | 100 | 1850 | 130 | 12 | 24 000 |
| MP+++ AMP media High output | 1995–1998 | ~100 | 2300 | 150 | 10–15 | 21 000 |
| AMP media Low output | 1999 | ~75 | 2400 | 110–140 | ~20 | ~10 000 |

Metal particle manufacturing technology continues to advance at a pace that addresses the requirements of high output, low noise, and acceptable $\Delta\sigma_s$ for AMP media, Okamoto *et al.* (1996). Metal particles can be customized to meet the requirements of specific applications. The current high output types have a $\sigma_s$ of $\sim 150\,\text{emu}\,g^{-1}$ which is approximately 25% higher than the first metal particles introduced for digital data storage cartridges in the 1980s, such as DLTIII. This is achieved while maintaining or improving other important properties such as $\Delta\sigma_s$. The very latest metal particle types have also been reported to have particle lengths in the range of 40–60 nm to meet the requirements for low noise applications. Table 1 illustrates the evolution of the metal particle since the introduction in the 1980s to the AMP media applications.

The advantages of higher coercivity, smaller particle size, and increased $\sigma_s$ gave considerable advantages in recording density and output. For example, a 'state of the art' single-coated MP data cartridge (DLTIII) of 1989 had a storage capacity of 10 GB and a transfer rate of $1.5\,\text{MBs}^{-1}$. This compares to a year 2000 data cartridge with 100 GB and transfer rate of $\sim 15\,\text{MBs}^{-1}$. As the flexible media recording industry moves to recording systems using magnetoresistive (MR) head technologies the demand for high-output metal particles is being replaced by the need for lower noise systems, i.e., smaller particles with better dispersion properties.

As the particle size continues to reduce it becomes more difficult to maintain the coercivity and narrow switching field distribution of acicular particles, which depend upon shape anisotropy for their coercivity. The need for maintaining the higher coercivity and narrow switching field distribution of particles in the sub-30 nm size range have led researchers to investigate nano-sized spherical particles, which depend upon crystalline anisotropy for their coercivity. Examples of these spherical nano-particles, with particle sizes of less than 20 nm, are FePt based particles (Hattori 2004) and iron-nitride based particles (Sasaki 2005).

## 2. *Underlayer Technologies*

The role of the underlayer is a crucial one for both the recording and tribological properties of AMP media. It is the underlayer in the dual coating process, which allows for the uniform thin, smooth magnetic coating required for the improved recording performance.

Saitoh *et al.* (1995) suggested that the role of the underlayer is to realize advantages in durability by replenishing the surface with lubricant from the underlayer. The head/media contact can also be adjusted by controlling the physical properties of the underlayer, and conductive agents in the underlayer can be used to control the electrical properties of the film. Initially the underlayer comprised of small, spherical $TiO_2$ particles to meet the required mechanical and durability properties. Saitoh *et al.* (1995) reported significant improvements in recording performance for the dual layer system compared to conventional single layer media.

The role of the underlayer was confirmed (Sasaki *et al.* 1997) and it was further reported that the friction coefficient of the dual layer tape could be lower than that of a single layer tape despite having a lower surface roughness. More recently, advanced nonspherical particles (nonmagnetic) have been used to control the interface between the magnetic layer and the underlayer (Inaba *et al.* 1998). The reliability/durability of recording systems using AMP media has been reported (Maness and Bradshaw 2000).

The underlayer may also be used to play a direct role in the recording properties of the media. Magnetic particles have been used in the underlayer to modify the long wavelength recording properties and

to improve the ability of the system to overwrite lower frequency signals with higher frequency signals (Veitch *et al*. 1999).

## 3. Substrates

The material science of substrates, or base films, has evolved with the quest for increased storage capacity per unit volume. Increasing the media length by reducing the substrate thickness has immediate advantages for increased storage capacity, provided that the transportation mechanics of the drive can handle the thinner media and that the desired conformance to the head contour (for stable head/media separation) can be satisfied. The development of linear recording formats using multiple data channels for higher transfer rate applications has led to the need for advanced substrates with very stable dimensional properties (Richards and Sharrock 1998).

### 3.1 Dimensional Stability

Dimensional stability is defined as the percentage change in either the transverse or the longitudinal direction when subjected to changes in temperature (thermal) or relative humidity (hygroscopic).

Polyethylene teraphthalate (PET) was the substrate material of choice for many generations of data tape, ranging in thickness from 39 μm (1960s, 9 track) to 6.2 μm (mid-1990s DLT). To achieve a 6 μm thickness in PET suitable for AMP media requires extensive processing in terms of increasing the film stiffness in either the longitudinal or transverse direction. The film process known as *tensilization* induces an orientation dependent crystallinity and increases the mechanical stiffness (Young's modulus, creep, etc.). PET has a lower thickness limit of 6 μm and the demand for even thinner media and increased stiffness has been met by the introduction of substrate materials such as polyethylene naphthalate (PEN) and polyaramid (PA). Table 2 illustrates typical properties of AMP media substrates.

PEN and PA substrates have lower thermal and hygroscopic expansion coefficients than PET. This improves the dimensional stability when subjected to environmental extremes and is a key requirement for AMP multitrack, linear recording systems where the effects of thermal and hydroscopic expansion can cause a dimensional change both in the transverse and longitudinal direction of the substrate. For example, the transverse dimensional change has to be controlled within a tolerance that allows sufficiently accurate alignment of the recording heads with the data tracks across the operating environment of the system. This is particularly important for AMP media in a system such as LTO Ultrium, which has a total of 384 data tracks across the 12.65 mm tape width (Simmons 2000).

It can be calculated for this particular recording system that the transverse dimensional change must be limited to a maximum of 0.12% across the operating environment of the system (10–45 °C and 10–80% RH). The primary properties of the substrate are dictated by the chemistry of the substrate, but these can be influenced by the relative degree of tensilization in the longitudinal and transverse direction. This balance of tensilization, determined in the manufacturing process, is critically important in determining the final dimensional stability properties of the substrate. Table 3 illustrates the effect of tensilization on dimensional stability.

***Table 2***
Advanced media substrate properties.

| Property | PET (tensilized in M/D) | PEN | PA |
|---|---|---|---|
| Minimum thickness | | | |
| AMP media | 6.2 μm | 5.0 μm | 3.2 μm is commercially available |
| Creep: | | | |
| Load 28 MPa at 20 °C | 0.7% | 1.3% | 0.8% |
| Tear strength | | | |
| M/D | 350 $gmm^{-1}$ | 150 $gmm^{-1}$ | 200 $gmm^{-1}$ |
| Heat shrinkage | | | |
| M/D 100 °C, 30 min | 1.8% | 0.1% | 0% |
| Transverse dimensional stability | 0.13% | 0.09% | 0.1% |
| Young's modulus | | | |
| M/D | 7200 MPa | 7800 MPa | 11300 MPa |
| T/D | 5800 MPa | 8100 MPa | 14700 MPa |
| Typical application | DLT IV (1996) | LTO Ultrium (2000) | DDS-3 and DDS-4 (1997 and 1999) |

***Table 3***
Effect of substrate tensilization on dimensional stability.

| | | PEN Substrate | | |
|---|---|---|---|---|
| Classification | | MD tensilized | MD semi-tensilized | Balanced |
| Young's modulus ($kg\,mm^{-2}$) | MD[1] | 900 | 800 | 700 |
| | TD[2] | 600 | 650 | 730 |
| Dimensional stability to thermal and hydroscopic expansion | MD[1] | Very good | Good | Fair |
| | TD[2] | Fair | Good | Very good |

Note: MD = machine direction (longitudinal), TD = transverse direction.

### *3.2 Dual Surface Substrate*

The requirement for higher and higher recording densities on thinner substrates have led the substrate manufacturers to focus on making smoother substrate surfaces to allow for a reduction in underlayer thickness. This has resulted in substrate surface roughness ($R_a$) decreasing from $\sim 40$ nm (1970s audio/video tape) to $< 10$ nm for the current generation of AMP media. Surface roughness is controlled by the addition of organic and inorganic filler particles with a tightly controlled particle size distribution.

These filler particles create protrusions at the surface of the substrate and a defined surface roughness, which is primarily dictated by the filler particle size. Smoother substrates ultimately give improved recording properties but smoother substrates are more difficult to transport and guide through the media manufacturing process. This presents the dilemma of satisfying the competing requirements of reducing the surface roughness for optimum recording performance while maintaining the substrates handling properties, required for the media manufacturer to precisely control the tension and winding of the substrate during a complex multistage coating operation. The major substrate manufacturers have met this challenge with the development of dual surface substrates, using their proprietary technologies that allow both of these requirements to be met.

The dual layer substrate results in an extremely smooth substrate 'front coat' surface ($R_a = 4$ nm) and a rougher 'back coat' surface ($R_a = 9$ nm), which aids processability of the substrate at the media manufacturer. The use of dual layer substrates, in place of single layer substrates ($R_a = 6$ nm), may yield an output increase of up to 1.5 dB. AMP media products are beginning to migrate to the use of dual layer substrates for production of media with improved recording properties.

### *3.3 Other Substrate Properties*

Other important substrate properties include creep and physical properties such as Young's Modulus and tear strength when subjected to load and thermal stresses typical of those the media is subjected to during normal drive winding and search operations. These properties are dominated by the polymer type but can be influenced by the processing in the same way as the dimensional stability characteristics can be customized for a particular application.

In a competitive data storage environment the substrate cost is important and undoubtedly is increasing due to the complex and evolving technology of substrate design and manufacturing.

## *4. Concluding Remarks*

The combination of the key developments in all of these component (particles, substrate, and underlayers) technologies has enabled AMP media to match or exceed the recording performance of thin film (ME) tape media, and development continues at a rapid pace. The emergence of MR read and thin film write head technology in multitrack linear tape recording systems promises a long future of continued growth in AMP media and will require further development of smaller particles and thinner magnetic layers ($< 100$ nm).

# Magnetic Recording Media: Particulate Dispersions

Magnetic particle dispersions or inks consist of magnetic particles suspended in a mixture of organic solvents by a wetting polymer (O'Grady *et al.* 1991). The particles are dispersed in a mill that applies shear forces to break apart aggregates. The wetting polymer adsorbs to the particle surface to provide a steric barrier that inhibits particle flocculation by magnetic attraction. The dispersion also contains lubricants and alumina particles to control the tribology (see *Magnetic Recording: Rigid Media, Tribology*) of the head–tape interface. Carbon black may be added to raise the conductivity of the coating, allowing the dissipation of static electricity. A polyisocyanate cross-linker is added immediately before coating. In this article we will consider the science of simple particulate dispersions that contain only magnetic particles, wetting binders, and organic solvents.

The ideal dispersion would have each particle separated from every other particle, the particles would have an adsorbed polymer layer, and the adsorbed polymer layer would be solvated by the organic solvents. The ideal dispersion of individually dispersed acicular particles is rare (Veitch *et al.* 1999) and more likely the particles are found in bundles.

## 1. Particle–Binder Interactions

### 1.1 Particle Size Distributions

The preparation of commercial iron particles is described in *Magnetic Recording: Rigid Media, Preparation*. The particles have a lognormal distribution of lengths, diameters, and aspect ratios. For particles used in high-end video tapes, our measurements found the average length was 190 nm, the average diameter was 22 nm, and the average aspect ratio was 9.8. The polydispersity of the distribution was 30.5%. The effect of this distribution on the physical properties of magnetic dispersions is not known. No one has ever prepared acicular particles with a monodisperse distribution of lengths and diameters. However, polydispersity in sizes does have an effect on the rheological properties of other colloidal systems (Roscoe 1952).

A suggestion of the effect of polydispersity in particle lengths comes from computer simulations of particle dynamics during orientation by an external magnetic field. A monodisperse distribution of sizes assembles into a smectic ordered phase consisting of layers with the particles oriented perpendicular to the layer (Visscher and Gunal 1997). When the particles have a lognormal distribution with a polydispersity of greater than 10%, the ability of the particles to form the ordered phases is suppressed (Visscher and Gunal 1998). Such ordering has never been observed in dispersions containing acicular magnetic particles. Commercial particles have a polydispersity ranging from 29% up to 53% (Inaba *et al.* 1998). It is interesting to imagine the potential benefits of highly ordered particle dispersions and the potential to achieve high degrees of orientation in the resulting magnetic coatings. One would first need to discover methods to produce monodisperse acicular magnetic particles.

### 1.2 Particle Surface Chemistry

Commercial iron particles have a thin oxide layer that serves three roles: (i) to prevent sintering during particle preparation, (ii) to modify the magnetic properties, and (iii) to passivate the iron surface. The thickness of the oxide layer is about 4 nm (Rosler *et al.* 1996). The oxide contains mostly aluminum, but can contain bismuth, boron, cerium, cobalt, neodymium, silicon, titanium (Gokturk and Maki 1997), or yttrium (Okamoto *et al.* 1996). Except for compositional data obtained from x-ray photoelectron spectra, little is known about the chemistry of the oxide layer.

The layer is amorphous, as one would expect, since the particles are processed at temperatures less than 500 °C. This is much lower than the crystallization temperature for alumina. If one considers the oxide layer to be a doped amorphous alumina phase, then the literature for alumina chemistry can provide

insight into the types of binding sites available for adsorbates (Henrich 1994). Alumina has both acidic and basic sites. The dopants play a role in determining the nature of the sites. Commercial iron particles are basic (Gokturk and Maki 1997, Veitch *et al*. 1999), which means there are more basic sites than acidic sites. The acid sites are coordinately unsaturated aluminum cations and the base sites are coordinately unsaturated oxygen anions (Hsaio *et al*. 1998).

### *1.3 Wetting Binders*

The wetting binders are moderate molecular weight polymers containing anionic functional groups, e.g., carboxylates, sulfonates, or phosphonates that have a high affinity for the particle surface. The binders chemisorb to the particle surface, anchored primarily by the anionic functional groups. Other functional groups in the binder, such as alcohols, also adsorb to the particle surface. The binder also has loops and tails that extend from the anchor points away from the particle. This provides the steric stabilization of the dispersion. Early wetting binders had the wetting groups randomly distributed along the polymer chains. Subsequently the use of block copolymers has been reported (Weingart *et al*. 1996). One block is responsible for adsorption and the other block for steric stabilization.

The two most important wetting binders for MP tape have been poly(vinyl chloride) (PVC) and thermoplastic polyurethanes (TPUs). The PVC is a copolymer of vinyl chloride and vinyl acetate, where a portion of the acetate groups has been hydrolyzed to give vinyl alcohol groups. The most important PVC is MR-110 from Nippon Xenon (Jeon *et al*. 1997), which contains 0.5 wt.% vinyl alcohol. The alcohol groups have an affinity for the particle surface; however, MR-110 also contains 0.7 wt.% sulfonate groups that have a high affinity for the surface.

The weight average molecular weight ($M_w$) is about 26 000. On average, each polymer chain contains about one alcohol and one sulfonate wetting group. TPUs, such as Estanes from BFGoodrich or Morthanes from Morton International, have either sulfonate or phosphonate wetting groups. These are block copolymers containing polyester blocks coupled together with urethane linkages. The sulfonate groups are introduced into the polyester blocks via copolymerization of 5-sulfoisophthalic acid (Yatsuka *et al*. 1997).

### *1.4 Solvents*

The solvents used in magnetic dispersions include ketones (methyl ethyl ketone (MEK), methyl isobutyl ketone (MIBK), or cyclohexanone), tetrahydrofuran (THF), and toluene. These are typically mixtures containing a highly volatile solvent (MEK or THF) and a less volatile solvent (MIBK, cyclohexanone, or toluene). The choice of solvent mixture is determined by dynamics of the drying process. After coating and orienting in a magnetic field, the more volatile solvent leaves the coating. This causes a large increase in viscosity that locks the particles in place. The less volatile solvent plasticizes the binder, allowing any stresses developed during drying to be relieved.

A problem with the organic solvents used in magnetic tape manufacture is their potential to cause air pollution. The US Environmental Protection Agency (EPA) has listed MEK, MIBK, and toluene as hazardous air pollutants. The regulations for the US magnetic tape industry have been published in the 1994 National Emissions Standards for Hazardous Air Pollutants (*Federal Register* 1994). In modern tape manufacturing plants the solvent vapors from the drier are recovered by use of a carbon bed adsorber. The carbon bed is stripped by steam, and the steam is condensed or put through a distillation column. This allows recovery and reuse of the individual components. Typically 93–95% of the solvents are captured and recycled. The coating operations are safe and the air emissions meet EPA standards. Considerable capital equipment is required to contain and recycle the organic solvents. With increasing worldwide concern for the environment, there will be increasing pressure to minimize or eliminate air pollution in tape coating operations.

### *1.5 Adsorption*

Adsorption of molecular or macromolecular dispersants onto commercial iron particles follows a Langmuir isotherm behavior. The amount depends on the choice of anionic anchoring group and the solvent mixture. Adsorption of stearic acid from THF solution gives a Langmuir capacity of $52\,mg\,g^{-1}$, while adsorption from toluene solution gives a capacity of $86\,mg\,g^{-1}$ (Papirer *et al*. 1997). Clearly THF is competing with stearic acid for the surface sites.

Adsorption of bis(2-ethylhexyl) phosphate from THF solution gives a compact monolayer on the particle surface with a Langmuir capacity of $36\,mg\,g^{-1}$. THF does not compete with bis(2-ethylhexyl) phosphate for binding sites. Incorporating sulfonate groups into the polyester blocks of TPUs increases the amount of polymer adsorbed to the particle surface (Table 1). For a polymer having no sulfonate groups, adsorption from 64/36 wt.% toluene/2-butanone gives a capacity of $80\,mg\,g^{-1}$. When 2.5 mol% 5-sulfoisophthalic acid is incorporated into the polymer, the adsorption amount increases to $185\,mg\,g^{-1}$. For both polymers the amount adsorbed is significantly lower when cyclohexanone is included in the solvent mixture. Cyclohexanone is competing with the polymer for binding sites on the particles.

***Table 1***
Effect of the presence of sulfonate groups and the choice of solvent mixture on the adsorption capacity of thermoplastic polyurethanes.

| Polymer[a] | Toluene (wt.%) | 2-Butanone (wt.%) | Cyclohexanone (wt.%) | Capacity ($mg\,g^{-1}$) |
|---|---|---|---|---|
| 1 | 36.5 | 36.5 | 27 | 19 |
| 1 | 50 | 50 | 0 | 64 |
| 1 | 64 | 36 | 0 | 80 |
| 2 | 36.5 | 36.5 | 27 | 140 |
| 2 | 50 | 50 | 0 | 170 |
| 2 | 64 | 36 | 0 | 180 |

## 2. *Characterization of Magnetic Inks*

### *2.1 Microstructure of Magnetic Inks*

The high concentration of magnetic particles in the ink results in strong magnetic and steric interparticle interactions. Figure 1(a) is a cryo-transmission electron microscopy (TEM) image of an MP ink (Chen and Nikles 2001). A microstructural simulation of an MP ink is shown in Fig. 1(b) (Visscher and Gunal 1997). A schematic that can be used as a model of the microstructure is shown in Fig. 1(c). Individual particles are usually held together in small bundles of particles in a side-by-side orientation of their magnetic moments. Weaker dipole–dipole magnetic attraction between the ends of these bundles link them together in a larger network or floc. The attractive magnetic interactions are countered by the steric repulsion force from the polymer adsorbed on the particle surfaces.

This microstructure determines the physical behavior of the ink and ultimately the properties of the final tape product. The interactions between aggregates determine the colloidal stability of the ink. The viscoelastic properties determine how the ink flows in the coating head and onto the web or onto an underlayer in the case of double coating. The net magnetic moment and size of the particles and aggregates and their interaction with other aggregates determines their ability to rotate in an orienting field. These properties also affect how quickly the particles and aggregates will disorient due to elastic recovery and Brownian motion once the web moves beyond the orienting field.

### *2.2 Physical Properties of the Magnetic Inks*

Many researchers have characterized the properties of magnetic ink using various rheological and magnetic techniques. The most common and meaningful test is to simply make a hand-drawn laboratory tape sample by spreading the ink on a plastic film or glass plate with a calibrated knife coater. When dry this sample can be observed optically with a gloss meter or microscope and tested in a VSM or BH loop tracer for magnetic properties such as coercivity, squareness, and switching field distribution. These tests are, of course, only an indirect measure of ink properties.

#### *(a) Optical methods*

It is difficult to use normal optical methods to view the ink because it is too thick to transmit light. Figure 1(a) was obtained by spreading a thin film of wet ink at its normal solids concentration onto a TEM grid with immediate quenching in liquid nitrogen to prevent the solvent from evaporating. It was kept frozen in a specialized TEM sample holder and observed at 10 000% magnification. Both the particle agglomerates and their network structure can be observed. However, one must search the TEM grid for regions thin enough to see through, leaving some doubt as to how representative any one region is. The ink can also be diluted with more solvent or other particles and dried on a TEM grid (Scholten and Felius 1990). The aggregates can be observed but their network structure is destroyed. These methods give qualitative insight into the structure of the ink.

#### *(b) Rheology*

It is common to test the rheology of the ink, especially the viscosity at high and low shear rates. In rheology

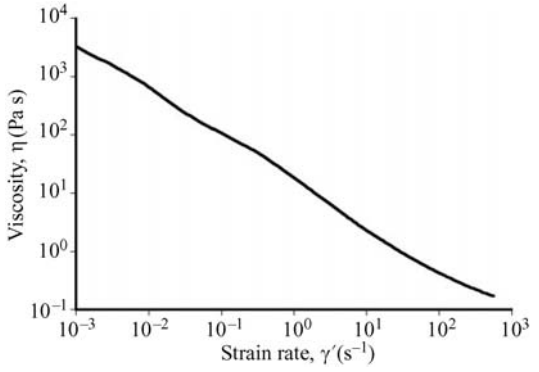

***Figure 2***
Viscosity as a function of shear rate for an MP dispersion.

measurements a force is applied to the surface of a fluid and the rate at which it moves is measured. A sample of ink is subjected to shear at a controlled strain rate and the resulting stress is measured in a controlled rate instrument or vice versa in a controlled stress instrument. There are many variations of this experiment with shear applied in a steady, transient, or oscillatory fashion, at various amplitudes and frequencies, in various geometries, and in the presence of other shear and magnetic forces.

The viscosity as a function of shear rate for an MP ink is shown in Fig. 2 (Chae, unpublished data, 2001). The viscosity is the ratio of shear stress to shear rate and should be constant for a Newtonian fluid. These inks are decidedly non-Newtonian because of the interactions between particles. At low shear rates the network structure breaks and reforms on a time scale faster than the shear rate resulting in a constant viscosity. But high shear rates tear apart the structure faster than it can reform, making the fluid easier to move. This is called shear-thinning behavior.

The shear can be applied in a sinusoidal fashion to obtain the storage ($G'$) and loss modulus ($G''$) that reflect the elastic and viscous nature of the ink. If the amplitude is kept small, the particle microstructure remains intact and can be probed. Figure 3 shows $G'$ and $G''$ of a Co–$\gamma$-$Fe_2O_3$ ink at various resin concentrations (Potanin *et al.* 1998). Magnetic inks are $G'$ dominant, unlike many polymer solutions. The elasticity of the particle network is very strong. Furthermore, the moduli are much higher than for the resin solution without particles, indicating that the viscoelastic properties of the ink are largely determined by the particle interactions. Note that the moduli undergo a minimum at around 5 wt.% polymer concentration. At low polymer concentration, the magnetic attraction between particles is very strong in the absence of good steric protection. At high polymer concentration, excess polymer builds up on the particles, giving them a different type of elastic response.

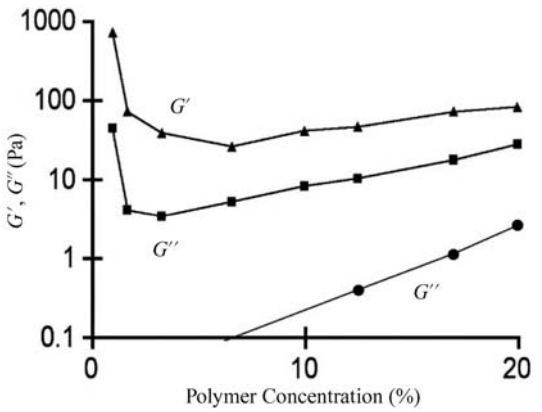

***Figure 3***
Storage ($G'$, ▲) and loss ($G''$, ■) modulus as a function of polymer concentration. $G''$ (●) is also shown for the polymer solution.

*(c) Magnetic measurements*

In a magnetic measurement an applied magnetic field acts on the individual particles inside the ink. A VSM measurement of a $\gamma$-$Fe_2O_3$ ink showed a "coercivity" of 100 Oe that is due to particle rotation in the wet ink and not magnetic switching (which can be seen as a much smaller transition at 800 Oe) (Greaves *et al.* 1996a). The complication in interpreting magnetic measurements of magnetic ink is that the particles readily move, a phenomenon that does not happen when measuring tape.

Methods have been demonstrated that effectively prevent the particles from moving in response to the magnetic field so that magnetic switching information can be obtained. In one technique, the ink is frozen at liquid nitrogen temperatures (with or without first applying an orienting field) and kept frozen during a VSM measurement. Figure 4 shows the interaction parameter, $\delta M$, for a dispersion of barium ferrite with different amounts of milling (Greaves *et al.* 1996b). The positive interactions (due to stacking of the hexagonal platelets) decrease as the time of milling increases. In another technique, a special pulse magnetometer is constructed to apply a field over a period of 50 ns, too fast for the particle to physically move, but slow enough for the magnetic moment to switch (Greaves *et al.* 1996a).

Much information about the ink can be obtained by observing the motion of the particles in a magnetic field. As with rheology there are many variations on this experiment with the field applied in a steady (d.c.), transient, or oscillatory (a.c.) fashion, at various amplitudes and frequencies, in various geometries, and in the presence of other shear and magnetic forces.

In a.c. susceptibility measurements, a low-amplitude a.c. field wiggles the particles while their motion

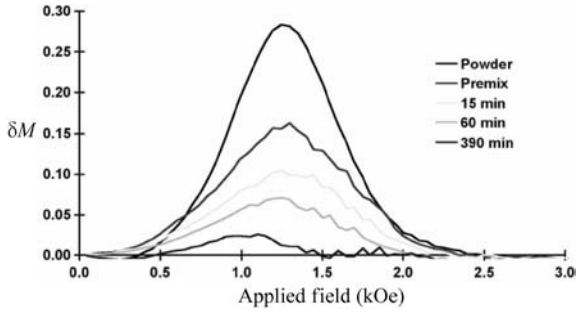

***Figure 4***
Interaction parameter, $\delta M$, as a function of applied d.c. field for barium ferrite inks milled for various times. The cryo-VSM technique was used to keep the ink frozen in order to eliminate particle motion.

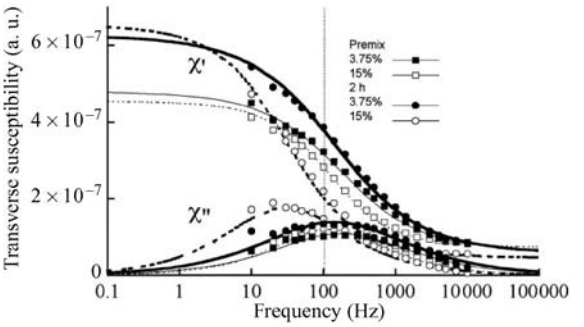

***Figure 5***
In-phase, $\chi'$, and out-of-phase, $\chi''$, a.c. susceptibility of a Co–$\gamma$-$Fe_2O_3$ ink prepared with different resin concentrations and milling time.

is sensed by a pickup coil. If a transverse d.c. field is applied, the particles rotate perpendicular to the a.c. field, increasing the signal. This motion is presumably larger for better dispersed particles. However, in a dispersion of Co–$\gamma$-$Fe_2O_3$ particles with 3.75% or 15% wetting binder, the susceptibility (at an a.c. frequency of 100 Hz) improves with milling for the low-resin ink but decreases for the high-resin ink. Figure 5 shows the in-phase ($\chi'$) and out-of-phase ($\chi''$) components of the a.c. susceptibility (with no transverse d.c. field) over a large frequency range (Peikov *et al.* 1999). The data are fit and extrapolated using a Cole–Cole model. The low-frequency a.c. susceptibility shows that both dispersions are actually improved with milling. The relaxation time, as indicated by the peak of the $\chi''$ curve, shows a shift to longer times (lower frequencies) consistent with a buildup of polymer on the particles.

## *3. Conclusions*

Much progress has been made in the understanding of the physical properties of magnetic inks and the underlying particle microstructure. It is still difficult, though, to determine exactly what makes a good ink become a good tape. Most techniques are demonstrated with very good and very bad dispersions (milling time, polymer concentration, solids content) and the differences are large and interpretable. But of more practical interest to industry is the difference between a very good and an excellent dispersion. This requires more fundamental research and development of a large body of experience.

# Magnetic Recording Systems: Spin Electronics

Hitherto, conventional electronics has ignored the spin of the electron. The charge carriers in ordinary electronic devices can not only have charges of different sign, they also possess spin which may be ''up'' or ''down'' with respect to a local quantization axis. However no use is made of this property.

Spin electronics is the new science and technology of electronic devices that recognizes the spin of the electron as a distinguishing label. Just as a conventional semiconductor transistor distinguishes families of electrons and holes by their opposite charge, a spin transistor divides the electrical carriers into differentially manipulated families (spin channels) which are either spin up or spin down.

Spin electronic devices function by transferring magnetic information from one part of the device to another by using nanoscale magnetic elements (mesomagnets) to encode it onto (and subsequently read it off) the spin channels. This coding may be changed by remagnetizing the mesomagnets thus enabling the creation of electronic components whose characteristics may be engineered to respond to applied magnetic fields.

The first (and simplest) spin electronic components were passive two-terminal devices—the giant magnetoresistance (GMR) trilayers that have already been adopted as the next generation read head technology in the hard-disk industry. Then followed the all-metal spin transistor, a passive three-terminal device. Its successor, the hot spin transistor, represents a very significant advance in that it is the first attempt to integrate silicon and ferromagnetic metals to make a hybrid spin-dependent electronic component.

Hybrid spin electronics (HSE) (which combine semiconductor and spin asymmetric technologies to make devices such as the hot spin transistor) is attractive because, in principle, it can offer nonvolatile memory function and sensitivity to magnetic fields in combination with the other functions generally available from semiconductors such as power gain, high input impedance, etc. Moreover, transport phenomena found only in semiconductors (such as depletion layers, diffusion currents, and the ability of junctions to screen out electric fields from adjacent material) offer a versatility of device design that is unthinkable in systems containing metals alone.

Two- and three-terminal spin-tunnel devices represent a parallel development, which has also generated two- and three-terminal memory and transistor devices with unusual characteristics. Spin tunneling would seem to have a number of advantages in terms of ease of fabrication, flexibility in design parameters, and size of output signal. Spin-tunnel devices seem set to dominate the magnetic memory market for the foreseeable future.

A development of the single electron transistor involving ferromagnetic electrodes has not been realized experimentally, but has wide potential application in information processing and electronic miniaturization.

Likewise the spin FET proposed by Datta and Das (1990) has received much attention but a working example has not yet been demonstrated.

## *1. Technical Basis of Spin Electronics: the Two Spin Channel Model*

The basis of spin electronics was established in the 1930s with the observation that features of electrical transport in ferromagnets distinguished them from other metals. Mott (1936) explained this by postulating that the transport was effected by two independent families of carriers whose members are distinguished by their being either up-spin or down-spin. Spin flip processes are rare on the timescale of the other scattering processes that control the transport, hence these two spin channels may be regarded as being pseudo-independent.

### *1.1 Spin Asymmetry*

The two-spin channel model is further qualified by the fact that the spin-up and spin-down electrons have different properties and this spin asymmetry

arises from the bandstructure splitting caused by the ferromagnetic exchange interaction. The splitting causes different densities of states at the Fermi energy and this in turn has two consequences: (i) the number of available carriers of a particular spin type or (in a tunneling process) the number of available final states for such carriers is different for each spin type; and (ii) owing to the different densities of final states for each spin type, they are differently affected by momentum-changing scattering processes and hence their mobilities are in general different. Most spin electronic phenomena are based on either or both of these asymmetries that have a common origin in the bandstructure splitting (Barthelemy and Fert 1991).

### *1.2 The Half-metallic Ferromagnet*

In the extreme limit of spin asymmetry lies the half-metallic ferromagnet (HMF) (de Groot *et al.* 1984), in which the bandstructure splitting is such that only one spin band is available at the Fermi surface and hence all current must be carried by these so-called majority spins. Practical examples include chromium dioxide, lanthanum strontium manganite, magnetite, and some Heusler alloys. In reality, obtaining half-metallic spin electronic behavior is fraught with problems mainly to do with the interfaces.

### *1.3 Density of States Asymmetry Versus Mobility Asymmetry*

The density of states asymmetry (which leads in the extreme case to half-metallic ferromagnets) and the mobility asymmetry compete with one another in spin electronics. The mobility asymmetry arises where the bandstructure at the Fermi surface contains components which have *s* and *d* character respectively. The *s*-like effective masses are small compared to the *d*-like masses and so the current is primarily mediated by *s*-electrons. However, the *d*-electrons are significantly split by the exchange interaction and present very different densities of states into which the *s*-electrons may be scattered. As a result, the *s* channel whose spin corresponds to the spin of the majority *d*-electrons suffers the most scattering and hence has lower mobility than the other *s* channel; the latter consequently carries most of the current. Thus, in a system with *s*- and *d*-like character at the Fermi surface, the tendency is for the current to be carried by the minority carriers (those with the lower density of states at the Fermi energy) whereas in a HMF clearly the current may only be carried by majority carriers.

This conflict between the two types of asymmetry is one reason why spin tunnel devices have an advantage over their competitors since they exploit only the density of states asymmetry and the mobility asymmetry has no chance to compete and reduce the overall device performance.

## *2. Spin Injection Across an Interface*

Clearly if one carrier spin type is dominant in the electrical transport of a ferromagnet, then when a current is passed from such a ferromagnet to a paramagnetic metal such as silver or aluminum, the electrical current brings with it a net injection of spin angular momentum and hence also magnetization (Johnson and Silsbee 1985).

### *2.1 Spin Accumulation and Spin Diffusion Length*

This magnetization that builds up in the new material is known as a spin accumulation. Its size in the paramagnetic metal is determined by a balance between the spin injection rate at the interface and the spin-flipping rate in the body of the paramagnet. The injected magnetization diffuses away from the interface and decays exponentially on a length scale called the spin diffusion length test $l_{sd}$ given by

$$l_{sd} = \sqrt{v_F \tau_{\uparrow\downarrow} \lambda / 3}$$

where $v_F$ is Fermi velocity, $\tau_{\uparrow\downarrow}$ is the spin flip time, and $\lambda$ is the mean free path. The actual size of the spin accumulation in terms of the spin density $n$ at distance $x$ from the interface is given as

$$n = n_0 \exp(-x/l_{sd})$$

where $n_0$, the density at the interface, is given by

$$n_0 = 3\alpha j l_{sd} / e v_F \lambda$$

where $\alpha$ is polarization of the ferromagnet and $j$ is current density at the interface. Substituting typical numbers of $j = 1000\ \mathrm{Acm^{-2}}$, $\alpha = 1$, $v_F = 10^6\,\mathrm{ms^{-1}}$, $\lambda = 5\,\mathrm{nm}$, $l_{sd} = 100\,\mathrm{nm}$ gives a value of spin density of $10^{22}\mathrm{m^{-3}}$ as opposed to a total electron density of about $10^{28}\mathrm{m^{-3}}$.

That such small asymmetries in spin density can give rise to such huge electrical transport effects as GMR is yet one more example of the dominance of the electrons at the metal Fermi surface which is where these spins are concentrated.

Various practical methods of measuring the spin diffusion length have been described (Yang *et al.* 1994). Measuring the spin density or its associated magnetization is difficult owing to its smallness and the difficulty in distinguishing convincingly the magnetic fields associated with the accumulation itself from those caused by the current that is generating the accumulation.

An elegant analysis of the spin accumulation phenomenon (Valet and Fert 1993) proceeds by treating

it as a divergence of the electrochemical potentials for spin-up and spin-down carriers either side of the interface. This treatment shows clearly the relationship between the accumulations both sides of the interface and also how the magnitude of the accumulation depends on the relative conductivities of each metal. This has implications for spin injection into low conductivity materials such as doped semiconductors.

### *2.2 The Role of Impurities in Spin Electronics*

From the expression above for spin diffusion length it is clear that introducing impurities into the material concerned diminishes $l_{sd}$ rapidly for two reasons: the impurities shorten the mean free path and also the spin flip time via spin-orbit scattering (Fert *et al*. 1995). The latter may be thought of as a relativistic effect: under Lorentz transform, electric fields assume a magnetic component. To electrons at the Fermi surface which have weakly relativistic velocities, the electric fields generated by impurity atoms appear weakly magnetic. If the symmetry of the impurity site is sufficiently low, this field may Zeeman couple to the $S^+$, $S^-$ operators that induce spin–flip transitions. Hence materials with point defects and low symmetry structural disorder are likely to exhibit reduced spin diffusion lengths (Dubois *et al*. 1999).

## *3. Two-terminal Spin Electronics*

The simplest spin electronic devices are called GMR trilayers or spin valves depending on their magnetic construction, i.e., whether the layers are RKKY-coupled or exchange pinned. They have two terminals and consist of sandwiches comprising three metal films: two ferromagnetic metal films flanking a film of nonmagnetic metal. If the terminals are contacted to the two ferromagnetic films the configuration of the device is described as current perpendicular to plane (CPP). However the terminals may also be attached to opposite ends of the film stack such that the current flows through all three films to transit the device: this configuration is known as current in plane (CIP). The magnetizations of the ferromagnetic layers are engineered to lie antiparallel in zero magnetic field (by either RKKY coupling or exchange biasing), but application of an external field may align them. When this happens the electrical resistance between the device terminals drops, a phenomenon known as giant magnetoresistance. For a fuller description see *Magnetoresistance, Anisotropic*; *Giant Magnetoresistance*, *Magnetoresistance: Magnetic and Nonmagnetic Intermetallic*.

### *3.1 CPP GMR*

CPP GMR may be explained, with recourse to the Valet/Fert model (Valet and Fert 1993), in terms of the electrochemical potential splittings at the successive interfaces. If the interfaces are separated by a distance less than a spin diffusion length, the successive spin accumulations interfere and generate additional electrochemical potential drops associated with the interfaces. These change with the magnetic configuration of the device and in turn they translate into changes in the resistance of the overall device (Lee *et al*. 1993).

### *3.2 The Analogy with Polarized Light*

A more immediate way to understand the physical significance of this phenomenon is by analogy with crossed optical polarizers. In the extreme case in which the ferromagnets are half metallic, they accept or dispense only electrons of one spin type, for example spin-up (parallel to the magnetization). Assuming that the intermediate nonmagnetic layer is thinner than a spin diffusion length, this means that the spin emitted by one magnetic layer preserves its polarization until it meets the other layer. Whether it gains access to this second ferromagnetic layer then depends on whether the magnetizations of the two layers are parallel or antiparallel. The analogy with optical linear polarizers is exact except in that the extinction angle in the spin electronic case is $180^\circ$ rather than $90^\circ$. As expected from this model, the GMR varies as the cosine of the angle between magnetic layers (Dieny *et al*. 1991).

### *3.3 The Resistor Model of GMR*

A simple parallel resistor model may thus be used to describe CPP GMR. The two parallel paths, each consisting of two series resistors, represent the respective spin channels and the first and second resistors in each path are the resistances which they experience at the first and second interfaces respectively.

If we arbitrarily assign resistance values of $1\,\Omega$ and $10\,\Omega$ to the majority and minority interface resistances, it is seen that the magnetization parallel and antiparallel configurations have overall resistance of $1.8\,\Omega$ and $5.5\,\Omega$ respectively.

### *3.4 CIP GMR*

This was in fact the first GMR to be experimentally demonstrated, its geometry being easier to realize than the CPP geometry, which requires sophisticated nanolithography (Baibich *et al*. 1988). CIP GMR is characterized by the same drop in electrical resistance of the thin film sample when a magnetic field is applied. However the explanation is fundamentally different. Symmetry considerations show clearly that no spin accumulation is set up in this case since current flow is parallel to the layers. Instead the explanation

invokes the differential mobilities of the spin-up and spin-down electrons and relies on the nonmagnetic interlayer being sufficiently thin that a high proportion of the current carrying electrons experience successive momentum scattering events in different magnetic layers. This in turn means that if the layers are antiparallel, either spin type has high mobility since each experiences heavy scattering in one or other layer. However if the layers are parallel, one spin type is heavily scattered in both layers and the other spin type is relatively unscattered and hence its high mobility electrically short-circuits the device. The resistor model above works equally for the CIP geometry: the two parallel paths are again representative of the spin channels and the resistors represent the scattering they experience in the respective layers, assuming that their trajectories sample both layers.

### *3.5 Comparative Length Scales of CIP and CPP GMR*

It is evident for this discussion that two quite different length scales are relevant to CIP and CPP GMR. For CPP GMR, the interlayer must be less than the spin diffusion length whereas for CIP GMR to appear the interlayer must be less than a mean free path which is a rather shorter distance. In practice typical CIP GMR multilayers use nonmagnetic spacers of the order of 10 Å or less.

### *3.6 Inverse GMR*

In the above discussion it is assumed that the metals in the two ferromagnetic layers are similar, or at least that the sign of their polarizations is the same. That is to say that the majority spin for each ferromagnet is parallel to the magnetization (positive polarization) or antiparallel to the magnetization (negative polarization). If a combination of two ferromagnets with opposite polarizations is used to make a GMR trilayer, the GMR is inverted which means that the resistance of the device increases on application of an external magnetic field. This is because when the ferromagnets have parallel magnetizations they disagree as to which spin direction is the majority type (Renard *et al*. 1996).

### *3.7 Obtaining Differential Magnetization: RKKY Coupling Versus Exchange Pinning—The Spin Valve*

There are two techniques used to engineer GMR systems such that the two ferromagnetic layers are differentially switchable in an externally applied field.

*(a) RKKY coupling*

The first technique involves making the metallic interlayer of such a thickness (of order 1 nm) that the RKKY coupling across it between the magnetic layers is antiferromagnetic and so the layers antialign in zero applied field but are parallel in applied field (Parkin *et al*. 1990). This technique imposes constraints on the device design, which may militate against obtaining the best GMR signal.

*(b) The spin valve*

The other technique is to make one layer magnetically hard by exchange pinning it to an antiferromagnet on the side opposite to that which abuts the GMR device. In this case only the unpinned soft layer moves in small magnetic fields. The resulting device is termed a spin valve (Dieny *et al*. 1991).

### *3.8 The Artificial Antiferromagnet (AAF)*

The AAF is a clever combination of the two above ideas. No RKKY coupling is used in the GMR spacer layer. However, one of the ferromagnetic electrodes is rendered magnetically hard by fabricating it from two distinct ferromagnetic layers A and B of almost identical thickness, which are RKKY-coupled such that in zero applied field they are antiparallel and hence their net moment is small. The switching field of this artificial antiferromagnet block (A + B) is thus enhanced by a so-called $Q$ factor which is the ratio of the total magnetic moment when A and B are aligned in a high field to the net moment when A and B are antialigned (Tiusan *et al*. 1999).

### *3.9 GMR in Nanowires*

An interesting practical realization of CPP GMR is by using electroplating technology to construct metallic nanowires in nanopores of a membrane (Piraux *et al*. 1994). With a suitable electrolyte containing a selection of ions, the material being deposited may be varied every few nanometers along the wire by switching the value of the electroplating potential, thereby creating a magnetic multilayer structure. This technique has the added convenience that the geometry of the wires is conducive to easy measurement, unlike thin evaporated films, which must be lithographed in order to obtain specimens whose resistance is high enough for practical purposes.

## *4. Quantum Tunneling*

If two conducting layers between which a potential is applied are separated by a thin insulating film, electrical current passes between the metal electrodes by quantum mechanical tunneling of the current carriers through the insulating tunnel barrier. The tunneling rate for carriers of a particular energy is proportional to the product of the carrier densities of states at that energy each side of the barrier. Also, the thinner the

barrier and the lower the barrier height, the larger the current. This phenomenon was extensively studied in the context of superconducting thin films where it enables accurate determination of the superconducting energy gap (Giaever and Megerle 1961).

### *4.1 Spin Tunnel Junctions*

Spin tunnel junctions are two-terminal spin electronic devices whose magnetotransport characteristics closely mirror those of CPP GMR trilayers, except that their parameters are more readily adaptable to practical applications. They consist of pairs of ferromagnetic electrodes separated by electrical insulators and they exhibit large changes in tunnel resistance depending on the relative alignment of the ferromagnetic electrode magnetizations. The thickness of the tunnel barrier must be in the low nanometer regime to obtain reasonable current densities. The effect may be understood, at least simplistically, according to a model of Julliere (1975) which was in turn inspired by the ideas of Merservey and Tedrow (1971), in which the tunnel current is proportional to the product of the densities of spin-states either side of the tunnel barrier.

In the simple case of HMF electrodes whose magnetic moments are anti-aligned, it is clear that the product of the initial and final densities of states is zero for either spin type and no current flows. However if the moments are aligned the half band of majority spins may tunnel and the device will have low resistance. It may be seen that this device is highly analogous to the CPP GMR trilayer except that it relies exclusively on asymmetry in density of states and does not invoke mobility spin asymmetry. This makes analysis cleaner and also means that in general the magnetoresistance (MR) effects are larger. Also, because tunneling and not ohmic conduction is involved, the resistance of a tunnel junction is higher than that of an all-metallic GMR system of comparable geometry and this makes spin tunnel junctions rather more easily adaptable to practical applications.

### *4.2 Refinements in the Understanding of Spin Tunneling*

The simple Julliere tunneling theory gives good insight into the physical basis of spin tunneling but is incapable of explaining the finer experimental detail. For example, most spin tunnel junctions display a bias-dependent magnetoresistance whose explanation needs a more sophisticated treatment (Chui 1997). Moreover, simple spin tunneling theory suggests that a particular spin asymmetric material should always exhibit the same characteristic polarization for tunneling processes and that this polarization value is closely related to and predictable from its bulk bandstructure. However, experiment reveals that, on the contrary, the polarization which magnetic electrodes manifest for tunneling purposes is found to be a function of the magnetic metal/insulator combination, not just of the magnetic metal itself. The polarization of a particular spin electronic material may actually change sign depending on which insulator accompanies it (De Teresa *et al*. 1999). The explanation is thought to be that the tunneling electrons come from the first few atomic layers of the metal which are hybridized with the insulator and hence do not have the bulk bandstructure. Since spin electronic effects are almost all interface related, it is generally these interface bandstructures that are more relevant to practical device performance.

### *4.3 Spin Tunnel Junction Resistance and Heat Dissipation*

Spin tunnel junctions are characterized by a real conductance per unit area. The associated junction resistance scales roughly exponentially (according to the very simplest theory) with thickness and barrier height. However the net dissipation associated with this tunnel resistance when a tunnel current flows is not dissipated in the junction itself but rather in the conducting material on its downstream side. Hot carriers are injected into this region from the junction insulator and thermalize rapidly owing to their being high above the Fermi surface where there is a high density of empty states into which they may scatter.

### *4.4 Coherent Spin Tunneling—Resonant Structures*

Clearly if two separate tunnel junctions are cascaded their resistances add according to Ohm's law. However, if the junctions are sufficiently close that the wavefunction of the electrons entering the first junction is coherent with those exiting the second junction, in other words the transport is ballistic in the layer separating the junctions, the analysis is more complex. This implies that, since the electrons have at least partially preserved their phase memory, they have not been properly thermalized in the intermediate layer and the concept of single junction resistance is not valid. The entire multiple tunnel structure must then be analyzed as an entity in similar fashion to that in which optical thin film interference filters are treated. Such resonant tunnel structures are potentially useful for making spin-tunnel devices with a high back-to- front electrical transmission ratio.

## *5. Superparamagnetism*

There are three main energy terms that govern ferromagnetic behavior: the magnetostatic energy stored in the magnetic field surrounding a ferromagnet with free magnetic poles; the exchange energy, which

varies with the cosine of the angle between adjacent spins; and the anisotropy energy, which increases if any individual spin orients itself at an angle to the easy direction in the material. Reduction of the magnetostatic energy is the reason for the existence of ferromagnetic domains. However, between any two domains is a domain wall whose width and energy are determined by a trade-off between the other two energy terms, the exchange and the anisotropy energies. The magnetostatic energy of a specimen scales as its volume $V$ and domain wall energy as cross-sectional area. This implies that for ferromagnetic systems below a certain dimensional threshold, the energy needed to create a domain wall in the system exceeds the magnetostatic energy reduction that this would effect.

Such particles are thus single domained and termed superparamagnetic since they behave as a single giant spin. This giant spin has lowest free energy when aligned along its easy axis. If the system has uniaxial anisotropy with the easy direction on this axis, then below a certain critical temperature $T_b$ (called the blocking temperature) given by $KV = k_B T_b$, single domain particles are trapped in one or other of the potential wells in free energy which correspond to magnetization parallel or antiparallel to the easy direction. Such a system is said to be blocked and, unlike a superparamagnet (i.e., itself at higher temperature) has a hysteretic magnetic response (Bean and Livingstone 1959).

### 5.1 Granular GMR Materials

When different proportions (say 20%, 80%) of two immiscible metals are cosputtered and then annealed, the initial interatomic mixture phase separates into granules of one metal in a matrix of the other. If the granules are ferromagnetic and the matrix paramagnetic, the resulting material exhibits GMR. Such materials may also be formed by mechanical alloying. The effect was first observed by Gerritson (1959) before the theory existed to explain the phenomenon. The GMR arises because in zero field the angle between adjacent magnetic granules is totally random whereas in high magnetic field the moments are virtually all aligned. Simple trigonometry shows that the GMR, which is again proportional to the cosine of these inter-grain angles, varies as the square of the sample magnetization (Barnard *et al*. 1992, Berkowitz *et al*. 1992). In the absence of significant interaction between the grains this is experimentally verified. Owing to the geometry of such granular systems, the GMR that they exhibit is a mixture of CIP and CPP and both characteristic length scales for these two phenomena are in play (see *Giant Magnetoresistance*).

### 5.2 Jitterbug Depolarization

Granular GMR systems comprise a spread of magnetic particle sizes whose span depends on the mode of preparation. The larger particles whose diameters are of the order of the electron mean free path contribute to the GMR. The smaller particles are insufficiently large to cause appreciable scattering but they nevertheless play a role in determining the magnetotransport by causing passing spins to precess. This spin precession causes the spin to turn through an angle, which is a function of the incident spin orientation, the particle magnetization orientation, and the particle thickness. The result is a progressive depolarization or mixing of the spin channels, which militates against the GMR. This spin mixing mechanism is called the jitterbug effect after the swing-dance of that name which the electron's successive random precessions resemble (Gehring *et al*. 1995).

## 6. Giant Thermal Magnetoresistance

Electrical current carriers are capable of mediating a variety of signals. These include not only electric current and magnetization but also heat. Thermal and electrical transport in metals generally are closely related, as witness the Peltier effect (using an electric current to produce cooling) and the thermoelectric effect (using a thermal difference to generate a voltage). The Wiedemann–Franz Law (see *Boltzmann Equation and Scattering Mechanisms*) also tells us that there is an intimate relationship between the thermal and electrical conductivities of metals under most circumstances. This close connection is further extended in the case of magnetoconductivity. Just as the electrical conductivity of a giant magnetoresistive material is a function of applied magnetic field, so also is the thermal conductivity, though the percentage effects may be different owing to the different way in which the thermal information is encoded onto the electrical carriers that mediate it (Daniel *et al*. 1995).

## 7. The Exchange Length in Spin Electronics: The Ferromagnetic Domain Wall as a Giant Magnetoresistor

Exchange length is an ambiguous term in nanomagnetism, which may be taken as the characteristic length scale defined by the exchange energy and the magnetostatic energy, or more practically by the exchange energy and the anisotropy energy. In the latter case it is closely related to the thickness of ferromagnetic domain walls.

The electrical resistivity associated with ferromagnetic metal domain walls has been a subject of intensive study for many decades (Berger 1991, Cabrera and Falicov 1974). A spin electronic interpretation of this resistance is possible which draws on the analogy between a ferromagnetic domain wall and a GMR trilayer (Gregg *et al*. 1996). When the wall is present the magnetizations either side are antiparallel and

when it is absent they are parallel. In the limit where the carrier spins traverse the wall with spin directions unaltered, the analogy with CPP transport in a GMR trilayer is complete. However, depending on the strength of the exchange field and hence the spin's pseudo-Larmor precession frequency, and also the wall thickness, the spin directions of the transiting carriers may track the magnetization rotation in the domain wall more or less adiabatically. Any mistracking gives rise to a quantum mechanical admixture of the opposite spin wavefunction which lays the spin open to momentum scattering by the normal processes which cause resistance. This model gives rise to an expression for the increase in resistivity of material in a domain wall of:

$$\delta\rho_W/\rho_0 = (\lambda^*/\lambda + \lambda/\lambda^* - 2)\langle \sin^2(\theta/2)\rangle$$

Unlike other previous models for domain wall resistance, this model predicts a percentage resistance change for such material which is independent of impurity content.

Very large magnetotransport effects (of the order of 600%) have been observed in ferromagnetic nanocontacts between oppositely magnetized domains of half-metallic ferromagnet (magnetite) (Versluijs *et al.* 2001).

## 8. Three-terminal Spin Electronics: The Johnson Transistor

Three-terminal spin electronics is the logical succession to GMR and TMR devices and is realized in the simplest case by attaching a third electrode to the intermediate layer in an all-metallic GMR system (Johnson 1993).

The result is the Johnson spin transistor. Its function may be briefly understood as follows. It is assumed for simplicity that the ferromagnets are half-metallic. We denote the new connection to the paramagnetic intermediate layer of the trilayer as the "base," and the connections to the ferromagnetic layers as the "emitter" and "collector," respectively. The device is biased by pumping an electron current through from emitter to base, thereby establishing a spin accumulation in the base, which extends to meet the base–collector interface. If the collector is left electrically floating, i.e., its potential is monitored by a high impedance voltmeter, which draws from it no current. Since the collector is capable of accepting only one spin type, it floats at a potential which equalizes its electrochemical potential with that of the corresponding spin type in the base. Since the base has a spin accumulation, this implies that its spin-up and spin-down electrochemical potentials are different and hence that the floating potential of the collector will alter by this differential if the magnetization of the collector (of the emitter spin injector) is reversed. Thus, we have the embodiment of a three-terminal spin electronic device: electrical characteristics of the third electrode determined by the relative conditions at the other two and in addition the capability of changing this dependence by applying a magnetic field.

## 9. Power Gain and Noise Considerations in All-metallic Spin Electronics

The Johnson transistor is an all-metal device that obeys Ohm's law and as such it cannot deliver signal power gain without further modification. This might take the form of additional terminals or a change to the internal structure. Moreover, the source impedances of such devices are small, particularly those with perpendicular structures. Optimizing noise figure when matching small source impedances to conventional electronics is difficult and requires impedance transformation, which is frequently bulky and impractical.

## 10. Hybrid Spin Electronics

A potential solution to these technical problems is found in hybrid spin electronics. This is the combination of spin-asymmetric materials with conventional semiconductors. It releases to the spin electronic designer a variety of constructional options such as deployment of reverse biased junctions with minimal admittance, depletion layers to screen regions of the device, and diffusive carrier transport.

### 10.1 The Monsma Transistor

The first hybrid spin electronic device was the Monsma transistor produced by the University of Twente which was fabricated by sandwiching a traditional spin valve device between two layers of silicon (Monsma *et al.* 1995). Three electrical contacts are made to the spin-valve base layer and the respective silicon layers. The spin valve is more sophisticated than that discussed above and comprises multiple magnetic/nonmagnetic bilayers, but the operating principle is the same. Schottky barriers form at the interfaces between the silicon and the metal structure and these absorb the bias voltages applied between pairs of terminals. The collector Schottky barrier is back biased and the emitter Schottky is forward biased. This has the effect of injecting (unpolarized) hot electrons from the semiconductor emitter into the metallic base high above its Fermi energy. The question now is whether the hot electrons can travel across the thickness of the base and retain enough energy to surmount the collector Schottky barrier. If not they remain in the base and get swept out the base connection.

By varying the magnetic configuration of the base magnetic multilayer the operator can determine how

much energy the hot electrons lose in their passage across the base. If the magnetic layers are antiferromagnetically aligned in the multilayer then both spin types experience heavy scattering in one or other magnetic layer orientation, so the average energy of both spin types decays rapidly as a function of distance. On the other hand, if the magnetic multilayer is in an applied field and its layers are all aligned, one spin class gets scattered heavily in every magnetic layer, whereas the other class is lightly scattered everywhere and hence retains its "hot" status over a longer distance. Thus, for parallel magnetic alignment, spins with higher average energy impinge on the collector barrier and the collected current is correspondingly higher. Once again we have a transistor whose electrical characteristics are magnetically tunable. This time, however, the current gain and the magnetic sensitivity are sufficiently large that, with help from some conventional electronics, this is a candidate for a practical working device.

Evidently, there is a tradeoff to be made in determining the optimum base thickness. A thin base allows a large collector current harvest but affords little magnetic discrimination. A thick base on the other hand means a large factor between the collector currents corresponding to the two magnetic states of the multilayer but an abysmally small current gain. (The low current gain has always been the Achilles heel of metal base transistors, and is probably the main reason for their fall from favor as practical devices despite their good high frequency performance owing to the absence of base charge storage).

An interesting feature of the Monsma transistor is that the transmission selection at the collector barrier is done on the basis of energy. Thus, the scattering processes in the base that determine collected current are the inelastic ones. Elastic collisions that change momentum but not energy are of less significance. This contrasts with the functioning of a spin valve-type system in which all momentum changing collision processes have the same status in determining device performance.

### *10.2 Spin Transport in Semiconductors*

The Monsma transistor represents a very important step in the evolution of spin electronics. It is the first combination of spin-selective materials with semiconductor. However, as yet, the semiconductor is used only to generate barriers and shield the spin-dependent part of the device from electric fields. To release the full potential of hybrid spin electronics we need to make devices that exploit spin-dependent transport in the semiconductor itself.

### *10.3 The SPICE Transistor*

The current gain of a conventional bipolar transistor is in part due to the screening action of the junctions either side of the base, which absorb the bias voltages and leave the base region relatively free of electric fields. The current which diffuses across the base is primarily driven by carrier concentration gradient and to a rather lesser extent by electric field and the randomness associated with concentration driven current flow helps to improve the current gain. The carriers injected by the emitter are forced to wander towards the base along the top of an extended cliff in voltage, at the bottom of which lies the collector. For example, 99% of the carriers stumble over the cliff and are swept out the collector and the remaining 1% make it to the base connection; this gives a very satisfactory current gain $\beta = I_c/I_b$ of 99.

Implementing spin-polarized current transport in a semiconductor enables a new concept in spin transistor design—the spin-polarized injection current emitter device (SPICE) (Gregg *et al*. 1997) in which the emitter launches a spin-polarized current into the electric field screened region and a spin-selective guard-rail along the top of the cliff determines whether these polarized carriers are allowed to fall into the collector. Thus, we have a device with a respectable current gain from which power-gain may easily be derived, but whose characteristics may again be switched by manipulating the magnetic guard rail via an externally applied magnetic field. A wide variety of designs are possible which answer to this general principle. For example the emitter and collector interfaces may be realized by *p–n* junctions, Schottky barriers, or spin tunnel junctions and the geometry of the device may be adjusted to allow a greater or lesser degree of electric field driving component to the diffusion current in the base depending on the application.

### *10.4 Measuring Spin Decoherence in Semiconductors*

The crucial question which needs to be answered in order to realize this kind of spin transistor is whether spin transport is possible at all in semiconductors, and, if so, whether it is possible over the sort of physical dimensions on which a typical transistor is built. In other words, we need an estimate of the spin diffusion length in a typical semiconductor. A subsidiary question concerns the role of dopants in the semiconductor and whether they introduce spin-orbit scattering, which militates against the spin transport by reducing the spin flip times. Some consideration has been given to allowed nonequilibrium spin configurations in a semiconductor (Flatte and Byers 2000).

### *10.5 Direct Spin Injection from Metals to Semiconductors*

Experiments have been performed (Gregg *et al*. 1997, Jia *et al*. 1996) in which ferromagnetic contacts

perform direct spin-injection into a semiconductor and analyze the polarization of the current that emerges on the other side. Transport results are observed which are insensitive to magnetic field direction, have even symmetry (thereby eliminating AMR and Hall effect as a possible cause) and they are compatible with the observed domain magnetization processes for the cobalt pads. They appear to correspond to spin transport through the semiconductor. However the spin transport effects are of the order of a few percent at best, yet the effect decays only very slightly with silicon channel length and was still well observable for 64 μm channels. This suggests that the spin diffusion length in silicon is many tens of microns at the least, but that the spin injection process at the metal/silicon interface is highly inefficient. Clearly the process is highly preparation sensitive as witnessed by the null results with evaporated silicon (Loraine *et al*. 2000).

This direct injection inefficiency is being widely observed and its cause is still hotly debated. It may arise from spin depolarization by surface states, or it may be explainable by the Valet/Fert model (Valet and Fert 1993) in which spin injection is less efficient for materials of very different conductivities. The discussion below in connection with spin tunneling concerning hybridization at the interface with the spin selective injector is no doubt relevant in this context also. It may also be because the spin injection is not being implemented at the optimum point in the semiconductor bandstructure. From the latter point of view, spin tunnel injection into semiconductors is a more versatile technique, since, for a given injected tunnel-current density, the necessary bias (and hence the point in the band-structure where injection occurs) may be tuned by varying the thickness and/or the tunnel barrier height.

### *10.6 Optical Polarized Carrier Generation*

A direct measurement of semiconductor spin diffusion length has been made by decoupling from the spin injection problem and generating the spin-polarized carriers in the semiconductor itself (Hagele *et al*. 1998, Kikkawa and Awschalom 1999). Gallium arsenide was used as the host that has the property that, when pumped with circularly polarized light, the selection rules are such as to populate the conduction band with predominantly one spin type. These spins can be made to precess by application of a small magnetic field. The resulting precessing magnetization is then detected using optical Faraday rotation using a probe beam from the same optics as provides the pump. The magnetization drifts under the application of a driving electric field and the spatial decay in precession signal gives a measure of the spin diffusion length. The results are of the order of many tens of microns, in accordance with the silicon direct injection experiment discussed above.

Thus, it would seem beyond doubt that the spin diffusion length in semiconductors is adequate for the design and realization of SPICE-type transistor structures—so long as means are provided for efficient delivery of the initial spin-polarized current.

### *10.7 Spin Injection from Magnetic Semiconductors*

An alternative method of generating spin-polarized carriers in a semiconductor is by injection from a magnetic semiconductor (Fiederling *et al*. 1999, Ohno *et al*. 1999). Striking results are obtained by injecting spin-polarized carriers from a magnetic semiconductor into a normal semiconductor light emitting diode structure. The polarization of the injected carriers is dependent on the magnetization direction of the magnetic semiconductor that supplies them. This is reflected in the polarization of the light emitted by the LED—its polarization is related to the spin of the electrons which cause it via the same selection rules as discussed above in the Awschalom experiment (Hagele *et al*. 1998, Kikkawa and Awschalom 1999). The polarization of the light emitted correlates well with the hysteresis loop for the magnetic semiconductor and decays with temperature exactly as the magnetic moment of the magnetic semiconductor, leaving little doubt that successful spin injection has been achieved. The percentage injection achieved here is more favorable than has been possible by direct injection from metals and it may be that magnetic semiconductors have an important role to play in future spin electronics development, notwithstanding the non-negligible materials problems which they pose.

Spin-tunnel injection into semiconductors is also a promising technique which offers higher injection efficiency than direct spin-injection (Prins *et al*. 1996).

## *11. The Rashba Effect*

The Lorentz transformation indicates that to a relativistic observer traveling with respect to the source of an electric field, it appears to have a magnetic component whose orientation depends on the geometry of the observer's travel relative to the field axis. If the electric field in question originates from crystal field effects or from the depletion layer in a semiconductor structure, then the magnetic component that appears to relativistic electrical carriers is capable of spin-splitting the conduction band if it is diagonal and of causing spin precession if it is off-diagonal. This is the Rashba effect.

### *11.1 The Datta–Das Transistor or Spin FET*

The Rashba effect gives rise to a novel spin electronic device concept proposed by Datta and Das (Datta and Das 1990), but not realized experimentally. The device has the construction similar to that of a

conventional field effect transistor with source and drain electrodes made in ferromagnetic metals and a semiconductor channel which is subject to a transverse electric field whose magnitude may be tuned by applying a gate voltage. Spin-polarized carriers leave the source with their spins parallel to the source magnetization and precess in transit through the channel owing to the Rashba effect. If the drain magnetization is parallel to that of the source and the carriers perform an integral number of precessions in transit, then the device conductance is high. However, slight modification to the gate voltage changes the precession rate and if the spins now execute $N + 1/2$ precessions in transit, the device conductance is minimized. The resulting device thus behaves like a normal FET with the additional feature that the differential magnetization of its electrodes (and hence its electrical characteristics) are sensitive to externally applied magnetic field.

Although the device has not been realized, much groundwork on the materials properties and principles exist in the literature and spin-valve effects have apparently been observed in experiments involving two-dimensional electron gases in which spin-polarized carriers are injected from a permalloy contact into an AlSb/InAs quantum well and analyzed by a second permalloy contact with a different switching field (Hammar *et al.* 1999).

However some skepticism has been voiced by other workers on the spin FET problem (van Wees *et al.* 2000), and theoretical signposts have been placed to spin precession-type data which will unambiguously confirm that Datta–Das-type device function has been observed (Tang *et al.* 2000). This is clearly an exciting topic which will continue to attract attention and research activity for the foreseeable future.

## *12. Coulomb Effects: Coulomb Blockade and the Single Electron Transistor*

The electrostatic energy of a charged capacitor is $\frac{1}{2}Q^2/C$. If $C$ is sufficiently small, this energy can compete with thermal quanta of size $k_B T$, even for $Q = e$, the electronic charge. Small metallic spheres or pads with physical dimensions in the nanometer range have capacitances in the right ballpark for this condition to be obtained. If such a metallic island is sandwiched between two physically close metallic electrodes (the source and the drain), a single electron transistor (SET) is formed (Devoret and Grabert 1992). A third electrode (the gate) which is capacitatively coupled to the metallic island is biased in order to pass current or to coulomb blockade the SET.

The physics involved is a competition between three energy terms; the electrostatic energy, $E_i$, of the island due to the presence on it of just one electron, the thermal quantum $k_B T$, and the energy $eV_b$ gained by an electron in falling through the bias voltage $V_b$. The first electron which arrives on the island from the source electrode charges it to a potential which is sufficient to prevent any further electrons hopping to the island until the first electron has left via the drain electrode. The charges are encouraged to jump from the island to the drain (and hence make room for more charges to arrive from the source) by appropriate bias on the gate electrode. If the thermal quantum size is arranged to be small compared with the electrostatic energies in play, the risk of random thermal interference with the current control is negligible.

### *12.1 The Ferromagnetic Single Electron Transistor*

In a spin transistor, there is a fourth energy term which we can now introduce into the problem, namely the electrochemical potential difference for spin-up and spin-down electrons associated with a spin accumulation. In practice this is achieved by making the electrodes and/or the island from ferromagnetic material. A ferromagnetic source electrode will in principle produce a spin accumulation on a nonmagnetic island and, under certain bias conditions, the associated electrochemical potential holds the balance of power between the main energy terms and hence has a large degree of control over the current flow to the ferromagnetic drain. Other configurations are possible in which the island also is magnetic. Fert and Barnas have made extensive calculations for various temperature regimes of the various possible modes of behavior of such devices which are called ferromagnetic single electron transistors (FSETs) or spin SETs (Barnas and Fert 1998).

### *12.2 Spin Blockade*

Another possibility which arises also if the magnetic island is itself a ferromagnet is that of a spin-blockaded system in which electrical transport across the device is switched by magnetizing the island (Sirisathitkul *et al.* 2001a). An example is a Schottky barrier on the edge of which has been placed a series of magnetic islands which are antiferromagnetically coupled (and hence blockaded) in zero applied magnetic field. Applying a field orients these superparamagnetic particles and the resistance of the structure decreases owing to a tunnel-hopping current between adjacent islands. Exposure to light increases the resistance of the structure owing to photon-promotion of electrons from the islands to the large density of adjacent surface states. The geometry of this system is not unlike that of a high electron mobility transistor (HEMT) in which the performance of the main current channel is controlled by localized states in a physically distinct nearby region of the device.

### 13. Three-terminal Spin Electronic Device Variants

Ounadjela and Tiusan (1999) have proposed a neat and versatile metallic spin-tunnel transistor with particular relevance to three-terminal spin-tunnel MRAM application. The device has two tunnel barriers between emitter/base and base/collector respectively. It operates on the SPICE principle and has numerous variants which differ in respect of the precise location of the encoder and decoder electrodes relative to the collector structure.

Mizushima *et al*. (1998, 1999) have also produced a variety of interesting tunnel transistor designs, again operating on the SPICE principle but, unlike the Ounadjela/Tiusan device they comprise semiconductor collector elements.

### 14. Spin Electronics in Carbon Nanotubes

An unusual but prophetic venture in spin electronics is the use of single-wall carbon nanotubes as spin conductors (Alphenaar *et al*. 2000). Surprisingly it is discovered that the spin diffusion lengths in such tubes are many tens of nanometers and their future application looks promising.

### 15. Voltage-induced Switching

Interesting predictions have been made with respect to the simple RKKY-coupled GMR trilayer structure to the effect that the interlayer magnetic coupling could be changed in sign by application of sufficient voltage across the structure (You and Bader 1999). The object of such endeavor is to produce a magnetic memory element or switch whose transport in one dimension may be altered by magnetic switching which is induced not by external magnetic fields but rather by an electric potential in *n* orthogonal direction. This remains to be demonstrated experimentally.

### 16. Current-induced Switching

Current-induced switching of a spin electronic structure has also been predicted and experimental results are available which appear to confirm it. The principle harks back to an idea of Luc Berger (Myers *et al*. 1999) in which he examines the relationship between current density and the torque/force on a ferromagnetic domain wall. If a sufficiently large spin-polarized current is incident normally on a domain wall, the spin angular momentum exerts a torque which twists the spins and hence effectively causes the wall to move. When implemented in ferromagnetic nanocontacts, the effect is attractive as an operating principle for simple MRAM memory elements (Coey 2001).

### 17. Quantized Conductance

When a point contact with dimensions of atomic size is made between two metallic nanowires, the lateral confinement causes mutual distancing of the k-states in a plane perpendicular to the direction of current flow (Ott *et al*. 1998). This means that only a small number of conductance channels are below the metal Fermi surface. By varying the contact width, the individual conductance quanta may be observed. Simple theory suggests that in the case of spin asymmetric contacts, the quanta should be halved, but so far this effect has eluded observation.

### 18. Measuring Spin Asymmetry

Various techniques are used for estimating the spin asymmetry of spin electronic materials. They include spin-resolved photoemission (Park *et al*. 1998), Andreev reflection (Soulen *et al*. 1998), measurement of the Zeeman effect of chemical potential (Sirisathitkul *et al*. 2001b), and by spin tunneling to a material with 100% polarization (de Teresa *et al*. 1999). The last tunneling technique relies on the control electrode genuinely behaving as if it is 100% polarized. Merely because its bulk bandstructure is fully polarized is no guarantee of this. As discussed above, the polarization which magnetic electrodes manifest for tunneling purposes is found to be a function of the magnetic metal/insulator combination, not just of the magnetic metal itself. Thus, it is important that the control electrode is always accompanied by the same insulator. This casts a new light also on the other measurement techniques for measuring spin polarization and shows not only the importance of establishing exactly what they are measuring, but it also begs the question as to what we really should be trying to measure for practical purposes.

### 19. Competing Magnetotransport Phenomena

There exists a large number of magnetotransport effects which are not strictly spin electronic in origin but which nonetheless can display similar characteristics. They include anisotropic magnetoresistance, Hall effect and anomalous Hall effect.

In this category, an interesting and potentially useful giant magnetotransport effect has been observed in a ferromagnet/semiconductor structure in which arrays of submicron ferromagnets are fabricated on a heterostructure containing a near surface two-dimensional electron gas. The magnetoresistance arises from electrons propagating in open orbits along lines of zero magnetic field (Nogaret *et al*. 1997).

### 20. Measurement Artefacts

In spin electronics the currents and voltages measured are frequently small and this heightens the need

for vigilance against interference from rival transport effect and spurious artefacts. The most obvious sources of such trouble are radiated electrical noise and earth loops. However there is also a more subtle artefact which may occur in a.c. transport measurements in applied magnetic field if the flying leads to the sample are free to move. The current carrying wires are subject to a harmonic torque in a magnetic field and if they are capable of mechanical displacement this leads to a harmonic flux variation. The result is a parasitic voltage and hence an apparent resistance which is proportional to the square of the magnetic field.

## *21. Applications of Spin Electronics*

Applications to date of spin electronics include hard disk read heads, advanced high density tape heads, and various position and motion sensors based on GMR and high frequency properties of spin electronic materials. Although not yet commercialized, spin tunnel MRAM is at an advanced stage of development also. More speculative uses with future potential include applications of spin FETS to quantum information processing and the radiofrequency ferromagnetic single electron transistor.

# Magnetic Recording Systems: Spin Valves

The rapid increase in information storage density in magnetic recording systems over recent years has been made possible in part by the development of spin-valve (SV) read heads. These rely on the phenomenon of giant magnetoresistance (GMR), in which a change in resistance is observed on application of a magnetic field (see *Giant Magnetoresistance*). This article discusses the GMR effect on which the devices are based, and also the parameters that are important in consideration of the design of spin-valve structures, such as the choice of materials for the various layers in the device, and thermal stability. The effect of microstructure and of magnetization reversal on device operation are also discussed.

## *1. Introduction*

A change in resistance on application of a magnetic field in magnetic materials gives rise to a tremendous number of applications in the electronics industry. One of the most spectacular examples is the application of giant magnetoresistance in ultrahigh-density magnetic recording technology, and one of the devices based on this phenomenon is the SV structure that has applications as read heads (Brug *et al.* 1996) in hard disk storage systems or as magnetoresistive random access memory (MRAM) elements (Daughton 1997). The rapid increase in interest in these devices has been motivated by the high demand for improvement in information storage density and performance, mainly for graphics-intensive applications.

Improvements in signal processing and disk media, plus the development of SV read heads, have allowed the density to be increased to 50 Gb/in$^2$ with a projected obtainable density of 80–100 Gbits/in$^2$. The limits on memory density that can be achieved using solid-state memory (for example DRAM) means that there has been renewed interest in the development of magnetic memory based on the GMR effect, namely MRAM. In addition, MRAM would be nonvolatile.

## *2. The GMR Effect*

GMR is observed in films consisting of alternate ferromagnetic (FM) and nonmagnetic layers, as a

large change in resistance with applied magnetic field. The resistance is a function of the relative alignment of the magnetization in the magnetic layers, and thus of spin-dependent scattering of the conduction electrons. It was first observed for Fe/Cr multilayers with thicknesses of a few nanometers.

(For a general description of GMR the reader is referred to a number of review papers, for example Dieny (1994).) The GMR ratio is defined as:

$$\Delta R/R = (R - R_P)/R_P \quad (1)$$

where $R_P$ is the resistance for parallel alignment of the FM layer magnetization directions. The maximum GMR ratio is observed when

$$R = R_{AP} \quad (2)$$

where $R_{AP}$ is the resistance of the antiparallel magnetization configuration.

## 3. The Spin Valve Structure

SV structures (see, for example, review of SV structures in Portier and Petford-Long (1999), however, offer greater possibilities for development for real applications than multilayer structures. In their simplest form, a SV consists of two ferromagnetic layers separated by a nonmagnetic spacer layer. The magnetization direction (easy axis) of one FM layer is fixed by an adjacent antiferromagnetic (AF) layer (pinning layer) through exchange coupling (see *Multilayers: Interlayer Coupling*). The magnetization direction of the other FM layer (sense layer) can be rotated by applying a small external magnetic field (of the order of a few oersteds) in the plane of the layers. A schematic illustrating the structure of a simple SV is shown in Fig. 1(a).

In a spin valve, unlike in a GMR exchange coupling of the two FM layers across it is small. For a spin valve, the GMR is linearly dependent on $(\cos\theta)$ where $\theta$ is the angle between the sense and pinned layer magnetizations:

$$R(\theta) = R_P + (R_{AP} - R_P)(1 - \cos\theta)/2 \quad (3)$$

When applying the external field perpendicular to the easy axis, the change in resistance is linear with low coercivity and a sense layer magnetization reversal characterized by coherent rotation (see Fig. 1(b)). This configuration is used for sensors. The second commonly used configuration is to apply the external field along the easy axis direction. In this case, two remanent states can be stabilized with either parallel (P) or antiparallel (AP) alignment of the magnetization of the pinned and sense layers. The magnetization reversal is then a hysteretic reversal process, with the P and AP states corresponding to the minimum and maximum resistance values,

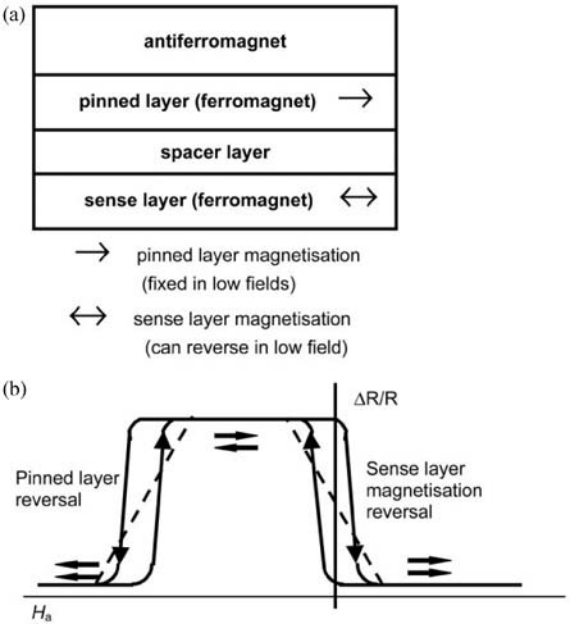

***Figure 1***
(a) schematic cross-section through a simple SV structure, (b) schematic GMR curve for a SV with the external field applied perpendicular to the easy axis of magnetization in the pinned layer (- - - - -) and with the external field applied parallel to the easy axis of magnetization in the pinned layer (——).

respectively. This is suitable for MRAM devices (high and low resistance could correspond to "1" and "0" bit states). A GMR ratio of up to 23.4% has been obtained for a SV structure at room temperature.

Despite the fact that SV materials have been introduced commercially as read heads in the latest generations of hard disk drives, a number of problems remain to be solved. These include magnetostatic coupling of the pinned and sense layers, which leads to an offset of the GMR curve with respect to remanence, and thus to a need for a higher operating magnetic field, low exchange coupling between the pinned and pinning layer for some configurations, and a reduction in GMR after lithographic processing. Solving these problems requires understanding the microstructure and local magnetic structure of the SV films.

### 3.1 Microstructure

To enhance the GMR ratio, several different SV structures have been proposed, for example the "top" SV (see Fig. 1(a)) and the "bottom" SV in which the layer order is reversed. Changing the deposition order changes both the crystallographic texture of the film

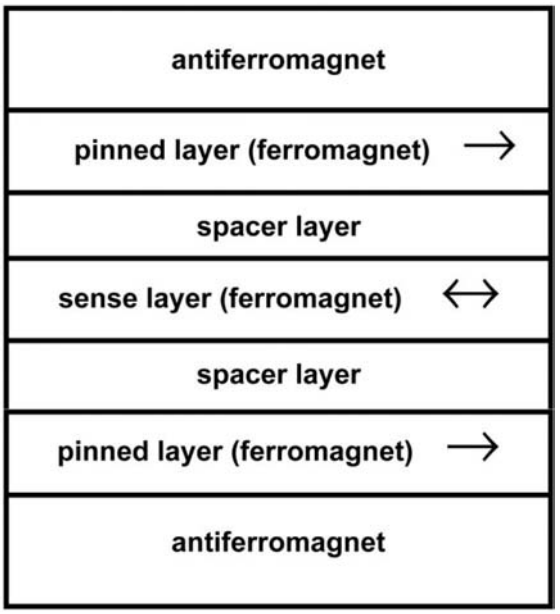

***Figure 2***
Schematic of dual SV structure.

and the interfacial roughness, which are of crucial importance in controlling the GMR. Figure 2 shows a schematic of the dual, or symmetric, SV, which contains one central FM sense layer and two biased FM layers. This structure has been found to increase the GMR ratio up to 23.4% compared with a top SV made with the same materials which gives only a 10% GMR ratio. In all cases, the FM material used for the pinned and sense layers can be either the same or different, depending on the properties required. The structures are usually protected from oxidation by a cap layer.

One of the important requirements in operating SV structures is to be able to reverse the magnetization of the sense layer in a low external magnetic field, hence the use of soft magnetic materials such as Permalloy ($Ni_{80}Fe_{20}$). Cobalt is also widely used and has a higher saturation magnetization, coercivity, and magnetocrystalline anisotropy, particularly for the h.c.p. structure, which tends to form for layer thicknesses greater than 4 nm. Sense layer *thickness* is also important, with an increase in thickness leading to a larger grain size and decrease in coercivity. A typical grain size is about 20 nm for an 8 nm-thick NiFe sense layer, which gives an optimal GMR ratio.

Another alternative for the pinned layer is to use an artificial antiferromagnet (AAF) such as Co/Ru/Co, in which the cobalt layers are antiferromagnetically exchange-coupled across the ruthenium, and one of the cobalt layers is pinned by an adjacent AFM material. The net magnetization of the pinned layer is then close to zero. SVs containing an AAF show good sensitivity to an external magnetic field because stray-field coupling between the pinned and sense layers in lithographically defined elements is very much reduced.

The spacer layer needs to be very conductive to reduce spin-independent scattering of the conduction electrons and is commonly copper, silver, or gold. Copper is most widely used as its structure matches well (1.85% mismatch) with those of cobalt or $Ni_{80}Fe_{20}$. Intermixing between NiFe and copper can lead to the formation of a paramagnetic interfacial alloy layer, resulting in spin-flip scattering and loss of GMR, but this can largely be avoided by inserting a thin cobalt layer at the NiFe/Cu interface. The GMR properties of SVs are very dependent on the nature of the interfaces between the layers, and three different types of interlayer coupling can arise across the FM/NM/FM interfaces:

- FM exchange coupling between the FM layers through pinholes in the spacer, although this is largely avoidable for spacer layers thicker than about 1.5 nm.
- Magnetostatic ''orange-peel'' coupling which arises because of the waviness of the FM layer/spacer layer interface leading to free magnetic poles of opposite sign across the spacer layer, for which Néel proposed a model relating the period and the amplitude of the waviness to the coupling strength.
- An oscillatory Ruderman-Kittel-Kasuya-Yosida (RKKY-like) coupling which is dependent on the spacer layer thickness and decays with increasing thickness in an oscillatory manner between FM and AFM coupling. The spacer layer thickness is usually chosen to be high enough that the RKKY coupling is negligible, but if it is too high, increased spin-independent scattering of the conduction electrons and increasing shunting of the current through the spacer layer lead to a decrease in GMR. The optimum thickness has been found to be $\sim$2.5–3 nm.

One of the key parameters for a SV device is the strength of the exchange coupling ($\mathbf{H_{ex}}$) between the antiferromagnetic (pinning) and pinned layers (see Nogués and Schuller 1999) for a review of exchange-biasing effects). The exchange field is set by applying a magnetic field during deposition or postdeposition anealing in order to align the magnetization of the first monolayer of the AFM material with that of the adjacent FM layer. The coupling strength depends on the AFM material used and on its microstructure, with the most commonly used materials being FeMn, NiMn, and IrMn, although other materials such as CoO, NiO, TbCo, $\alpha$-$Fe_2O_3$, and other manganese alloys are being considered. An increase in $\mathbf{H_{ex}}$ and in the pinned-layer coercivity are observed when reducing the thickness of the FM material, and an increase of $\mathbf{H_{ex}}$ and of the blocking temperature (the temperature above which no exchange field is observed) have been linked to an increase in grain size.

The surface topology is also important since a smoother interface between the pinning and pinned layers tends to improve $\mathbf{H_{ex}}$.

The first systems to be studied used FeMn because it is structurally very similar to the FM and spacer layers. However, $\mathbf{H_{ex}}$ ($\sim$150 Oe) and the blocking temperature ($\sim$150 °C) are relatively low and its corrosion resistance is not very high (this can be improved by adding chromium, iridium, platinum, rhodium, or ruthenium during deposition). The most promising AFM material to date is MnNi with $\mathbf{H_{ex}}$ up to 500 Oe after annealing, a blocking temperature of $\sim$380 °C, a reasonable corrosion resistance, and very good thermal stability. The as-grown MnNi is cubic and nonmagnetic, but an anneal at about 220 °C for 1 hour leads to a phase transformation to the antiferromagnetic face-centred-tetragonal (f.c.t.) phase. A difficult task is to determine the real proportion of MnNi grains with the f.c.t. structure compared to those still with the f.c.c. structure.

The most common deposition techniques used for fabricating SVs are ion-beam deposition (IBD), DC magnetron sputtering, and MBE. MBE-grown films tend to be epitaxial and single crystal, whereas the sputtered films are polycrystalline. Films grown by IBD usually have higher resistivities and lower GMR than DC magnetron-sputtered films because of greater intermixing between the layers. Polycrystalline films tend to show better GMR properties than MBE-grown films, but a good $\langle 111 \rangle$ texture between the pinning and the pinned layers is preferable for a strong pinning effect. In addition, the coercivity of the sense layer is lower for a well-textured film, which enables a rapid transition between the P and AP states for MRAM applications.

To increase the grain size and degree of texture in the film, a seed layer such as niobium, tantalum, titanium, or zirconium is commonly used. Tantalum is the most widely used, as it induces the $\langle 111 \rangle$ texture for most of the various FM materials used as the sense layer resulting in a columnar growth from bottom to top in the SV structure. In addition, the tantalum/FM layer interface usually has a good thermal stability. However, an intermixed, magnetically "dead" layer of a few monolayers is often observed between the seed and the FM layer. Note that for bottom SV structures it is sometimes necessary to deposit a thin FM layer below the AFM material to obtain a good crystallographic texture.

## 4. Thermal Stability

The GMR amplitude decreases linearly with temperature by a factor of about three from 4 K to room temperature. The main effect is magnon scattering of the conduction electrons in the bulk of the FM layers which has been correlated to the Curie temperature of the FM material, but another contribution will be phonon scattering in the NM layer preventing the exchange of conduction electrons between the sense and pinned layers. Operating a SV structure at elevated temperatures thus leads to a decrease of the GMR effect, but the critical temperature above which the linear dependence is lost depends strongly on the structure used.

The critical temperatures are much lower than in bulk materials because of the numerous grain boundaries whose diffusion coefficients are much higher than the bulk values, favoring layer interdiffusion at lower temperatures. In addition, changes to the interface between the seed layer and the sense layer can degrade the GMR effect following annealing, because of the formation of a high-resistivity alloy at the seed layer/FM interface. The cobalt/copper system is more thermally stable than other systems such as NiFe/copper, for example, because cobalt/copper is a phase-separating system and, because the Curie temperature of cobalt is high in comparison with NiFe, although the GMR properties are not as good.

## 5. Micromagnetic Considerations

### 5.1 Sense-layer Reversal

One of the important parameters for the operation of a SV is the magnetization-reversal mechanism of the sense layer, because of its influence on the GMR response of the SV. If the applied field is along the easy axis direction, the reversal of the sense layer magnetization occurs via domain wall motion for NiFe, and by magnetization rotation mechanisms for cobalt, with a higher reversal field for the cobalt-based SVs. This is expected because of the higher saturation magnetization and magnetocrystalline anisotropy of cobalt. However, some other features can be seen, which are directly attributable to the FM interlayer coupling. First, the domain structure for a NiFe-based SV is more complex than for a single NiFe film. In addition, domain walls are observed to lie at an angle with respect to the easy axis direction because of the residual torque associated with coupling to the pinned layer.

Third, the P–AP and AP–P reversal are not symmetric, with more magnetization rotation observed for the AP–P reversal. This is a result of the combination of the unidirectional anisotropy imposed by the exchange field of the AFM layer on the pinned FM layer and the FM "orange-peel" magnetostatic coupling between the pinned and sense layers.

A further important feature is that the hysteresis loop is shifted with respect to zero field, and there are a number of terms that contribute to this effect. The first of these is the orange-peel coupling ($\mathbf{H_{FM}}$), which is FM in nature. Second, there is a magnetic field induced by the current passing through the device ($\mathbf{H_I}$), whose effect depends on the direction of current flow and its magnitude.

A simple model based on Ampere's law:

$$\mathbf{H_I} = 0.75I(4\pi \times 10^{-3})/2h \quad (4)$$

where $I$ is the current and $h$ is the height (width) of the element, provides good agreement with experimental observations. Third, magnetostatic stray-field coupling occurs at the edges of a lithographically defined SV element because of the demagnetizing field ($\mathbf{H_d}$) between the pinned and sense layers. This phenomenon becomes of primary importance as the element size is reduced and is strongly dependent on element size and shape. The stray-field coupling is AFM in nature, and $\mathbf{H_d}$ can be simply estimated using:

$$\mathbf{H_d} = -(4\pi Mt/h)u_y \quad (5)$$

where $M$ and $t$ are the saturation magnetization and thickness of the sense layer, respectively, $h$ is the width of the element, and $u_y$ is a unit vector in the easy axis direction. A possible expression for the offset field ($\mathbf{H_{off}}$), by which the GMR curve is displaced from zero, can then be given as:

$$\mathbf{H_{off}} = \mathbf{H_{FM}} + \mathbf{H_I} + \mathbf{H_d} \quad (6)$$

As mentioned previously, a decrease in sense-layer thickness and/or the use of an AAF as the pinned layer lead to a substantial reduction of the stray field coupling. Flattening the FM/NM/FM layer interfaces, for example by the use of a surfactant such as indium, can reduce the orange peel coupling. $\mathbf{H_{off}}$ should be kept as low as possible to reduce the external field that must be applied to reverse the sense layer magnetization.

Finally, 360° domain walls are often observed, mainly at the end of the P–AP transition, which consist of a pair of very close domain walls separated by a very narrow region of film in which the magnetization in the two FM layers is still in the P configuration.

These defects remain up to a much higher applied field value and act as domain nucleation sites for the opposite reversal, which can result in differences in reversal field for different devices with nominally exactly the same structure. Applying an external field perpendicular to the easy axis results in a magnetization reversal of the sense layer via coherent magnetization rotation with a single domain behavior.

Assuming that the magnetization of the pinned layer remains parallel to the easy axis during the reversal, the change in resistance is only due to the change in magnetization direction in the sense layer. This assumption is based on the fact that the exchange bias field is usually much higher than the reversal field of the sense layer. An important issue is thus the uniformity of the pinned layer magnetization. Nonuniformity can result in different responses from nominally identical devices, since the GMR is determined by the misorientation between the magnetization directions of the FM layers, and can be caused by variations in the exchange coupling imposed by the adjacent AFM layer, for example because of incomplete transformation to the f.c.t. phase for MnNi.

The operating temperature of devices such as read heads in hard-disk systems can be of the order of 150 °C, so the thermal behavior of SV films is an important issue. An increase in temperature results in a reduction in both the field value and the field range over which the sense layer magnetization reverses. This is believed to be a result of the increase in thermal energy which compensates the effect of the FM interlayer coupling. If the temperature becomes too close to the blocking temperature, then $\mathbf{H_{ex}}$ becomes zero, leading to simultaneous magnetization reversal of the two FM layers and loss of the GMR effect.

Current density through the SV is an important parameter in operating SV elements since it imposes the amplitude of the signal to be read for distinguishing the P and AP remanent states. A typical value is of the multilayer, the spacer layer thickness is such that the order of $10^7\,\mathrm{Acm}^{-2}$ and a decrease in GMR and in coercivity are usually observed with increasing current density. The current can also have a more subtle effect on the sense layer magnetization reversal because the increase in thermal energy supplied to the device can counteract the coupling between the sense and pinned layers. There will also be a current density limit above which the film resistance increases dramatically and, consequently, above which the element begins to be damaged by heating effects. The critical current density depends on the size and shape of the element.

# Magnetic Recording Technologies: Overview

Magnetic recording technology is the key element of large-scale information storage and retrieval. In addition to its obvious importance in science and engineering, it has become indispensable to our daily lives. When we make a bank transaction, reserve an airplane ticket, use a credit card, or watch a movie from a videotape, we are using the technology of magnetic recording. The general requirements for data storage are information integrity, fast access, and low cost. In its simplest form, a magnetic recording system consists of a magnetic head and a magnetic medium, as schematically shown in Fig. 1. The head is made of a piece of magnetic material in a ring shape, with a small gap facing the medium and a coil away from the medium.

The head records and reproduces information, while the medium stores the information. The recording process is based on the phenomenon that an electric current $i$ generates a magnetic flux $\varphi$ as described by Ampere's law. The flux $\varphi$ leaks out of the head core at the gap, and magnetizes the magnetic medium. The orientation of the magnetization is determined by the current direction. As the medium moves from left to right with a velocity $V$ under the head gap, magnetization is retained in the medium at different locations.

There are two types of head used in reproducing. One senses magnetic flux change rate, and the other senses the magnetic flux. During the reproduction process, a magnetized medium is placed under the head gap. A part of the flux coming out of the medium surface enters the head through the gap. As the medium moves, the prerecorded information is reproduced by the head.

The distance between two closest transitions in the medium is the flux change length $B$, and the distance between two adjacent data tracks is the track pitch $W$, which is wider than the data track width $w$. The flux change length can be directly converted into bit length with the proper coding scheme. The reciprocals of the bit length and the track pitch are termed the linear density and the track density, respectively. Their product yields the areal density of the information stored in the medium. This areal density is a figure of merit for a recording system.

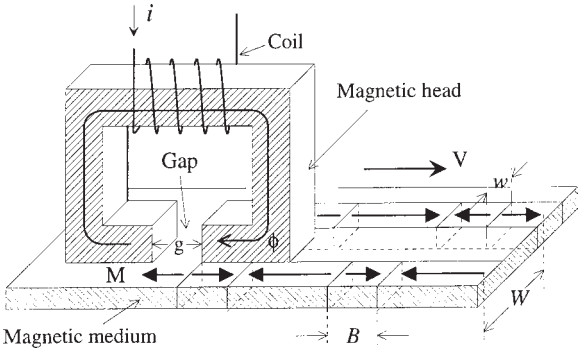

***Figure 1***
Conceptual diagram of a magnetic medium and an inductive head.

The research and development efforts of the magnetic recording industry have been focused on increasing the areal density. During the 1990s, the areal density was increasing at 60% annual rate. More recently, the rate has been accelerated to more than 100%. At present, hard disk drives used in desktop computers feature areal densities of more than $30\,\mathrm{Mb\,mm^{-2}}$ ($B<0.06\,\mu\mathrm{m}$ and $W<0.6\,\mu\mathrm{m}$). This yields a total storage capacity of more than 30 Gb for a disk of 95 mm diameter.

## 1. Magnetic Media and Magnetic Heads

Magnetism is the result of uncompensated electron spin motions in an atom. Only transition elements exhibit this property, and nearly all practical interest in magnetism centers on the first transition group of elements (manganese, iron, nickel, and cobalt) and the rare earth elements (gadolinium, and terbium). While the first transition group of elements and their alloys are the materials used in magnetic recording, amorphous rare earth-transition metal alloys are the only commercially used magneto-optical storage medium. The strength of magnetism is represented by magnetization $M$, and is related to magnetic field $H$ and magnetic flux density $B$ by

$$B = \mu_0(H + M) \tag{1}$$

where $\mu_0$ is the permeability of vacuum. The ratio of $B$ with and without a magnetic material is the relative permeability $\mu$ of that magnetic material.

When a magnetic field $H$ is applied to a piece of demagnetized magnetic material, the magnetization $M$ starts increasing with $H$ from zero. The rate of increase gradually slows down and $M$ asymptotically approaches a value $M_s$. If $H$ is reduced to zero, $M$ follows to a lower value $M_r$. Further reduction of $H$ to a very high negative value will magnetize the material to $-M_s$. In order to bring the material to the demagnetized state, a positive field $H_c$ is required. Continuous increase in $H$ field will bring the trace of $M$ to a closed loop. This loop is the major hysteresis loop, as illustrated in Fig. 2.

The hysteresis loop shows that magnetic material has memory. It is this memory that is used in the medium for storing information. $H_c$ is the coercivity, indicating the strength of magnetic field required to erase the memory of a magnetic material. Magnetic materials with high $H_c$ are "hard" magnets, and are

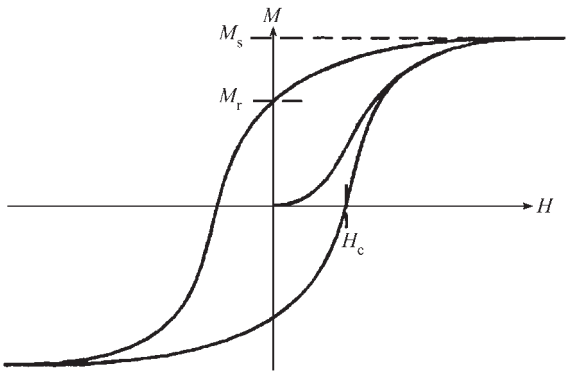

***Figure 2***
Hysteresis loop of a magnetic material.

suitable for recording media applications if they also have high $M_r$. On the other hand, magnetic materials with low $H_c$ are "soft" magnets, and are candidates for head core materials if they also have high $M_s$ and high $\mu$. $M_r$ and $M_s$ are the remanent and saturation magnetization, respectively, and their ratio is the remanent squareness.

There are two groups of magnetic media. The first group is called particulate media because the magnetic materials are in the form of particles. This group includes oxide ($\gamma$-$Fe_2O_3$), cobalt-modified iron oxide ($\gamma$-$Fe_2O_3 + Co$), metal particles, and barium ferrite ($BaFe_{12}O_{19}$). Some of these have been used in magnetic recording for several decades. The other group of media is called the thin-film media, because the magnetic layer can be deposited as a continuous thin film. Most materials in this group are cobalt-based alloys. Compared with particulate media, the thin-film media usually have a higher coercivity $H_c$ and a higher remanence $M_r$, and are suitable for high areal density applications.

Magnetic media can be classified into three general forms of applications. Tape is the oldest form and remains an important medium today. It is central to most audio, video, and instrumentation recording, although it is also used in the computer industry for archival storage. It is economical and has a large capacity, but suffers slow access time. Hard disk is traditionally the primary storage unit inside a computer, and is just being introduced in the consumer market (audio/video box). It provides the user with fast data access, but has poor transportability. Flexible disk is designed for easy data removability, but is limited in capacity. Besides these three general forms of applications, a hybrid of flexible medium and hard disk has appeared recently. It is a removable rigid disk capable of holding up to several gigabytes of digital data. In addition, magnetic stripes are getting widely used in various forms of cards.

The magnetic layer alone cannot be used as a medium. It needs additional components to improve its

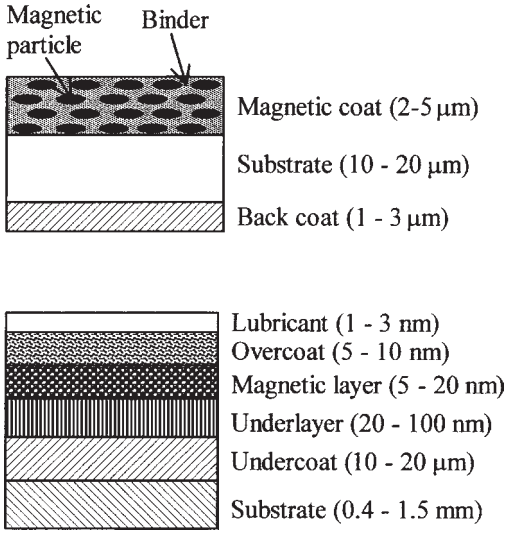

***Figure 3***
Cross-sections of a particulate magnetic tape (top) and a thin-film hard disk (bottom).

chemical and mechanical durability. Typical cross sections of a particulate magnetic tape and a thin-film hard disk are shown in Fig. 3. In the case of tape application, iron particles with a typical size of 0.5 μm long and 0.1 μm wide are dispersed in a polymeric binder, together with solvents, lubricants, and other fillers to improve magnetic and mechanical durability. This dispersed material is then coated on a biaxially oriented polyethylene terephthalate substrate. An optional back coat may also be applied to the other side of the substrate. The cross section of a hard disk is more complex. A high-purity aluminum–magnesium (5 wt.%) substrate is diamond-turned to a fine surface finish, and then electrolessly plated with a nonmagnetic nickel–phosphorus (10 at.%) undercoat.

This layer is used to increase the hardness, reduce the defects, and improve the finish of the aluminum–magnesium alloy, and is polished to a super surface finish. Next, an underlayer of chromium is sputtered to control the properties of the magnetic film, followed by sputtering the magnetic film. Finally, a layer of hydrogenated or nitrogenated carbon is overcoated on the magnetic film, and an ultrathin layer of perfluorinated hydrocarbon liquid lubricate is applied on top. The carbon and lubricant layers are used to improve the corrosion and mechanical resistance of the disk. To achieve high shock resistance, glass disk is sometimes used, especially in mobile applications. For a 95 mm disk, the finished product should have a surface flatness better than 8 μm and an arithmetic average roughness ($R_a$) of less than 0.3 nm.

Magnetic heads serve three functions: recording, reproducing, and erasing. Two groups of head are employed to carry out these three functions. The

first group is the inductive heads, as schematically illustrated in Fig. 1. The evolution of the inductive head follows the selection of core materials, as shown in Fig. 4. Early heads used laminated molybdenum Permalloy (Ni–Fe–Mo, 79–17–4 wt. %). The primary drawbacks are frequency limitation, gap dimension inaccuracy, mechanical softness, and frequency limitation caused by eddy current loss. One way to reduce eddy current loss is to increase core material electric resistivity. Two types of ferrite material have high resistivity (four to nine orders higher than Permalloy) and reasonable magnetic properties: nickel–zinc and manganese–zinc.

These materials are also very hard, providing greater head durability during head/medium contacts. The major deficiency of ferrite materials is their low $B_s$ values. In order to record in high $H_c$ media, high flux density $B$ is needed in the head core. When the flux density in the core material reaches its saturation $B_s$, it will not increase despite the increase of recording current or coil turns. This saturation starts from the corners of the gap due to its geometry. To remedy this deficiency, a layer of metallic alloy material with much higher $B_s$ is deposited on the gap faces. This type of head is called the metal-in-gap (MIG) head.

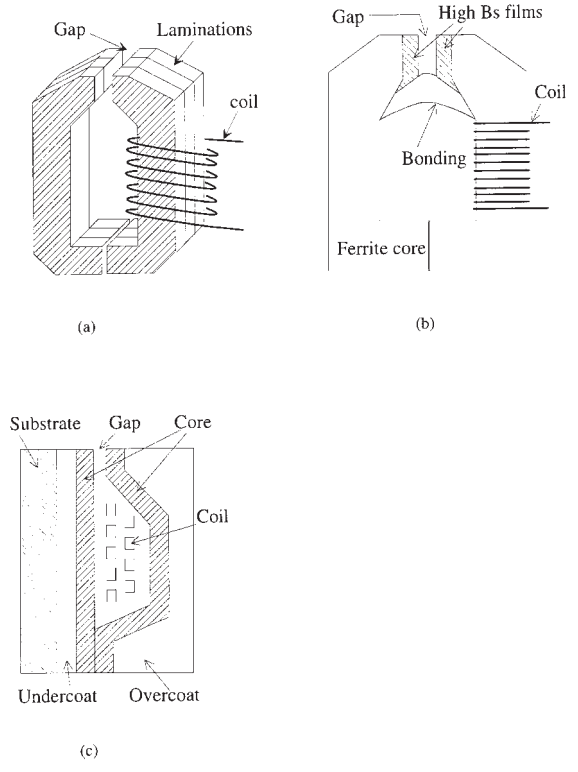

***Figure 4***
Various inductive head structures: (a) laminated, (b) MIG, and (c) thin film.

Thin-film heads capitalize on semiconductor-like processing technology to reduce the customized fabrication steps for individual heads. The core, coil, gap, and insulator layers are all fabricated by electroplating, sputtering, or evaporation. Due to the nature of the semiconductor process, the fabrication is more accurate for small dimensions. Small gap dimensions are suitable for high linear and track density, and small core dimensions allow the use of high $B_s$ Permalloy material (nickel–iron, 80–20 wt. %) as a core with low inductance for high data-rate applications. The high cost of the semiconductor-like process is offset by high throughput: a 150 mm × 150 mm wafer can produce 40 000 pico-slider heads (1.25 × 1.00 × 0.30 mm). One disadvantage is the limited band-recording capability because the small pole length limits low-frequency response. A second disadvantage is the Barkhausen noise, which is characterized as the sudden jump of magnetic flux flowing around the head, and is caused by the relatively small number of magnetic domains in the core.

The recording and erasing functions are performed by an inductive head in all magnetic recording devices. The reproducing function, however, can be carried out either by an inductive head or by a magnetoresistive (MR) head. The reproducing performance of an inductive head is described by Faraday's equation:

$$v = -nV\frac{\mathrm{d}\phi}{\mathrm{d}x} \tag{2}$$

where $v$ is the output electric voltage from the head, $n$ is the number of the coil turns, $V$ is the medium moving velocity, and $\mathrm{d}\varphi/\mathrm{d}x$ is the derivative of the magnetic flux with respect to medium moving direction.

When an inductive head is used for reproducing, this head is usually also used for recording and erasing. The optimal performance cannot be achieved because recording and reproducing have contradictory requirements for head design. To solve this problem, a new reproduction head was introduced in the 1990s. This is the MR head. An MR head is always integrated together with an inductive head in such a way that the MR head performs the reproducing and the inductive head carries out the recording and erasing.

The first generation of MR head introduced in 1990 is the anisotropic type (AMR). As shown in Fig. 5, conceptually, an AMR head has a magnetoresistive element (MRE) and two electric leads. The MRE is a Permalloy stripe (nickel–iron, 80–20 wt.%), with thickness $t$, width $w$, and height $h$. An electric current, with density $J$, passes through the MRE through the leads. The electric resistivity of the MRE is a function of the angle $\theta$ between $J$ and MRE magnetization $M$:

$$\rho_\theta = \rho\left(1 + \frac{\Delta\rho}{\rho}\cos^2\theta\right) \tag{3}$$

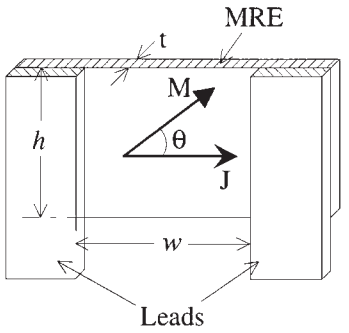

***Figure 5***
Conceptual diagram of an AMR head.

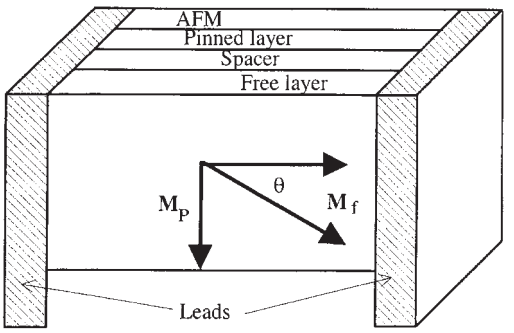

***Figure 6***
Conceptual diagram of a GMR head.

where $\rho_\theta$ is the resistivity at $\theta$, $\rho$ is the resistivity at $\theta = 90^o$, and $\Delta\rho$ is the resistivity difference between $\theta = 0^o$ and $\theta = 90^o$. $\Delta\rho/\rho$ is the anisotropic magnetoresistive ratio of the MRE. Usually a transverse magnetic field is applied to the MRE so that $\theta = \theta_0$ when the head is not reading a magnetic signal.

Assume that a magnetic signal from the medium rotates $M$ from $\theta_0$ to $\theta$, then an electric voltage change $v$ will be detected across the MRE as the output signal:

$$v = Jw\rho\frac{\Delta\rho}{\rho}(\sin^2\theta_0 - \sin^2\theta) \tag{4}$$

where $\theta_0$ is the bias angle and is set to 45° for good linearity. Equations (3) and (4) tell us that while inductive head output is proportional to medium velocity and not suitable for low-velocity applications, the MR head can be used for either high- or low-velocity applications.

The second generation of MR head introduced recently is the Giant Magnetoresistive (GMR) head (see *Giant Magnetoresistance*). The most commonly used implementation of the GMR head is the spin valve configuration. As depicted in Fig. 6, it has four basic layers. The antiferromagnetic material (AFM) provides an exchange field to pin the magnetization of the adjacent (pinned) layer to the direction 90° from the medium surface. A nonmagnetic spacer (typically copper) separates the magnetic free layer from the pinned layer. When there is no magnetic field from the medium, the magnetization of the free layer parallels with the medium surface.

When a magnetic field is applied from the medium, the magnetization of the free layer rotates an angle $\theta$ from its original direction. $\theta$ is a function of the strength and direction of the magnetic field. Similar to the AMR head, the resistivity of the MRE changes with magnetic field, yielding

$$v = \frac{1}{2}Jw\Delta\rho\sin\theta \tag{5}$$

Compared with the AMR head, the GMR head has higher sensitivity, better linearity, and needs no bias.

With some modifications and enhancements, the GMR head may be able to achieve an areal density around 100 Mbits mm$^{-2}$. Engineers and scientists in the magnetic recording industry and universities are exploring new reproducing heads to extend the areal density beyond that limit. A promising technique is the tunneling magnetoresistive (TMR) head. It is composed of two ferromagnetic layers separated by a thin insulating layer. The electric current flows in the direction perpendicular to the layers, in contrast with the GMR head where the current flows in the direction parallel to the layers. The TMR head promises to deliver higher linear density (smaller bit length $B$) and higher signal amplitude, but has the disadvantage of very high impedance.

## 2. *Recording and Reproducing Process*

Due to the nonlinear nature of the hysteresis loop, the recording process is complex and we need to adopt some approximation to simplify the analysis. If we set the origin of a coordinate system at the center of the gap with the $x$-axis on the head surface and the $y$-axis pointing away from the head, then the longitudinal magnetic field $H_x$ of this head can be expressed by the Karlqvist approximation:

$$H_x = \frac{ni}{\pi(g + lA_g/\mu A_c)}\tan^{-1}\left[\frac{yg}{x^2 + y^2 - (g^2/4)}\right] \tag{6}$$

where $n$ is the number of coil turns, $i$ is the current in the coil, $g$ is the gap length, $l$ is the core length, $A_g$ is the core cross-sectional area, $\mu$ is the relative permeability of core material, and $A_c$ is the gap cross-sectional area. Equation (6) shows that the contours of constant $H_x$ field are circles nesting on the two gap corners, as shown in Fig. 7. The greater the diameter of the circle, the weaker the magnetic field.

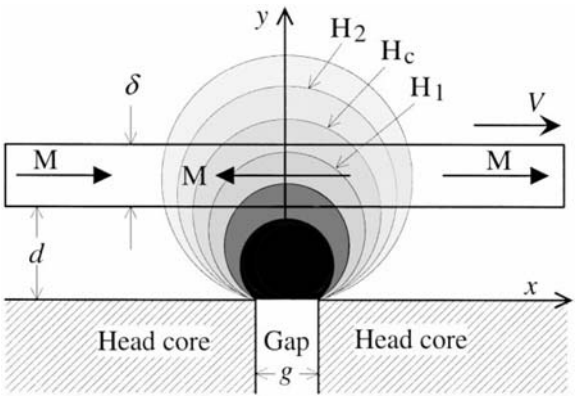

***Figure 7***
The contour of a longitudinal magnetic field from the Karlqvist approximation.

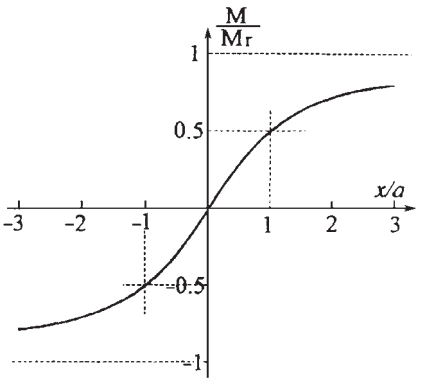

***Figure 8***
An isolated arctangent magnetization transition from negative $M_r$ to positive $M_r$.

Assume a magnetic medium, moving from left to right with a distance $d$ above the head, has a thickness $\delta$ and a magnetization $M$ pointing to the right. At some instant the recording current turns on and generates the magnetic field $H_x$ above the gap as depicted in Fig. 7. On the circumference of $H_x = H_c$, half of the medium material has its magnetization reversed and half remains the same, resulting in zero total magnetization. Since $H_x$ has a gradient, the medium closer to the gap (inside a smaller circle) gets its magnetization reversed more completely than the medium further away from the gap (outside a bigger circle). Therefore, magnetic transition is gradual in the medium even if the change of recording current follows a step function.

Assume the original magnetization is $M$ and the completely reversed magnetization is $-M_r$, this gradual change of magnetization for an isolated transition can be modeled by:

$$M = \frac{2}{\pi} M_r \tan^{-1}\frac{x}{a} \tag{7}$$

where $x$ is the distance from the center of transition, and $a$ is a parameter characterizing the sharpness of the transition as shown in Fig. 8. For a thin-film medium, $a$ is found to be

$$a = \frac{(1-S^*)(d+\delta/2)}{\pi Q} + \sqrt{\left(\left[\frac{(1-S^*)(d+\delta/2)}{\pi Q}\right]^2 + \frac{M_r\delta(d+\delta/2)}{\pi Q H_c}\right)} \tag{8}$$

where $S^*$ is the medium loop squareness, and $Q$ is the head-field gradient factor. For a reasonably well-designed head, $Q \approx 0.8$. It is obvious that we want to make parameter $a$ as small as possible so that we can record more transitions for a unit medium length. If the head gap length $g$ and medium thickness $\delta$ are small compared with head/medium separation $d$, and the medium has a squareness of one, then the minimum possible value of $a$ is:

$$a_m = \begin{cases} \dfrac{M_r\delta}{2\pi H_c} & \text{for } \dfrac{M_r\delta}{4\pi H_c d} \geqslant 1 \\ \sqrt{\dfrac{M_r\delta d}{\pi H_c}} & \text{for } \dfrac{M_r\delta}{4\pi H_c d} < 1 \end{cases} \tag{9}$$

In order to decrease the value of $a$ and therefore increase areal density, we need to reduce the medium remanence $M_r$, thickness $\delta$, head/medium separation $d$, and to increase the coercivity $H_c$.

In contrast to the recording process, the reproducing process is well understood. The flux density induced in the head core is small, yielding a linear process easier for mathematical treatment. The goals for higher areal density in magnetic recording are to reduce the pulse width ($PW_{50}$) and to increase the reproducing amplitude. The effect of various head parameters on pulse shape can be comprehended by studying the head reproducing voltage over an isolated transition (Fig. 8) with a thin magnetic layer. For an inductive head the output voltage is:

$$v(x) = \frac{-2\mu_0 V w M_r \delta n}{\pi(g + lA_g/\mu A_c)} \times \left[\tan^{-1}\left(\frac{g/2+x}{a+d}\right) + \tan^{-1}\left(\frac{g/2-x}{a+d}\right)\right] \tag{10}$$

where $x$ is the distance between the center of the head gap and the center of the transition, $\mu$ is the relative permeability of the core, $n$ is the number of coil turns, $g$ is the head gap length, $d$ is the head/medium separation, and $x$ is the distance between the center of the medium transition and the center of the head gap.

The term $lA_g/\mu A_c$ is closely related to $g$ for head efficiency. When an MR head is used for reproducing,

the sensor is usually sandwiched between two magnetic shields to increase its spatial resolution to medium signals. For an AMR head with small gap and 45° bias angle, it becomes:

$$v(x) = -\frac{2\sqrt{2}EJw\Delta\rho M_r\delta}{\pi t M_{fs}}\frac{g+t}{g} \times \left[\tan^{-1}\left(\frac{g/2+x}{a+d}\right)+\tan^{-1}\left(\frac{g/2-x}{a+d}\right)\right] \quad (11)$$

where $E$ is the head efficiency, $J$ is the current density, $t$ is the AMR film thickness, $g$ is the gap length (the distance between the MRE and the shield), and $M_{fs}$ is the saturation magnetization of the MR film. For a GMR head, the output is

$$v(x) = -\frac{EJw\Delta\rho M_r\delta}{\pi t M_{fs}}\frac{g+t}{g} \times \left[\tan^{-1}\left(\frac{g/2+x}{a+d}\right)+\tan^{-1}\left(\frac{g/2-x}{a+d}\right)\right] \quad (12)$$

It is clear from Eqns. (10) and (12) that the pulse shape versus $x$ is similar for an inductive, an AMR, and a GMR head. Since the MR film thickness $t$ is typically one order of magnitude smaller than the gap length $g$, the term $(g+t)/g$ is approximately a constant. This indicates that $g$, $a$, and $d$ affect pulse shape similarly for all three types of head, provided half of the gap length needs to be used for an MR head while the full gap length has to be used for an inductive head. In fact, the $PW_{50}$ can be derived as

$$PW_{50} \approx \sqrt{g^2+4(a+d)^2} \quad (13)$$

for all three types of heads. To increase linear density, we need to reduce gap length $g$, transition parameter $a$, and head-to-medium separation $d$.

The amplitude of a reproducing pulse is adversely affected by adjacent transitions because of the opposite polarity of the adjacent magnetizations. At high linear density, the magnetization variation in the medium approaches a sinusoidal wave,

$$M(x) = M_r \sin\frac{2\pi}{\lambda}x \quad (14)$$

where $\lambda$ is the wavelength. The reproducing voltage in an inductive head becomes:

$$v(x) = \frac{-\mu_0 VwM_r ng}{g+lA_g/\mu A_c}\left(e^{-\frac{2\pi}{\lambda}d}\right) \times \left(1-e^{-\frac{2\pi}{\lambda}\delta}\right)\left(\frac{\sin\frac{\pi g}{\lambda}}{\pi g/\lambda}\right)\cos\frac{2\pi}{\lambda}x \quad (15)$$

This equation presents all the important features of the high linear density reproducing process. The term $\exp(-2\pi d/\lambda)$ is the spacing loss. It shows that the reproducing voltage falls exponentially with the ratio of head/medium spacing to wavelength. The second term $1-\exp(-2\pi\delta/\lambda)$ is the thickness loss.

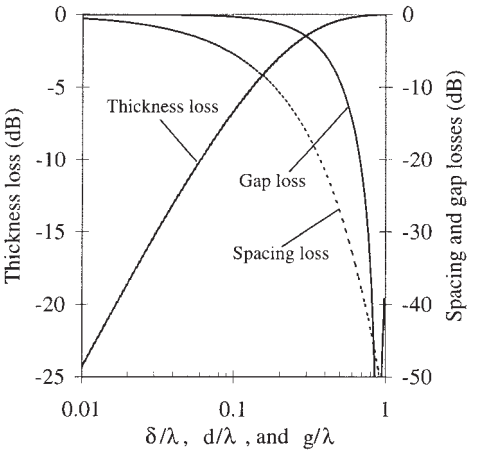

***Figure 9***
The spacing loss, thickness loss, and gap loss for high linear-density recording.

The name of this term is misleading because its value increases with a greater medium thickness. However, the rate of increase diminishes for a thicker medium. In fact, 80% of the maximum possible value is achieved by a medium thickness of 0.25 $\lambda$. The last term $\sin(\pi g/\lambda)/(\pi g/\lambda)$ is the gap loss. This term is based on the Karlqvist approximation. If a more accurate head fringe field is used, this term is modified to $\sin(\pi g/\lambda)/(\pi g/\lambda)$ $(1.25\ g^2-\lambda^2)/(g^2-\lambda^2)$. It shows a gap null at $\lambda = 1.12\,g$, and limits the shortest wavelength producible. These three terms are plotted in Fig. 9. The most significant loss comes from the spacing loss term, which is 54.6 dB for $d=\lambda$. Therefore, one of the biggest efforts spent on magnetic recording is to reduce the head/medium spacing as much as possible without causing mechanical reliability issues. The effects are similar for an MR head.

## 3. *The Challenge for High Areal Density*

Since areal density is the product of linear density and track density, the increase in areal density translates into the reductions in pulse width and track width. Both magnetic media and heads play important roles in these areas. One of the most prominent parameters affecting pulse width is the transition parameter $a$. Equations (7) to (12) indicate that it affects both the recorded transition length and reproducing pulse width. From the medium viewpoint, we can reduce $a$ by increasing coercivity $H_c$, reducing $M_r\delta$, or reducing $S^*$. Since 1990, $H_c$ has been increased from around 1000 Oe to 3800 Oe. The primary limitation to higher $H_c$ is the recording head. Presently it is

difficult for a head to generate a magnitude field with the required gradient for recording on a medium with $H_c$ over 4000 Oe, especially at high frequency.

This is described by Sharrock's law:

$$H_c(t) = H_0\left\{1 - \left[\frac{kT}{K_u V}\ln\left(\frac{f_0 t}{0.693}\right)\right]^n\right\} \qquad (16)$$

where $t$ is time, $T$ is absolute temperature, $k$ is the Boltzman's constant, $K_u$ is the uniaxial anisotropy energy per unit volume, $v$ is the grain volume of the magnetic particle, and $f_0$ is the Larmor frequency. If we reduce $M_r\delta$, we will sacrifice amplitude. In addition, it is more difficult to produce a uniform thin film than a thick film.

Magnetic medium noise has three components: transition noise, particulate noise, and modulation noise. While both particulate noise and modulation noise are independent of or decrease with linear density, transition noise generally increases with linear density. Consequently, reduction of transition noise becomes necessary for high areal density application. The signal-to-transition-noise ratio is

$$\mathrm{SNR} \approx \frac{D_c B^2 w}{2\pi D^3} \qquad (17)$$

where $D_c$ is the channel density, and $D$ is the grain diameter.

Obviously we need to reduce the grain size to achieve adequate SNR if we reduce $B$ or $w$ to increase areal density. A major obstacle to the reduction of grain size is the superparamagnetic limit, which indicates the thermal instability of magnetization if the grain size is smaller than a critical volume $v_p$:

$$v_p = \ln(2tf_0)\frac{2kT}{\mu_0 M_s H_a} \qquad (18)$$

where $H_a$ is the total anisotropy field. First-order calculation shows that a grain diameter of 10–12 nm is required for ten-year data retention.

Although we can increase either track density or linear density to increase areal density, it is more advantageous for us to increase track density from the balance of SNR and thermal stability. This is because higher linear density requires a thinner magnetic layer, resulting in shorter grains with smaller volume and lower thermal stability, whereas a higher track density allows us to keep the same magnetic layer thickness, leading to higher areal density for the same thermal stability. Consequently, the aspect ratio (w/B) needs to reach 4 for 100 Gb $\mathrm{in}^{-2}$, which is presently around 8 in the 50 Gb $\mathrm{in}^{-2}$ demonstration and was about 20 at 100 Mb $\mathrm{in}^{-2}$.

When two transitions are recorded very close, the demagnetization field from one transition affects the transition position of the other. This shift in transition position can cause difficulty in channel detection, and is termed nonlinear transition shift (NLTS). As linear density gets higher and higher, NLTS will become more of a problem.

From the recording head viewpoint, the challenge lies in writability and high frequency response. Writability is usually expressed as overwrite, which is a measurement of a head's capability to write over a preexisting signal on the medium. With the increase in medium coercivity, the recording field needs to be increased accordingly. However, the magnetic material at the corners of the recording head gap may get saturated before the required fringe field is achieved. This saturation will deteriorate the field gradient, leading to poor recording. To prevent this from happening, a high Bs layer magnetic material is deposited on the inside surfaces of the gap, similar to the MIG head in Fig. 2. The challenge is to find a material that has both high $B$ values and high corrosion resistance. Commonly used materials are iron and cobalt alloys.

We have implied in our analysis that the recording field responds instantaneously to recording voltage pulse. In other words, the recording field has perfect square waves in time domain. When we deal with low frequency, this assumption is valid. However, when the frequency is high, it is not valid because the head has both an inductance and the core material needs finite time to rotate its magnetization. If the field rise time $\tau$ is too large compared with transition time $T$, then additional NLTS will be introduced. $\tau$ is typically between 1 and 5 ns, indicating frequency limitation occurs around 1 Gb $\mathrm{s}^{-1}$. To reduce $\tau$, we need short and thin magnetic yokes with high $B$ and high electric resistance.

From the reproducing head viewpoint, the major amount of research and development emphasis has been placed in the areas of signal sensitivity and stability. With narrower track width and shorter flux change length for higher areal density, the recording head picks up less magnetic flux from each transition. To ensure adequate SNR, the recording head needs to have a higher sensitivity to the magnetic flux from the recorded signal. The change from inductive head to AMR head then to GMR head and maybe to TMR head is to achieve high SNR.

The reproduced signal must be stable for the channel to detect. This requires a stable magnetic domain in the MR film. A hard magnetic material (hard bias) is deposited adjacent to the leads along the MRE width direction to stabilize the magnetic domain and reduce large Barkhausen noise. If the strength of the hard bias field is not enough, the reproduced signal may experience jumps. This phenomenon is called baseline shift. However, if the field is too great, the head will suffer poor sensitivity. The head stability can also be a result of the change of the pinned magnetization, and the loss of exchange field of the AFM.

To address these concerns, synthetic antiferromagnetic (SAF) pinned layers are used. The SAF layer, consisting of two ferromagnetic layers separated by a thin ruthenium layer, provides a more

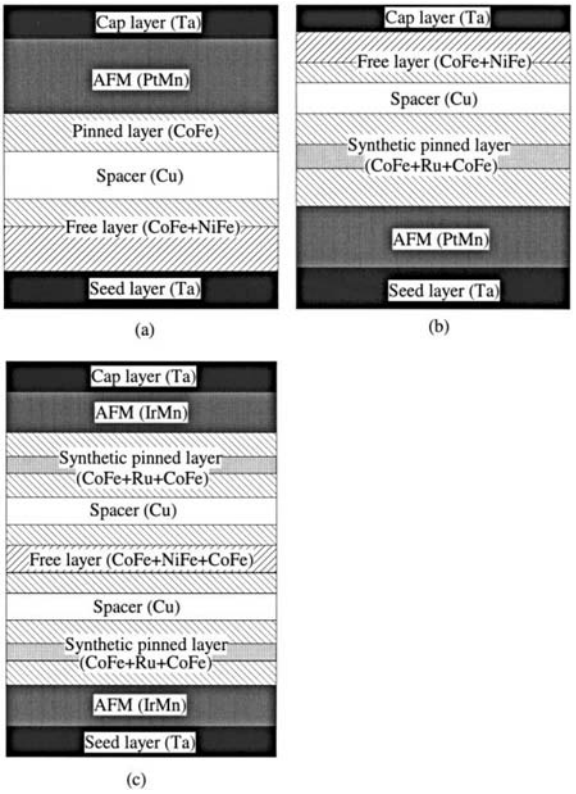

***Figure 10***

stable pinned magnetic field, as depicted in Fig. 10. Various AFM materials have been employed to increase its block temperature and pinning field. In addition to sensitivity and stability, manufacturability and durability are important. Practical issues such as dimension control, ESD safety, and corrosion resistance all need to be resolved.

Both Eqn. (13) and Eqn. (15) show the importance of head-to-medium spacing $d$. To reduce $PW_{50}$ and increase amplitude, we need to minimize $d$. If $d$ is too small, however, mechanical interactions will occur on the head and/or the medium, leading to severe damage. The science and art for the balance between areal density and head/medium interface durability belongs to the field of tribology. For low duty-cycle applications such as in a floppy drive, the head is in contact with the medium surface. For high duty-cycle applications such as in a hard drive, the head flies over the disk surface during operation. The flying height is between 10 and 20 nm. This small and stable flying height is achieved by using an air-bearing surface on the head, a flat and smooth surface on the disk, and a pressurized air film in between. The scientific and engineering foundation is the hydrodynamic lubrication, governed by the Reynolds equation.

## Magnetic Recording: Flexible Media, Tribology

The data densities demanded of magnetic media have increased monotonically and much work has been done to respond to these demands. The tribology of these systems has, however, been largely neglected and problems which occurred were solved largely by a combination of good design, lower contact pressures, better lubricants, better materials for heads and media, and by mature use of natural tribological laws. Thus by a combination of good system design,

exploitation of materials technology, and good fortune, the tribology of the systems has, until recently, seldom been a limiting factor in their development. Good fortune can no longer be relied upon and there is an urgent need for more effort to be made in understanding the basic mechanisms of contact in these very complex systems.

As recording densities increase, recording wavelength is reduced and the trend is to thinner magnetic coatings, two or more layered structures, thinner polymer substrates, zero head/media spacing, and smaller head dimensions. Magneto-resistive (MR) read head elements are employed which may run at temperatures of 70 °C or more. In future, giant magneto-resistive (GMR) heads will probably be used which will necessitate the use of ultrathin head coatings. In particulate media this necessitates the use of magnetic layers of different structure, with different resin binders with higher glass transition temperatures and new, more effective lubricants and lubrication systems. In addition, magnetic particle loadings must increase and particle size must be reduced. All of these factors produce acute tribological contact problems and are now significant limiting factors in the development of dynamic magnetic storage technology, and will be so increasingly in the future.

With the miniaturization of components and the consequential changes detailed above, any factor which adversely affects the intensity of the output recorded signal or which produces recording errors becomes of prime importance. For example, any process or mechanism which introduces spacing between the media and the recording head or which leads to the physical removal of material from the magnetic media must be understood and its effects eliminated. The signal falls exponentially with an increase in this spacing.

The materials aspects of the problem will be discussed later, but it is worth considering some basic tribological laws which have aided the magnetic media cause. A simple law describing the wear of materials under a wide variety of conditions is the Archard wear law:

$$\omega = kW/P_{\mathrm{m}} \qquad (1)$$

where $\omega$ is the volume of material removed per unit distance of sliding, the wear rate; $W$ is the applied load; and $P_{\mathrm{m}}$ is the material flow pressure, or hardness.

From this simple law one can see that increasing head and media hardness will decrease wear, as will reduction in head loads. Here, however, the industry is further helped by nature, in that $k$ does not remain constant, but can fall by almost an order of magnitude for a ceramic head vs. a $\gamma$-$Fe_2O_3$ media at low load. However, the friction coefficient increases at low pressures, particularly with very smooth surfaces. As a consequence of this effect, dynamic and static friction problems arise under low-load conditions, which are not noticed at higher loads.

## 1. The Media

Flexible magnetic media consist of a thin magnetic coating applied to a polymeric substrate carrier film. The magnetic coating may be applied as a slurry containing magnetic particles (particulate media) or as an evaporated magnetic metal film (metal evaporated media). In addition to the magnetic side of the media there is often a backside coating applied to tape to give desired mechanical and tribological properties, to prevent adhesion when rolled, and to give antistatic protection. Traditionally, the base coat has been produced from polyethylene teraphthalate, but for the very thin substrates used in the continued drive towards miniaturization, materials with higher elastic modulus such as polyaramide and polyethylene naphthalate are required.

### 1.1 Particulate Media

In particulate media, the magnetic coating consists essentially of acicular magnetic particles bound together by means of a polymeric resin. Thus the magnetic layer in contact with the read/write heads will have the tribological properties of a filled polymer. This consists not only of the magnetic pigment (at up to 80% by weight, 50% by volume) and the polymer binder, but also a head-cleaning agent (HCA) (typically 4–8% by weight of a relatively large abrasive particle such as Al or Zr oxide) and a possible combination of wetting agents, cross-linking agents, solvents, antifungal agents, carbon black (to prevent surface charging), and the essential lubricant (typically fatty acid/fatty acid esters). Until recently, oxide magnetic pigment (Co doped $\gamma$-$Fe_2O_3$) was used in flexible recording media. The necessity for higher coercivity and squareness has meant that current development is concentrated on passivated metal (Fe) acicular particles (MP media) with a secondary interest in barium ferrite hexagonal platelets.

Magnetic constraints demand that particle sizes and layer thicknesses are continually decreasing with particles now being produced of about 70 nm in length (4:1 acicular ratio) with projected layer thicknesses of about 10 particles. The mechanical integrity of such a layer would not provide sufficient durability and hence tapes must be produced where the magnetic layer is formed on a thicker nonmagnetic undercoat. The most popular current method of providing lubrication in particulate media is to incorporate the lubricant in the magnetic layer. However, as layers become thinner the volume of lubricant may not be sufficient to provide the required durability over the projected lifetime of the media. Hence lubricant is incorporated into the undercoat and reaches the surface through pores in the magnetic layer.

Considering the tribology of this system, the most important part of the contact layer is the binder which must have the ability to accept high magnetic particle loading, provide good wear resistance, good substrate and particle adhesion, low surface energy (low friction), be resistant to temperature and humidity effects, and exhibit sufficient flexibility for the continual deformation required of a tape or floppy disk. To satisfy these requirements the polymeric binders consist of at least two phases, a ''hard'' glassy phase to give the system mechanical integrity and a ''soft'' rubbery phase to provide the flexibility required. The blend is cross-linked to increase phase separation and to ensure that the glass transition temperature is below the operating temperature of the media. Many present polymer blends use a dispersing or wetting agent to ensure polymer–particle adhesion and homogeneous dispersion, but dispersing binders are being developed with modified functional end groups. This results in better binder particle bonding, higher cohesive strength, higher particle loading, and better wear properties. One disadvantage may be that such binders are more polar and this may increase the adhesive forces between heads and media.

### *1.2 Metal Evaporated Media*

In order to satisfy high areal recording density requirements, thin metal films such as Ni–Co alloys evaporated under vacuum onto a flexible polymer substrate were introduced. This media has potentially more effective magnetization than particulate media due to the increased grain density. The media consists of single, or possibly, multilayers of evaporated metal magnetic layers on a polymer substrate, covered by a protective carbon overcoat which is in turn topically lubricated. Tribologically the system is inherently simpler than the particulate media, but presents its own unique problems. Major among these is that, unlike particulate media, surface coverage of the lubricant must be complete, must remain so for the projected lifetime of the media, must afford complete corrosion protection, and should not be more than about 5 nm thick in order that spacing losses are not excessive. Metal evaporated (ME) thin film flexible media has the advantages of the porosity and surface chemistry of the particulate media, thus the demands on the lubricant present a severe challenge. The lubricants are the perfluoropolyethers, often with end group modifications. It should also be borne in mind that these thin metal films are far less compliant than particulate-filled polymer films and should not be subject to excessive strain if cracking and catastrophic failure are to be avoided.

## *2. Contact and Forces at Head–Media Interfaces*

When two surfaces interact, the real area of contact is dependent on the physical properties of the surface, but is generally lower than the apparent area of contact. This is because contact will only occur at asperity tips. When contact occurs, these asperities may deform either plastically or elastically and it is important to know the mode of deformation before wear and friction can be understood. Bhushan (1984) adapted the work of Greenwood and Williamson (1966) and defined a plasticity index $\psi$ for such that:

$$\psi = \frac{E^*}{Y\left(\frac{\sigma}{r_a}\right)^{1/2}} \tag{2}$$

where $E^*$ is the complex modulus of elasticity, $Y$ is the yield strength or hardness, $\sigma$ is the standard deviation of asperity heights, and $r_a$ is the mean radius of those asperity peaks. He suggested that for polymers if $\psi < 1.8$ the contact is elastic, and if $\psi > 2.6$ the contact is plastic. Consideration of particulate media reveals that most contacts are elastic. From the above relationship, therefore, the real area of contact, $A_r$, can be calculated for elastic contact from:

$$A_r \approx 3.2 \frac{W}{\psi Y} \tag{3}$$

The classical analysis of Halliday (1955) also shows that the contact must be almost entirely elastic for particulate media and elastic/plastic for metal evaporated media.

Thus for particulate media, the forces generated when contact occurs are largely adhesive and the real areas of contact are governed by the elastic properties of the media. For metal evaporated media the contact is more complex, but, considering the elastic/plastic combination, adhesive forces probably still dominate contact.

## *3. Surface and Contact Temperatures*

Surface and contact temperatures can have a substantial effect on the nature and magnitude of wear and friction processes. There have been many attempts to measure and calculate surface temperatures. Bhushan (1987) reported a detailed thermal analysis in which he predicted contact temperature rises for typical head–tape contacts of 7–10 °C, although he concedes that if magnetic particles are exposed the contact temperatures can be very much higher at 600–900 °C. There is some correlation of these results with IR measurements made on a simulated head/tape interface by Gulino *et al.* (1987). Our calculations, however, suggest that contact or hot spot temperatures much higher than Bhushan's figures can occur in practice.

In this model the heat generated due to friction is equated to the sum of the heat lost due to conduction into the head surface, conduction into neighboring

asperities, and that due to forced convection to the air. Taking atomic force micrographs of the surface as a basis for a realistic model, the surface was modeled into a network of nodes, each node representing an asperity. It was assumed that the asperities were subject to random Raleigh distribution of volumes and base radii. On the basis of this model, maximum contact temperatures for a typical linear tape system were calculated to be over 100 °C, although the mean surface temperature was low. If it is assumed that all the load is carried by one asperity, and we have evidence to show that this may occasionally occur, then very high temperatures are predicted.

## 4. Friction

Friction is an important parameter in the design of magnetic recording systems. With the continual move towards miniaturization and the use of low power drives, friction which is too high can cause speed variations, high interfacial temperatures, or, ultimately, failure of drive motors. In tape systems, it is not only head–media friction which must be considered, but the tape has to negotiate a complex transport system and backcoat friction can lead to problems. Dynamic friction must therefore be understood and controlled, but equally as important is the static or "start-up" friction.

### 4.1 Dynamic Friction

The frictional force, $F$, consists of an adhesive component, $F_A$, plus a deformation component, $F_D$, which in turn consists of a plastic deformation or ploughing term and a hysteresis loss term, hence, $F = F_A + F_D$. Considering the viscoelastic nature of the magnetic layer, the nature of the contact, and the surface topography, then, except at very low speeds and at high temperatures, the deformation term in the friction equation is negligible. Hence friction may be regarded to a first approximation as being due to adhesion. All the frictional energy is dissipated in the contact region and the frictional force may be written as:

$$F \approx F_A = \tau A_r \tag{4}$$

where $\tau$ is the interfacial shear stress. $\tau$ is not constant, but will increase with pressure and will, in general, fall with increased temperature within the operating range of the media. Friction will also be speed dependent due to the time dependence of the elastic properties of the polymer and the increase in temperature with increase in velocity.

With particulate media, a fatty acid/fatty acid ester type lubricant is normally incorporated into the bulk of the magnetic coating. The coating thus acts as a reservoir to replenish lubricant molecules removed by wear. Using angle resolved x-ray photoelectron spectroscopy (XPS) we have measured the thickness and areal coverage of lubricants on a wide variety of tape and diskette surfaces and found current lubricants to be about two or three molecular layers thick, with coverages as low as 10% of the total surface area. Taking into account the presence of the lubricant, the frictional force can be written as:

$$F = A_r\{\tau(1-\alpha) + \tau_l\}\alpha \tag{5}$$

where $\tau_l$ is the shear stress in the lubricant and $\alpha$ is the fractional areal coverage of the lubricant. The lubricant provides an easily sheared layer separating the two surfaces and will also produce some plasticization at the surface of the polymer.

Polymer surfaces have low surface energy and this together with the low areal coverage means that the frictional force will not change substantially with lubrication, but the presence of this lubricant is essential to reduce wear. Since the lubricant film will not affect the frictional force, this force must be governed by the properties of the magnetic layer. Thus a high hardness, high complex modulus material should be used to reduce friction, with due regard to a suitable glass transition temperature and toughness. Rougher surfaces produce lower frictional forces; however, due to the need for minimum spacing loss, surfaces need to be as smooth as possible.

Friction increases with time of running, at least over the first few passes. This is to some extent due to the surface becoming smoother, but this is not entirely consistent with the assumptions that contact is elastic. Our findings indicate that the outer layers also change chemically. The chemical changes are confined to the outer polymer covering on the magnetic particles. Assuming the contacts to be mainly adhesive, the changes may be sufficient to influence the frictional force.

In the case of ME media, the lubricant layer coverage is complete and hence $\alpha = 1$. This is a case of classical boundary lubrication, where the friction force is wholly determined by the shear stress of the lubricant/head interface. Here, the deformation component of friction is negligible. If lubrication fails, however, friction forces can become catastrophically high.

### 4.2 Static Friction—Stiction

In all materials there is a distinction between dynamic and static friction, with the force required to initiate motion, static friction, being higher than that required to maintain it, dynamic friction. In magnetic recording systems where the head is often parked in contact with the media, this difference can be particularly pronounced and can lead to acute start-up problems. This results in a jerky and uneven motion of the tape or disk. There are a number of reasons for this high initial friction. As mentioned before the

filled polymer magnetic layer is in a viscoelastic state at normal operating temperatures. In this state the strain is rate dependent. This means that the real area of contact increases with time and increasing static friction. In addition to this, van der Waals forces operate between the smooth surfaces of the magnetic layer and the head and these will increase the surface area above that predicted by theory. There is some controversy over the importance of electrostatic forces, but it is likely that they account for increases in friction at very low loads.

Very high static friction forces are most apparent under conditions of high humidity. This may be due to a meniscus effect at the head–media interface or the effect of water plasticization of the polymer in the contact zone. Meniscus effects are possible since high friction is also observed if too much lubricant is present; it is more likely, however, that increased moisture levels instigate hydrolysis and plasticization takes place. To overcome these problems similar polymer properties of high complex modulus and high hardness are required with an additional requirement for the binder to be hydrophobic.

## 5. *Wear at the Head–Media Interface*

Although the ultimate life of head and tape are of importance and determined by absolute wear, the actual wear rates are, in engineering terms, very small indeed and in general it is the effect of wear on signal performance that has a greater influence on useful life than material removal rates. Any effect which introduces a spacing between the magnetic media and the read/write sensors or which results in loss of data is of prime importance. Thus media degradation and wear, head wear, differential wear, head surface modifications, and transfer film formation must all be considered. Wear is classified as adhesive, fatigue, abrasive, corrosive, or erosive. Although it is clear that the contact is largely adhesive in head–media contact, it is probable that most of these forms of wear apply at some time.

### *5.1 Particulate Media*

#### *(a) Transfer film—head stain*

The first stage of wear usually consists of material transfer from media to head. Our x-ray spectroscopic measurements show that at the surface the magnetic particles are covered with polymeric resin to a depth of about 5 nm. Thus the initial head–media contact is between head and the polymer surface of the media. The adhesive forces formed at this contact may be either physical, involving van der Waal bonds, or chemical, involving electrostatic, ionic, or covalent bonding. Typical van der Waal bond strengths indicate that their contribution is not significant. The chemical bonds are probably more significant and these will depend on the nature of the head material. For polymer/metal contacts covalent bonding occurs and for polymer/ceramic contact, ion-dipole bonds are formed. Each of these bond types will give strong adhesive junctions.

Within the polymer binder, atoms are covalently bound (bond strengths up to about 10 $eVatom^{-1}$) and chains bound together via dipole–dipole interactions. Dipole–dipole interactions are typically a few tenths of an $eVatom^{-1}$, although interchain bond strengths approach those of the covalent bonds due to cross-linking. Bond strengths of the adhesive junctions formed at the various polymer/head interfaces can be greater than those of the binder/particle interfaces within the magnetic layer and this, if the conditions are right, leads to adhesive transfer from media to head. (Transfer is not observed for relative humidities above about 45–60%, where water saturation of active sites on the head material surfaces prevents the formation of adhesive junctions.) Transfer is particularly evident on MR metal elements due to high temperature enhancement of covalent bond formation and reduction of surface saturation due to expulsion of water vapor and other contaminants. Thus transfer films occur readily between polymer/metal and polymer/ceramic surfaces and these can substantially affect wear properties of the junctions and may introduce spacing losses. This phenomenon is known as "head stain."

Transfer does not occur in homogeneous layers, but as a discontinuous lumpy film, with thicknesses corresponding to one magnetic particle. The thickness of these layers indicates that the depth of material removed from the media in this early phase of wear is not sufficient to produce data errors in current media.

These transfer films have been variously described as friction polymer, brown, blue, or white stain. In XPS and Auger electron spectroscopic studies we have found no friction polymers. Our XPS analysis (careful measurement of Fe 2*p* binding energies) indicates that the layer consists of magnetic pigment from the media and we conclude that color is determined by thickness and substrate.

These results are entirely consistent with the mechanisms where the thin surface polymer is adhesively bound to the head. This results in cohesive failure within the media and laminae of media that are one particle thick transferring and adhering to the head surface. Once the film has been formed contact is between it and the media, although one would expect the situation to be dynamic with continual removal and replacement of the stain. After formation, the junction strength between load bearing surfaces of the transfer film and the polymeric media is not sufficient to duplicate the transfer process and hence films will not normally increase in thickness. In tribological terms, the formation of a transfer layer is beneficial in reducing wear. However, the layer may

introduce unacceptable spacing losses and may, under certain circumstances, short out MR elements and shields. A function of the head-cleaning agent added to the magnetic layer is to limit the thickness of this stain and to reduce spacing losses. (Another and perhaps less well understood function of the head cleaning agent is to act as a bearing surface and effectively protect the soft media against wear.) During this phase of wear, surfaces of the particulate media generally become smoother and errors are reduced (Hempstock *et al.* 1998).

*(b) Delaminative wear and head clogging*

The second stage of wear of particulate media is due to fatigue and results from continuous cyclic stressing of the media by contact with the head. When two solids are in sliding contact, the maximum stress occurs not at the asperity junction, but below this surface. When an asperity approaches an opposing asperity the subsurface is in compression; as the asperities separate the subsurface is in tension. Hence for repeated contact the subsurface immediately below the asperity contacts is subject to cyclic stressing. This leads to the initiation of subsurface fatigue cracks which grow to the surface and produce delaminative removal of particles, which leave crater-like recesses behind (Hempstock and Sullivan 1998). This delaminative particle removal process is analogous to that described by Suh (1986) for metals. For fatigue-induced crack initiation there needs to be defects in the matrix. Stress concentrations at these defects will then enhance crack initiation and propagation. There are three possible candidates for this: the boundary between hard and soft phases of the copolymer binder, the boundary between head cleaning agent particles and binder, or the boundary between acicular magnetic particles or agglomerates of these particles and the binder.

Although this wear phase is relative rare, it has many effects on signal performance and error growth. The removal of delaminative wear particles from the media can result in loss of bits of information. Hempstock and Sullivan (1997) have observed a correlation between such surface damage and increase in dropouts (hard errors). The released debris then forms third body particles which may damage head and media and lead to head clogging. Head clogging is due to loose debris expelled from the contact area agglomerating on the exit side of the head. The agglomerates are then picked up by the tape and eventually transferred to the head where they accumulate in the gap region, leading to spacing losses with a consequent decrease in the reproduced signal. Head clogging can produce a transfer film which is somewhat like the ''stain'' described above. The differences are that the film is very much thicker, more easily removed by wiping with solvents, and is more likely to be produced at high humidity, the latter probably due to water assisted breakdown within the magnetic layer, due to a chain scission mechanism. We have also seen such an effect and have shown that this can also cause gap damage which affects the high-frequency response of the system. The wear phase eventually leads to the production of more debris and an avalanche catastrophic failure mode observed by ourselves and others.

It should be noted here that increasing the magnetic particle loading to a figure of about 50% by volume leads to an increase in complex modulus and decrease in wear. Increasing loading beyond this level, however, will reduce the modulus and increase wear.

*(c) Abrasive wear*

There are two forms of abrasive wear. Two-body abrasion occurs when a hard, rough surface slides over a softer one resulting in ploughing action and removal of material. Three-body abrasion occurs when hard particles become entrapped between two sliding bodies, resulting in the same effect. An essential requirement for abrasive wear is that plastic deformation should occur beneath a penetrating asperity or abrasive particle. Our calculations indicate that localized contact temperatures can be quite high and could lead to softening of the polymer matrix, thus aiding plastic flow, but reference to plasticity criteria (Greenwood and Williamson 1966) reveals that with current surface roughnesses two-body abrasive wear should not occur either in the media or at the head.

However, agglomerates of wear debris entrapped between head and media may be of sufficient size to give rise to three-body abrasion. This is almost certainly the origin of scratches seen on tape and diskette surfaces after wear. For polymeric materials the abrasive wear rate is proportional to $S^{-1}\,e^{-1}$, where $S$ is the breaking strength of the material and $e$ the elongation to break. The addition of magnetic particles will increase $S$, but reduce $e$ and hence the filled polymer is no more resistant to abrasion than the polymer itself. This is not true of other forms of wear where the increased hardness and elastic modulus may reduce wear. In general, abrasive wear of the media is not too important when considering loss of signal, but may cause errors. The same cannot be said when considering the head.

*(d) Effect of lubricants*

Wear of media and heads is reduced by introducing a boundary lubricant between the opposing surfaces and by reducing the polar molecule content of the binder. Sullivan and Sharma (1992) found lifetimes reduced by two orders of magnitude in the media without lubricant. Friction values were relatively unaffected. Our angle-resolved XPS measurements have shown areal coverages between 10% and 40%, and the thickness of the polymer/lubricant covering the

magnetic pigment is between 4 nm and 8 nm, depending on tape manufacturer and media type (this could represent a signal loss of something less than 1 dB). The coverage is sufficient to protect the media surfaces against premature failure, although durability increased with coverage.

Other forms of wear, if they occur, have negligible effects on signal, although polymer interaction with water vapor may have an effect on adhesion, abrasion, and fatigue. Our examinations of heads produce some circumstantial evidence that Cl from degeneration of Cl-containing polymeric binders may under some circumstances produce corrosion. In general, high humidity reduces wear and increases durability of particulate media, but adversely affects the head and reduces signal through this route.

## 6. Metal Evaporated Media

ME media relies on a complete boundary lubricant film, about 2–3 nm thick, and operates under pseudo-classical boundary lubrication conditions. The surface of the evaporated metal film is oxidized and sometimes carbon coated to give additional protection in the case of a momentary breakdown of the boundary lubricant. This provides a low surface energy contact which can survive occasional head/media asperity interaction, but the lubricant must be capable of self-healing any breach if high wear is not to ensue.

The lubricants used are usually perfluoropolyethers with suitable functional end groups to anchor to either a carbon overlayer or a metal oxide. Ideally there should also be a semi-mobile component in the lubricant layer to satisfy the self-healing requirement. These lubricants are chosen for their good affinity to the surface, good viscosity range, low volatility, and good chemical and thermal stability. More traditional metal boundary or antiwear additives, such as triaryl and trialkyl phosphites, may provide improved tribological performance, but probably do not satisfy anticorrosion requirements.

The asperity contacts on the tape will be mainly elastic, with a small plastic component. This takes into account the effect of the substrate-generated texture included to prevent adhesion of the very smooth surfaces. If lubricant breakdown does occur then this can lead to transfer of material from media to head. The roughening of the head can then lead to abrasive grooving of the media and the possibility of errors due to material removal. In the absence of lubricant breakdown, the dominant wear mechanism, however, is one due to fatigue.

Hempstock and Sullivan (1998) have studied the wear of commercial ME Hi-8 video tape and correlated this to signal performance. Single and double magnetic layer structures were studied in this investigation and signal degradation and error growth were monitored as functions of running time. Scanning electron microscope (SEM) examination of the surfaces clearly identified the wear mechanism. In the initial stages of wear little change occurred at the surface and few wear particles were produced. As contact continued, delaminative removal of material was observed in the media surface and consequent micron-sized wear particles appeared. The increase in delaminative craters on the surface correlated exactly to an increase in measured signal errors. The thickness of laminar particles removed from the tape was less than the thickness on the ME layer, except when the process proceeded until catastrophic fatigue, cracking, and delaminative failure of the film occurred at the ME substrate interface.

The single layered structures proved to be the most durable. Here, the failure of the media corresponds to the depletion of lubricant in the area of the scar. In the case of the dual layer media both error growth and ultimate failure occurred at an earlier stage (corresponding, for example, to 6–8 hours pause motion in helical scan mode, compared to 10–12 hours for the single layer tape). XPS analysis of dual layer media showed that substantial delamination and ultimate failure of the media both occurred before the lubricant film showed significant signs of failure.

In both types of ME media the mechanism of wear is classic Suh delamination (Jahanmir and Suh 1977), where subsurface changes and fatigue lead to the production of an immediate subsurface discontinuity which acts to concentrate fatigue cracks. This then leads to delaminative removal of material. In the case of the single layer film, gradual breakdown of the lubricant film allows more head–tape contact to occur and this will greatly accelerate fatigue-induced crack formation and propagation, since under these circumstances more energy will be dissipated in the ME layer, and less in the lubricant film. In the case of the dual layered films a discontinuity already exists at the boundary between the two layers and this concentrates subsurface stresses and provides a location for crack formation and propagation. Thus delamination takes place at an earlier stage in this media before substantial amounts of lubricant layer have been removed from the surface. Thus although dual layers may have magnetic advantages, such media are inherently less durable than single layers.

Tape drive components and tape magnetic side/back side contacts must also be taken into account. In general, the wear mechanisms outlined above are also evident in these situations with similar consequences for signal loss.

## 7. Read Write Heads: Wear

### 7.1 General Wear

There are many types of recording heads for tape systems, including ferrite, metal in gap and sandwich

heads for helical scan, and inductive write/MR read based heads for linear recording formats. All are similar in that they are multicomponent and are constructed from materials which are hard. With current thin film head constructions the allowable wear is very small, being perhaps less than a micron over the life of the component. The tribology of these hard materials is still at a very immature stage. The materials generally have high elastic modulus, high fracture strength, high chemical stability, and high thermal stability, but because of the ionic and/or covalent nature of their bonds, they are also brittle. The high chemical stability means that interfacial adhesion and the shear strength of the junction are low compared with bulk cohesive forces, hence adhesive transfer from head to tape does not occur.

The surface roughnesses and particle sizes associated with current tape formats ensure that conventional two-body abrasive wear cannot take place. The materials are not ideally brittle, however, and plastic flow and hence abrasion can occur with large third-body particles. Polishing (a form of adhesive at the nanoscale), however, can take place. Here, the hardness of the tape particles need to fulfil the Richardson (1967) criteria, but can be relatively low. Conventional polishing normally occurs when small hard particles imbedded into an elastic backing medium are passed at high speed and low load over the surface to be treated. This is exactly the situation which occurs in head/ particulate media contact. Polishing has been described by Suh (1986) in terms of microdelamination of the wearing surface. The soft magnetic materials, for example NiFe, CoZrTa alloys, used in MIG and sandwich heads, and the MR elements and shields in linear recording heads, are of similar hardness to the ceramics and exhibit similar wear mechanisms.

Reaves and Sullivan (1992) showed that this form of wear was the dominant mechanism in ferrite video heads, Harrison *et al.* (1999) and Bijker *et al.* (2000) have shown that it is also the dominant mechanism in terms of volume of material removed in sandwich heads and linear recording heads, respectively. In none of the cases, however, was it the most important mechanism in terms of signal degradation. In the case of the ferrite head, signal degradation was caused by gap damage due to third bodies becoming entrapped between head and tape, and in the case of the sandwich and linear heads was caused by pole tip recession. This mechanism is operative in glass, ceramics, and ferrites. With ferrite single crystals, however, there is the additional effect of crystal orientation. It is far more pronounced in some iron oxide or metal particle media than it is in chromium dioxide media and this may be explained in terms of plastic deformation in the ferrite crystal. This effect must be taken into consideration when, for magnetic reasons, the two halves of a head are aligned in different directions. In this case the different wear rates lead to pole piece height differences which result in spacing loss.

Although abrasive wear should not be possible in these systems, relatively deep scratches are observed on heads and these are obviously caused by three-body abrasion, possibly as a result of agglomerate debris from the tape becoming entrapped between head and media. Such scratches not only change the surface topography, which may effect spacing, but may also destroy MR elements. If the loading in particulate tape becomes too high and the complex modulus falls, more such third bodies will be formed. Third-body abrasion will be even more important in GMR heads, when the damage could have catastrophic consequences for head performance.

### *7.2 Differential Wear and Pole Tip Recession*

In terms of signal loss, differential wear is of greater importance than absolute wear, since this introduces spacing between media and the active areas of the head. When using a combination of different materials in the recording head, it is very difficult to exactly match wear rates. Since there is poor correlation between static measurements of elastic/plastic properties and wear over a range of different materials, model experiments must be devised, but even then it is not certain that the modes of wear measured in these experiments are appropriate in practice. The choice of materials is a compromise and the best individual material may not be suitable for use in a given head application because of mismatch in wear properties. This is the reason that a number of two-phase ceramics are used in head applications. Even with careful choice of materials, differential wear still occurs and is a major cause of spacing loss.

Harrison *et al.* (1999) have studied pole tip recession in sandwich video heads, where the recession is caused by differential wear. The soft magnetic metal sandwich is worn at a greater rate than the surrounding ceramic. In many circumstances this results in hollowing out the metal to a depth where contact with the media cannot occur. In these heads the soft magnetic materials and ceramic body have comparable wear rates, measured by simulation tests. Harrison *et al.* (1999) found that the major material removal mechanism for soft magnetic materials and ceramics was nanoadhesion (polishing), but this could not account for the recession. This was the result of two separate effects: fatigue wear of the ceramics, which resulted in the plucking out of laminar crystallite-sized particles from the surface, and the entrapment of these particles in the soft magnetic sandwich region, which produced erosive wear. The ensuing pole tip recession was then a function of the relative fracture toughness rather than hardness. The production of fatigue ''pull outs'' from the ceramic is probably increased for multiphase ceramics.

The pole tip recession observed in these heads was greatest for ME media because the material removed by nanoadhesion was far less than that removed in the case of the aggressive MP media. Thus smoother, more compliant ME tape allowed more fatigue-induced particles to form than in the case of MP tape, where the surface was being removed at a greater rate, thus removing fatigue cracks.

This form of wear has also been shown to be responsible for pole tip recession in other systems. Hempstock *et al*. (2000) have shown similar mechanisms in different linear recording systems. In these systems it is found that pole tip recession is most pronounced under conditions of high humidity. The effect of humidity on ceramics is a very complex problem. In many ceramics there is a tribo-chemical reaction at the wearing surface which generally produces hydroxides. This effect can either reduce wear by providing an easily sheared, low surface energy film at the surface, or, if the film is removed too rapidly due to the wearing conditions, can increase wear. If chemical interaction does not occur, mechanical process due to water molecule ingress may be responsible for wear. This effect is well known in the pitting of metals. Sintered ceramic materials are always porous. Water under hydrostatic pressure can enhance crack formation and propagation within individual ceramic grains within the surface.

The crack depth relates to the region of maximum stress and may be calculated from Hertzian analysis of the subsurface stresses within the ceramic surface. This can lead to two possible effects: (i) increased rates of removal of the surface due to microfatigue which enhances polishing wear, and (ii) fatigue-induced granular delamination which can lead to the formation of ''third body'' abrasive particles. Those particles are then fragmented and result in pole tip recession. In the case of the most popular ceramic used in linear heads, that is $Al_2O_3$/TiC, delaminative wear occurs preferentially at the TiC phase. In the cases cited above simple wear ranking experiments would not be expected to predict the differential wear observed in the final product.

## 8. Coatings

Most differential wear problems could be reduced either by using more abrasive tapes and suffering higher overall wear or by using coatings on the head. The first of these solutions is not acceptable in modern media. The second is the only viable solution and much effort needs to be expended in the development of an ultrathin surface coating. This is particularly true if GMR sensors are to be used in future generation heads, where coatings will be necessary, not only for wear protection, but also as an essential corrosion barrier. The most likely candidates for such a film are diamond-like carbon (DLC) or chromium oxide based films such as those developed by Philips/Onstream, but the challenges here are enormous. The coatings must be no more than about 7 nm thick and be capable of lasting the life of the head in continuous contact with tape.

There are two modes of wear with such thin coatings, one due to the microadhesions/microabrasions detailed in previous sections and one due to delamination. In order to survive the first of these modes with conventional advanced MP tape containing head-cleaning agents (HCA), the coatings should have a hardness (determined by the Richardson criteria) of about twice that of the HCA particles, that is about 50 GPa. Filtered cathodic arc deposition of DLC films is probably the favored process for the production of such a film. An alternative solution may be to substantially reduce the hardness of the HCA in the tape, but results of this change on transfer film formation (head stain) are difficult to predict. Similarly, the effects on tape durability cannot be predicted, since a major function of HCA is to act as a bearing surface and give the tape mechanical stability.

If other forms of wear can be eliminated, fatigue-induced delamination at the film/substrate interface will still present a major problem which may only be solved by the formation of very high strength adhesive junctions. Such junctions have not been developed at this time.

## 9. Altered Layers

A further consequence of wear, particularly at ferrite heads, is the production of a work-hardened amorphous magnetic dead layer, or Beilby layer, at the surface of the crystalline ferrite. Such a layer might also be present in metal elements of linear heads. These layers have been identified and measurements of thickness attempted using magneto-optic Kerr effect measurements, but the evidence so far only confirms the possible presence of Beilby layers at thicknesses of less than 100 nm. Some reliable method needs to be developed for these measurements before the effect on signal spacing loss can be properly assessed.

## 10. Conclusion

This is a brief review of the tribology of flexible magnetic recording media, and the effect on signal performance. Where possible, original tribological source material has been quoted. The review shows that much of the pioneering work in tribology may be used to elucidate mechanisms of wear in these systems, with the proviso that scale effects must be taken into account. The contact between media and heads is complex, but is largely elastic in nature. Fatigue-induced delamination is the major wear mechanism

in media. Microabrasion is the major wear mechanism in head materials, although other mechanisms such as delamination, three-body wear, and erosion may be more important in terms of signal degradation. Hence the major mechanisms of material removal do not necessarily have the greatest effect on signal output performance.

## Magnetic Recording: Particulate Media, Micromagnetic Simulations

Colloidal magnetic dispersions of submicron acicular magnetic particles have been used for many years as precursors of particulate storage media. Advances in the production of the advanced metal particle (MP), Okamoto *et al.* (1996), and its use in the production of advanced ultra-thin media, Richter and Veitch (1996), mean that particulate media remain technologically competitive for a number of applications, including tapes for digital video and back-up applications. In order to understand and optimize particulate recording media for these high-density storage applications, it is necessary to understand the microstructure of the media that ultimately has its origins in the behavior of the dispersion itself.

A magnetic colloidal dispersion is a careful blend of fine magnetic particles, surface-active agents to provide stability against aggregation via short-range forces, secondary pigments, resins, and other additions such as lubricants. These are generally dispersed in a mixture of one or more solvents. Generally speaking, the resin system is the critical element in the dispersion since it is used to separate the particles in the final coating as well as for binding them together. Thus, dispersions are a very complex physical system in which the magnetic particles are merely one component, albeit an important one. A prerequisite to understanding storage media is an understanding of the magnetostatic interaction between particles and its influence on the magnetic and physical properties of the dispersion. The overall properties of dispersions have been reviewed by O'Grady *et al.* (1991) and show a rich variety of phenomena of physical interest and technical importance.

The complexity of the interaction problem requires that realistic theoretical approaches must be based on computational solutions. The microstructure of the dispersion and the magnetic media is sensitive to physical and magnetic history, therefore particular attention must be given to the generation of realistic microstructure in micromagnetic studies of particulate media.

A computer model of particulate media was proposed by Voss *et al.* (1993), treating the particles as single spins exhibiting coherent rotation, but taking into account interparticle interactions. More recently, Bertram and Seberino (1999) produced simulations taking into account incoherent reversals by representing individual particles as chains of spheres. Both these approaches suffer from the disadvantage that the microstructure of the system studied is nonrealistic, though gross features such as particle alignment can be simulated. The model and simulation described below is a first attempt to simulate the physical and magnetic properties of Advanced MP media from first principles.

The starting point for the simulation of magnetic media is a dispersion model. A model is usually based around a specific dispersion where, in an effort to maximize the available computer facilities, only the relevant physical properties of the particulate and continuum phase are taken into account. From these considerations, a choice of the most appropriate simulation method must then be made. A useful and practical introduction to simulation methods can be found in Allen and Tildesley (1990). One of the first simulations undertaken with elongated magnetic pigment in viscous medium was that of Deymier *et al.* (1994) using a Stokesian dynamic method.

The calculation of the long-range magnetostatic interaction is always problematic due to its computation demand, particularly for large systems. An approach to the development of an efficient computational algorithm can be found in the Brownian dynamic simulation of colloid aggregation made by Gunal and Visscher (1996). It is pertinent to note here that the choice of the micromagnetic model employed for the interaction calculation, and its relation to particle geometry, has been shown by Visscher and Gunal (1997, 1998) to be an important influence on the simulation predictions.

The basis of the multistage model described below is an Advanced Metal Particle Molecular Dynamic model developed by Coverdale *et al.* (1997, 1998). It has been designed to simulate dynamic particle behavior in a Newtonian fluid arising from particle interactions, surface interactions, simple shear, and a uniform magnetic field.

The model is first used to investigate the influence of shear and magnetic field on the microstructure of a magnetic pigment dispersion. It is then used in a multistage simulation of the production of magnetic media. Each stage of media production has been simulated by modeling the process assumed to be the dominant influence on the determination of the microstructure. The stages employed in the model are summarized as follows. A rectangular slab of dispersion in magnetostatic equilibrium is generated. The computation cell is $0.8\mu \times 0.8\mu \times 0.4\mu$ with a particle volume packing fraction (VPF) of 20%. The microstructure of the initial coating is modeled by shearing for $5 \times 10^{-4}$ ms at a shear rate of $5 \times 10^{6}\,s^{-1}$, being analogous to a model line speed of $120\,m\,min^{-1}$. The dispersion is allowed to relax towards equilibrium for 1 ms after shearing. The dispersion is then field-oriented at 2000 Oe for 4 ms and dried to yield a $0.2\,\mu$ coating at a VPF of 40%.

## 1. Molecular Dynamic Model of a Particulate Dispersion

Several of the more common algorithms used for molecular dynamics are unsuitable for a viscous system because they have a tendency to overestimate the particle velocity during a given time-step, and as a result cause problems with the estimation of the velocity-dependent viscous forces and torques. Rather than accept an unreasonably small time-step as a possible solution in order to stabilize an algorithm, it is better to choose a less sophisticated algorithm with the advantage of being more rugged and simpler to implement for a strongly interacting system.

The modeling of the motion of a particle ensemble in a viscous medium would require a full hydrodynamic description to take account of regions of flow induced by a disturbance, for example a rotation, in the neighborhood of a particle. As of 2001, it is only reasonable to address a simple case where the constraint on particle motion due to the viscous medium is approximated via the forces and torques resulting from the motion of an isolated particle in a Newtonian fluid.

The assumption is also made that the motion of a particle over a computation time-step is predominately determined by a "terminal velocity" and a "terminal angular velocity" which is a consequence of the forces acting on the body being balanced by the forces of resistance to the motion. This gives rise to a motion of constant velocity and a constant angular velocity over each computation time-step.

## 2. Translational Motion

The equations of translational motion of a particle of mass $M$ subject to a resultant force $F$ due to the magnetostatic and surface interactions is given by, $M\dot{\vec{v}} = \vec{F} - N\dot{v}$, where the viscous "drag" $-N\vec{v}$ on the particle is proportional to the velocity.

Motion parallel, //, to the particle axis can be expected to give rise to less drag than motion perpendicular, $+$, to the axis and so the velocity must be resolved into the appropriate components. The term $N$ is therefore written,

$$N\vec{v} = R_{+}(\vec{e} \times \vec{v}) \times \vec{e} + R_{//}(\vec{v} \cdot \vec{e})\,\vec{e}$$

where $\vec{e}$ is a unit vector in the direction of the particle axis. The terms $R_{+}$ and $R_{//}$ provide the essential hydrodynamic terms and have been employed following Newman and Yarbrough (1969). These terms depend on the individual particle dimensions and the viscosity of the medium.

In order to derive a computation algorithm, this equation is put in a form with dependence directly on the velocity components,

$$N\vec{v} = R_{+}N^{B}\vec{v}_{+} + R_{//}N^{A}\vec{v}_{//}$$

The term $N^{B}$ will now be derived. Employing an intermediary matrix,

$$\mathscr{B} = \vec{e} \times \vec{v} = \begin{pmatrix} \vec{x} & \vec{y} & \vec{z} \\ e^{x} & e^{y} & e^{z} \\ v^{x} & v^{y} & v^{z} \end{pmatrix}$$

the components of the corresponding vector are extracted as,

$$\mathscr{B}^x = (e^y v^z - e^z v^y)$$

$$\mathscr{B}^y = (e^z v^y - e^y v^z)$$

$$\mathscr{B}^z = (e^x v^y - e^y v^x)$$

The expression may now be derived,

$$N^B \vec{v} = B \times \vec{e}$$

$$= \begin{pmatrix} \vec{x} & \vec{y} & \vec{z} \\ (e^y v^z - e^z v^y) & (e^z v^x - e^x v^z) & (e^x v^y - e^y v^x) \\ e^x & e^y & e^z \end{pmatrix}$$

Expansion and manipulation yields,

$$R_+ N^B \vec{v}_+$$

$$= R_+ \begin{pmatrix} (e^z e^z + e^y e^y) & -e^y e^x & -e^x e^z \\ -e^x e^y & (e^x e^x + e^z e^z) & -e^y e^z \\ -e^x e^z & -e^y e^z & (e^y e^y + e^x e^x) \end{pmatrix} \begin{pmatrix} v_+^x \\ v_+^y \\ v_+^z \end{pmatrix}$$

Now considering the right-hand vector term and following a similar method:

$$R_{//} N^A \vec{v}_{//} = R_{//} (\vec{e} \cdot \vec{v}) \vec{e} = (v^x e^x + v^y e^y + v^z e^z) \begin{pmatrix} e^x \\ e^y \\ e^z \end{pmatrix}$$

Therefore:

$$R_- N^A \vec{v}_{//} = R_{//} \begin{pmatrix} e^x e^x & e^y e^x & e^x e^z \\ e^x e^y & e^y e^y & e^y e^z \\ e^x e^z & e^y e^z & e^z e^z \end{pmatrix} \begin{pmatrix} v_{//}^x \\ v_{//}^y \\ v_{//}^z \end{pmatrix}$$

For the translational motion, with the equilibrium condition $M \vec{\dot{v}} = 0$,

$$F = R_+ N^B \vec{v}_+ + R_{//} N^A \vec{v}_{//}$$

The velocity of a particle during each time-step may now be derived from the resultant force acting on a single particle.

### 3. Rotational Motion

The angular velocity $\vec{\omega}$ is not used in the formulation of the rotational motion but the unit vector in the direction of the particle axis $\vec{e}$ and the velocity $\vec{u}$ of the axis vector, after Fincham (1993), where

$$\vec{\dot{e}} = \vec{u}$$

and

$$\vec{\dot{u}} = \vec{G} - N \vec{u} - (\vec{u} \cdot \vec{u}) \vec{e}$$

First, the torque $T^{\text{mag}}$ due to the magnetostatic forces is considered,

$$T^{\text{mag}} = \sum_i \vec{r}_i \times \vec{f}_i = \vec{e} \times \sum_i d_i \vec{f}_i = \vec{e} \times \vec{g}$$

It is convenient to resolve only the perpendicular component:

$$g_{\text{p}} = \vec{g} - \vec{e} (\vec{e} \cdot \vec{g})$$

Thus:

$$\vec{T}^{\text{mag}} = \vec{e} \times \vec{g}_{\text{p}}$$

The torque due to rotational viscosity is proportional to the angular velocity,

$$\vec{T}^{\eta} = R_{\phi} \vec{\omega}$$

The term $R\phi$ is the hydrodynamic term and has been employed following Newman and Yarbrough (1969).

The rate of change of angular velocity may now be written,

$$\vec{\dot{\omega}} = I^{-1} (\vec{T}^{\text{mag}} - \vec{T}^{\eta})$$

Employing,

$$\vec{u} = \vec{\dot{e}} = \vec{\omega} \times \vec{e}$$

and differentiating with respect to time,

$$\vec{\dot{u}} = \vec{\dot{\omega}} \times \vec{e} + \vec{\omega} + \vec{\dot{e}}$$

Therefore,

$$\vec{\dot{u}} = I^{-1} (T^{\text{mag}} - \vec{T}^{\eta}) \times \vec{e} + \vec{\omega} \times (\vec{\omega} \times \vec{e})$$

to yield the second equation of motion,

$$\vec{\dot{u}} = I^{-1} g_{\text{p}} - I^{-1} R_{\phi} \vec{u} - (\vec{u} \cdot \vec{u}) \vec{e}$$

Note that the term $-(\vec{u} \cdot \vec{u}) \vec{e}$ is the centripetal force that is necessary to maintain the constant length of the axis vector by balancing the force generated by the rotation.

The rotational motion is dealt with in a similar way to the translational motion but first the centripetal term is removed. The effect of this term is then

replaced by a normalization of the unit vector $\vec{e}$ after each time-step, together with the condition that the time-step, thus the displacement, is kept small.
For the translational motion, with the condition $\dot{u} = 0$,

$$I^{-1} g_{\mathrm{p}} = I^{-1} R_{\phi} \vec{u}$$

The velocity of the axis vector during each time-step may now be derived from the torque.

## 4. The Microstructure of a Magnetic Dispersion

Study of the dispersion is made to clarify the influences that determine the behavior of the microstructure.

The dispersion simulation is based on an advanced metal particle dispersion with a volume packing fraction of 3.8%. Simulations of the zero-field equilibrium state show that the microstructure consisted of a "honeycomb" structure brought about under the influence of the magnetostatic interactions (Fig. 1). This equilibrium state was used as the starting point for all the dispersion simulations that follow. Any change in microstructure must be brought about by overcoming the magnetostatic interaction energy that gives rise to this low-energy state.

A well-defined structure is also found in a strong magnetic field, which has the characteristic structure of long filaments of particles aligned in the field direction. The formation of filaments, viewed transverse to the field direction in Fig. 2(a), gives rise to a network of open channels, viewed along the field direction in Fig. 2(b).

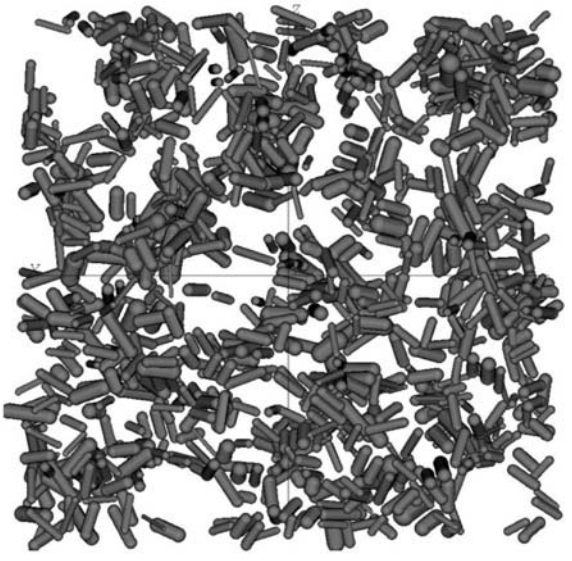

***Figure 1***
Zero-field equilibrium.

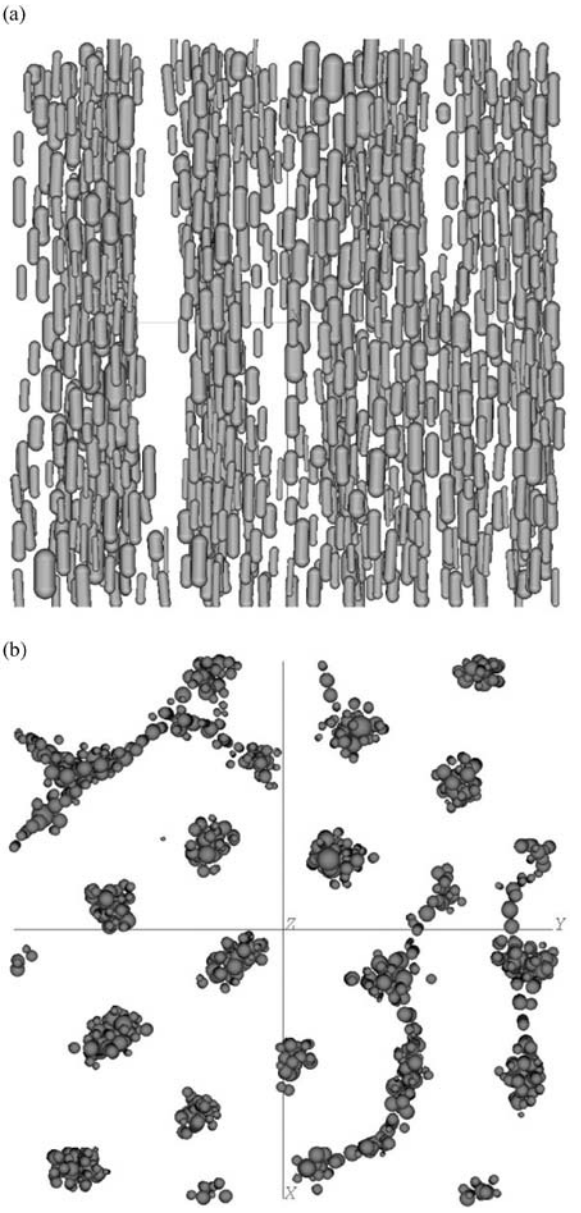

***Figure 2***
(a) Field equilibrium, view transverse to field direction. (b) Field equilibrium, view along field direction.

The molecular dynamic (MD) method will allow the introduction of a velocity gradient and thus simulate the dynamic behavior of the particles, i.e., the microstructure, in a shear flow. In the absence of an applied field, the simulations predict that for a

***Figure 3***
Zero-field shear flow, low shear breaking up equilibrium structure.

relatively low shear rate, $1000\,s^{-1}$, the magnetostatic interactions give rise to localized structure within the flow (Fig. 3). The structures are continuously breaking up and reforming under the influence of the velocity gradient but structure is observed at each time-step.

The microstructure may be investigated both in the shear flow alone and in a shear flow subjected to a magnetic field, thus the simulation may be used to model shear magnetometry experiments (Veitch 1996). There are two directions in which a field may be applied so that it is transverse to the direction of particle flow. The simulated effect of shearing the dispersion is modeled between two parallel plates aligned in the $x$–$y$ plane moving with equal and opposite velocity in the $y$ direction. In this configuration, a transverse field may be applied along the $x$-axis or the $z$-axis. The more common configuration used in a shear magnetometer employing a rotating cylinder is the transverse $x$ direction.

The model has been employed to predict the microstructure for shear flow in the two transverse directions for a relatively strong applied field of 2000 Oe. When the applied field is in the transverse $x$ direction, the particles orient into the field direction and thus lie transverse to the flow field. A typical particle configuration to be found at each time-step is shown in the two views of Fig. 4(a) and Fig. 4(b). Although the particles are strongly orientated in the field direction, they do not exhibit a tendency to form filament structures that are characteristic of zero-shear simulations.

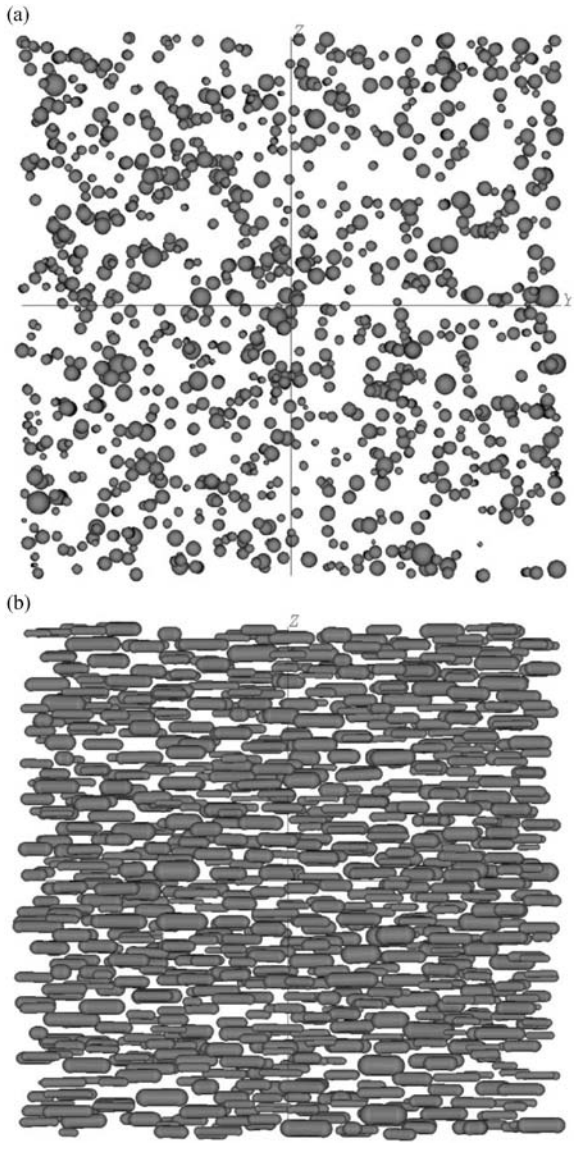

***Figure 4***
(a) Transverse field $x$-direction, high shear, transverse to field view. (b) Transverse field $x$-direction, high shear, flow direction view.

A very different response for the same field magnitude and shear rate is predicted when the field is applied in the transverse $z$ direction, shown in the two views of Fig. 5(a) and Fig. 5(b). It can be seen that a very well-defined microstructure has been developed, which may be described as curtains of particles arranged parallel to the flow direction and magnetically orientated in the field direction.

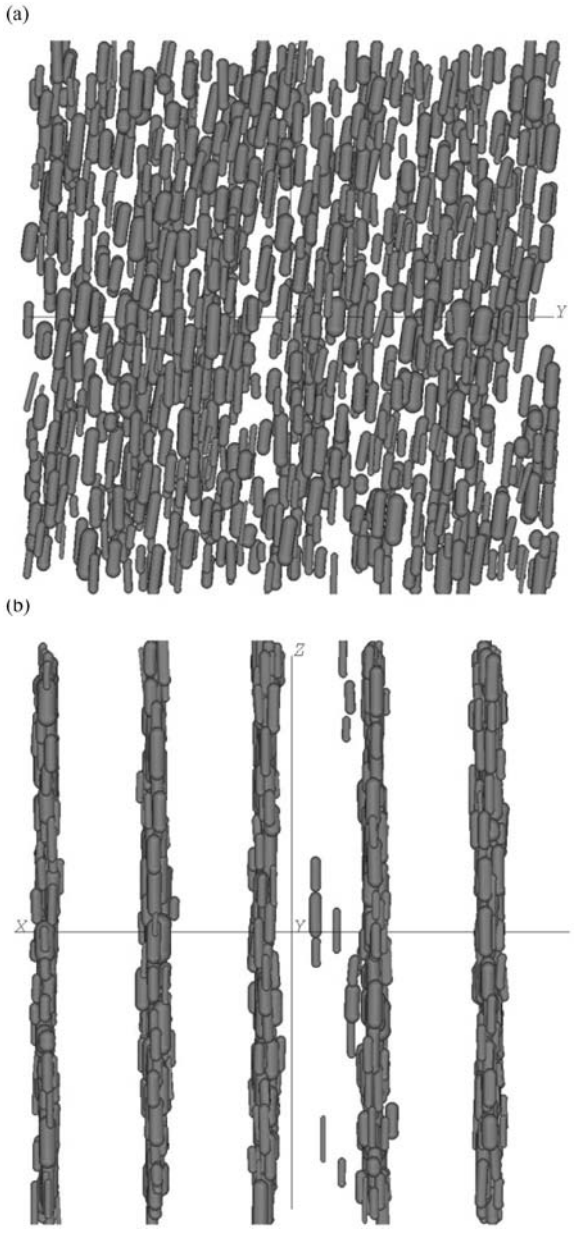

***Figure 5***
(a) Transverse field $z$-direction, high shear, transverse to field view. (b) Transverse field $z$-direction, high shear, flow direction view.

Thus, enhanced magnetization in shear magnetometry experiments, at least in systems of highly elongated particles, can be partially interpreted in terms of a combination of mechanical orientation due to the shear flow as well as the aligning torque of the magnetic field. The structures appear to retain their form in conditions of medium shear rate of around $10000\,s^{-1}$, but become less well defined at the very high shear rates.

## 5. *The Drying Process*

The drying algorithm, used to model the transition from the dispersion to the media, is an important stage in the simulation of media with realistic microstructure. This is because the microstructure of the dispersion is retained as a ''memory'' and acts as a significant influence on the microstructure of the media.

The drying process is difficult to model because the dispersion undergoes rapid solvent loss, which may give rise to local chaotic behavior, while at the same time the resins are cross-linking to form long-chain polymer molecules that tend to inhibit particle mobility. As a result of these processes, there is expected to be a large variation in media viscosity on the local scale during drying.

For these reasons, a phenomenological approach to the drying model is taken whilst attempting to retain some of the important physical properties. The drying simulation is based on the MD-dispersion simulation with the additional feature of a forced-settling algorithm that acts as the volume-reducing scheme.

The model employed here assumes that the particle environment remains at a constant viscosity of 1 P throughout the simulated drying, although in reality the viscosity increases dramatically as the solvent escapes and the resins tend to cross-link. At each MD time-step, the height $z$ of each particle above the base of the media is reduced by an amount $dz = z\Delta(t)$ proportional to $z$. The parameter $\Delta$ is a function of the drying time $t$ and is calculated so that the reduction in coating thickness occurs at a rate proportional to $\log(t)$. This is in keeping with observations made on solvent loss in particulate media by Gilson (1993), Fig. 6.

## 6. *Magnetization Modeling*

The magnetic behavior of the dispersion in the coating and drying stages has been modeled via a pole–pole interaction model. This scheme is assumed to be a good approximation for the high-coercivity particles while they exhibit reasonable mobility. Magnetization modeling of the media has been carried out using a chain-of-spheres model in order that nonuniform magnetic states of a particle may be taken into account. The behavior of a particle moment is determined by a Landau-Lifshitz equation with the addition of a stochastic field term after Chantrell *et al.* 1998. This method employs estimations of the usual anisotropy, exchange, dipole and interaction field terms together with the behavior associated with thermal effects.

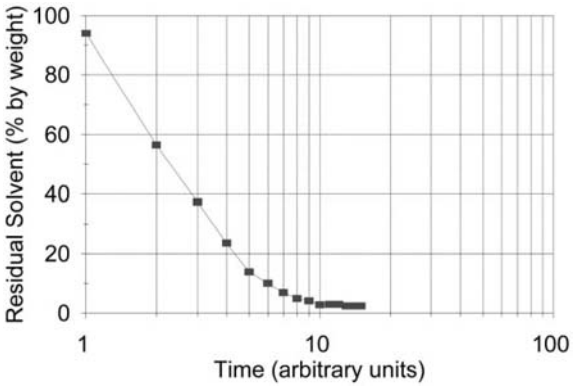

***Figure 6***
A typical drying curve from production of a modern data tape product, indicating the presence of three regimes.

The Landau-Lifshitz equation, describing the motion of a unit vector $\vec{m}_i$ in the magnetization direction $\vec{M} = \vec{m}\, M_s V_i$, of volume element $V_i$ may be written,

$$\frac{\mathrm{d}\,\vec{m}_i}{\mathrm{d}t} = \frac{\gamma}{1+\alpha^2}\vec{m}_i \times \vec{H} - \frac{\alpha\gamma}{M_s V_i(1+\alpha^2)}\vec{m}_i \times (\vec{m}_i \times \vec{H})$$

where $\gamma$ is the gyromagnetic constant, $\alpha$ is a damping constant.

The total local field $H$ experienced by a moment $i$ is the sum of contributions from the dipole field,

$$\sum_j V_j M_s \left( \frac{(\vec{m}_j\, \vec{r}_{ij})\, \vec{r}_{ij}}{\vec{r}_{ij}^{\,3}} - \frac{\vec{m}_j}{\vec{r}_{ij}^{\,3}} \right)$$

where $V_j$ is the volume of volume element $J$, and $r_{ij}$ is the unit vector from element to $j$ to $i$. The exchange field derived from moments in the same particle,

$$\frac{2A}{M_s}\sum_j \frac{\vec{m}_j}{d_{ij}^2}$$

where $A$ is the exchange constant between elements in the same particle, and $d_{ij}$ is the distance between elements of the same particle.

The anisotropy field is representative of the crystalline and shape anisotropy,

$$\frac{2K}{M_s}(\vec{e}\cdot\vec{m})\,\vec{e}$$

where $K$ is the anisotropy constant, and $\vec{e}$ is the unit vector in the direction of the anisotropy axis.

The thermal fluctuation field is implemented in the computation algorithm so that after a large number of statistical samplings it will exhibit a Gaussian distribution with variance according to Brown (1979) as

$$\frac{k_B T \alpha}{K V_i (1+\alpha^2)\cdot \Delta\tau}$$

where $k_B$ is the Boltzman constant, $T$ is the temperature, and $\Delta\tau$ is the integration time-step. Finally, there is the applied field term.

## 7. *The Microstructure of Magnetic Media*

This study of the effect of the coating process on the bulk magnetization properties of coated media represents first-principle micromagnetic calculations since the microstructure has been realistically derived at the microscopic level.

Starting from a "wet" precursor with a VPF of around 20%, the model has been employed to study two extreme cases of drying, which yield the two extreme values of hysteresis properties for media, 40% vpf. The two cases being (i) drying without an orienting field (Fig. 7(a)), and (ii) drying in a strong orienting field (Fig. 7(b)). Both the sections shown are $0.8\,\mu \times 0.8\,\mu \times 0.2\,\mu$ in cross section.

Three fine 3D sections of the simulated microstructure are shown in Fig. 7(c). The top view of Fig. 7(c) is a $0.8\,\mu \times 0.2\,\mu \times 0.1\,\mu$ cross section, taken along the web direction of media dried in zero field which clearly shows the poor orientation of the particles. The middle view is the corresponding section of field-dried media (Fig. 7(b)), which shows very strong alignment in the web/field direction. The lower view is a finer section of the middle view showing more clearly the lack of homogeneity in the distribution of particles. The microstructure of the field-dried media contains small voids predominantly aligned in the field direction. These voids can be traced back to open regions in the dispersion microstructure. They are predicted to act as "drying channels" through which the solvent can evaporate. It has been proposed by Gilson (1993) that channels are necessary to allow the coating to dry rapidly enough and so it would appear that voids in the final coated medium are an unavoidable consequence of the drying process itself.

Particle orientation is an important property of media and may be characterized for study by a suitable correlation function. The function employed here correlates particle alignment with respect to the plane of the medium web, the $x$–$y$ plane, with the plane perpendicular to the media web aligned along the web, the $y$–$z$ plane. (Certain correlations are seen to be physically forbidden, such as, for example, a particle lying perpendicular to both planes.) The correlation function of the zero-field media made from nonsheared coating is shown in Fig. 8. The dispersion does not exhibit any preferential alignment but the drying process tends to alignment in the plane of the media; the $x$–$y$ plane.

Strong shearing of the dispersion tends to align the particles in the shear direction but the drying process disrupts and weakens this strong orientation. The strong particle alignment seen in the dispersion

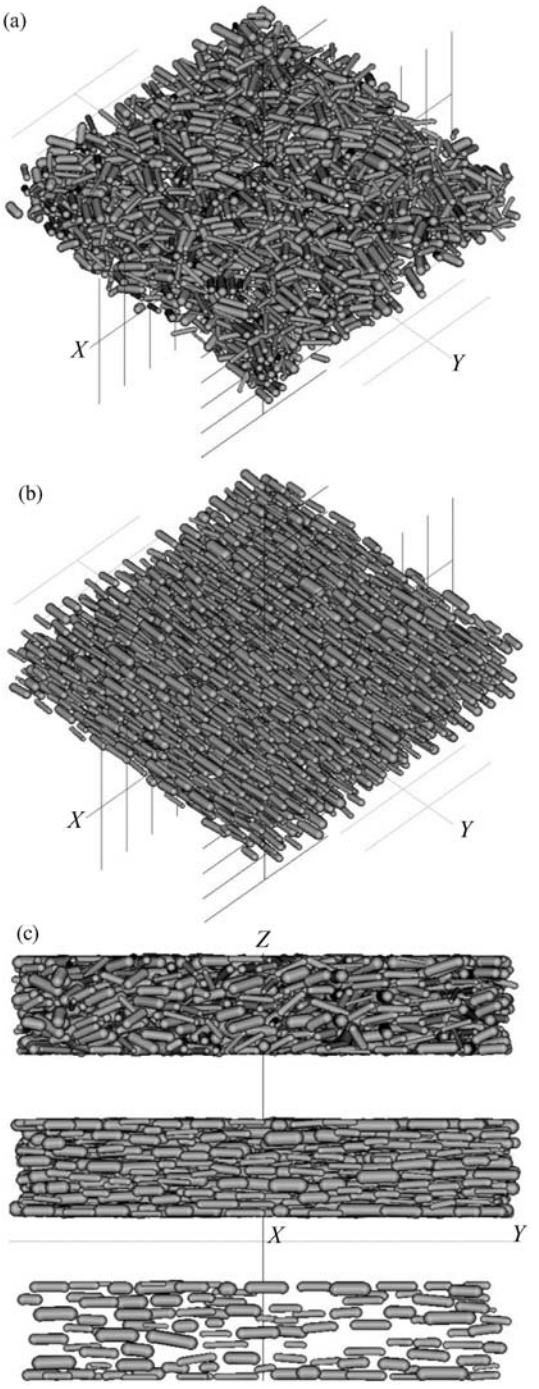

***Figure 7***

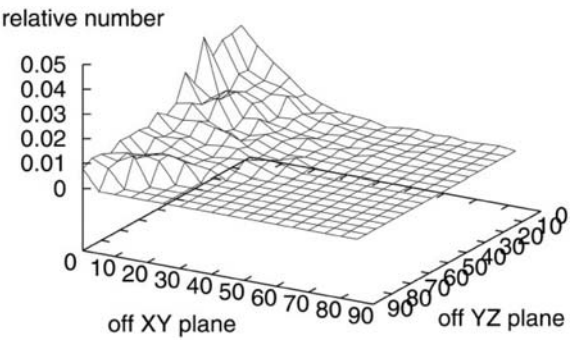

***Figure 9***
Correlation function of the zero-field media made from sheared coating.

coating is lost during the simulated drying but the media nevertheless exhibits a tendency for particle alignment in both the plane of the web and along the web direction. The correlation function for this medium is shown in the Fig 9.

In contrast, the media made by drying the dispersion in a strong magnetic field exhibits very strong alignment in the field direction, shown in Fig. 10. The predicted alignment is expected to overestimate particle orientation as the model is not able to include the disruptive effects arising from the high rate of solvent loss. This strong alignment is necessary for the production of good-quality magnetic storage media.

## *8. Magnetic Properties of Magnetic Media*

Two hysteresis curves, one for an interacting and the other for a noninteracting system, have been calculated from an initial saturated state for the zero-field media (Fig. 7(a)) and the field-dried media (Fig. 7(b)). The results for the interacting and noninteracting

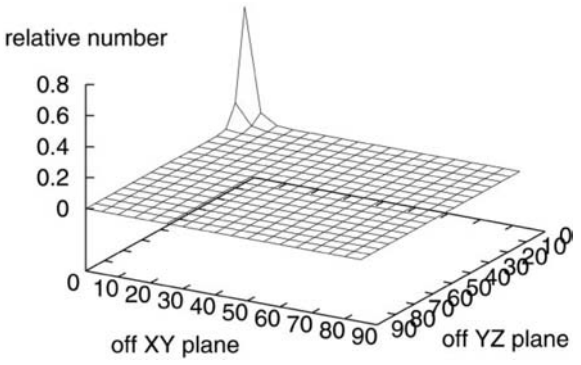

***Figure 10***
Correlation function of the field-dried media made from sheared coating.

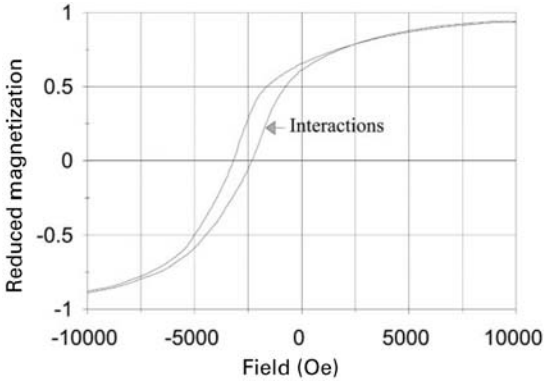

***Figure 11***
Hysteresis curve with and without interactions for zero-field media.

cases have been calculated using the same simulated microstructure, therefore a direct comparison of effects may be made.

The hysteresis curve for the zero-field media (Fig. 11) shows a relatively high squareness seen in the noninteracting case and is indicative of the partial alignment during the coating process. As expected, the interparticle interactions give rise to a reduced remanence and coercivity. Although the coercivity of the medium is reasonable in comparison with experiment, the remanence is rather low. The hysteresis curve for the field-dried media is shown in Fig. 12. The coercivity is rather large, however the remanent squareness is larger than the experimental result of 0.85–0.9. It would appear therefore that these two cases represent extreme bounds with the properties of real media lying somewhere between.

The d.c. demagnetization remanence curves have also been calculated, from which the switching field distribution has be derived. For the well-aligned

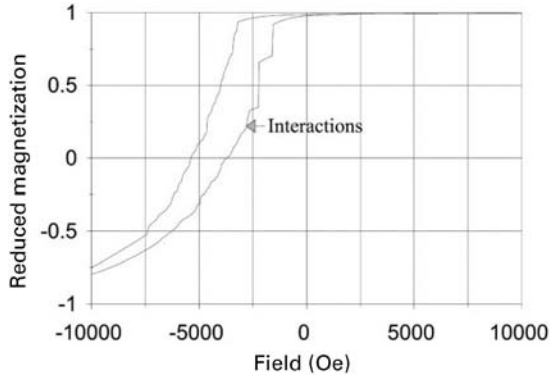

***Figure 12***
Hysteresis curve with and without interactions for field-dried media.

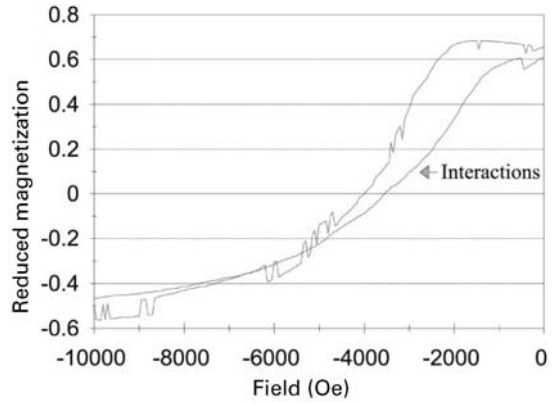

***Figure 13***
D.c. Demagnetization curve with and without interactions for the zero-field media.

field-dried media, the magnetization was found to be essentially perfectly irreversible with no significant difference between the hysteresis loop and d.c. demagnetization curve. The d.c. demagnetization curves for the poorly aligned zero-field media are shown in Fig. 13.

The effect of interactions is to lower the remanence and coercivity, which is to be expected and is normally observed experimentally. A second effect is also clear, this being a dramatic increase of the initial shape of the remanence curve in small fields. This is accompanied by an increase in the width of the switching field distribution, (SFD), shown in Figs. 14 and 15, which presumably reflects a dispersion of the local interaction field, which seems reasonable.

In terms of recording properties, the increase in the initial remanence shape due to interactions is significant. It might be expected, for example, to lead to

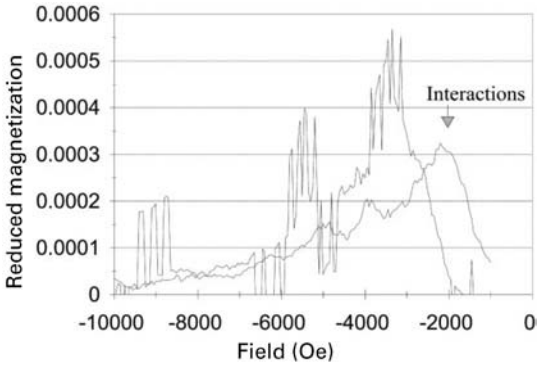

***Figure 14***
Switching field distribution with and without interactions for zero-field media.

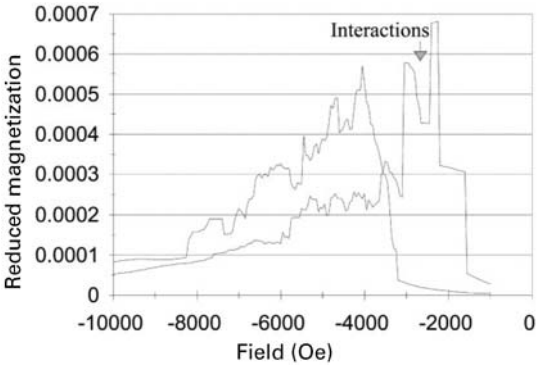

***Figure 15***
Switching field distribution with and without interactions for field-dried media.

transition broadening given that the increased remanence shape represents a reduced stability against demagnetization. A further factor in this respect is the relationship between the irreversible susceptibility $\chi_{\mathrm{irr}}$ and the time-dependent magnetization, i.e., $S_v = \chi_{irr} H_f$, where $S_{\mathrm{v}}$ is the coefficient of magnetic viscosity and $H_{\mathrm{f}}$ is the fluctuation field. The differentiation of the remanence curve (equivalent to the SFD) is an experimental approximation to $\chi_{\mathrm{irr}}$. Hence, an increase in the SFD fields of the order of those occurring in magnetization transitions must be expected to lead to an increase in the magnetic viscosity and a consequent reduction in the thermal stability of stored information. This effect is crucial to the potential degradation of the data during the long-term storage of magnetic media.

## *9. Conclusion*

''First principles'' calculations of the magnetic properties of the coated medium, i.e., one without *ad hoc* assumptions relating to the physical microstructure, have been made by employing a micromagnetic model of coated particulate media used in conjunction with a molecular dynamic simulation of the medium microstructure.

The calculations give good qualitative agreement with experiment and demonstrate a strong dependence of the magnetic properties on the detail of the coating and orientation process, as is to be expected. Detailed comparisons with experimental data are difficult because of the proprietary nature of information relating to the coating process. However, this approach could form the basis of a systematic experimental investigation which would be of great benefit in understanding both the magnetization processes of coated media and the effects of the coating process on magnetic and recording properties.

# Magnetic Recording: Patterned Media

The term "patterned media" refers to the storage of data in arrays of discrete magnetic elements, such as small, lithographically patterned pillars or bars. The direction of magnetization in each element represents a binary one or zero. This differs from data storage in conventional hard disk or flexible media, in which regions of a magnetic film are magnetized to represent the stored data. Patterned media systems are in their infancy, but have excited great interest because they should in principle be capable of storing data at much higher density than is possible with conventional media.

In conventional hard disks, data are stored as magnetization patterns written onto a continuous thin film (Fig. 1(a)). The film consists of small grains of an alloy such as CoCrTaPt, 10–15 nm in diameter. The grains are exchange-decoupled due to segregation of nonmagnetic elements at the grain boundaries. Each bit written onto the medium covers an area (cell) of hundreds of grains. As recording densities increase, it is desirable to reduce the grain size in order to maintain a large number of grains per bit cell and thus to obtain a good signal-to-noise ratio. However, as grain sizes are decreased, the magnetization of the grains become thermally unstable, leading to the decay of recorded data patterns. This occurs when thermal energy, $kT$, is sufficient to cause reversal of the magnetization within individual grains. Here $k$ is Boltzmann's constant and $T$ is the temperature. This superparamagnetic behavior occurs when $KV < 60\,kT$ (Lu and Charap 1994), where $K$ is the magnetic anisotropy energy per unit volume of the material and $V$ is the grain volume. This behavior sets a lower limit on the grain size of the medium, and therefore limits the achievable signal-to-noise ratio of the media. Increasing the anisotropy $K$ allows $V$ to be decreased, but for high $K$ it becomes difficult to write data patterns on the medium because unreasonably large write fields would be required. An upper limit for recording density on conventional media of 40 Gbin$^{-2}$ was suggested (Charap *et al.* 1997). However these predictions have proven to be pessimistic, and improvements in longitudinal and perpendicular media have continued. In 2005, for example, Hitachi demonstrated 230 Gb/in$^2$ recording. Any practical patterned media will need to support densities well above those achievable with continuous thin film media in order to be economically viable.

Patterned media have been suggested as a means of increasing storage density beyond that achievable with thin film media. A patterned medium (Fig. 1(b) and 1(c)) consists of an array of nanoscale magnets, each of which can store one bit of information depending on its magnetization state. It is important that each element behaves as a single magnetic domain, whether it is single crystal or polycrystalline. The elements in patterned media are still subject to thermal instability, but now the volume $V$ can be as large as the entire volume of the element instead of equal to the grain volume. The elements could be as small as 10 nm, potentially representing an increase in density of 1000 times over thin film media. The difficulties inherent in patterned media storage schemes concern the fabrication of large-area, uniform arrays of magnetic particles, and developing methods for reading and writing the arrays. This article will discuss how arrays can be made, what magnetic properties are desirable in a patterned medium, and what schemes have been proposed for incorporating patterned media into practical storage devices.

## 1. Fabrication of Magnetic Media

The concept of patterning a hard disk using lithography was first proposed as a means of improving tracking and signal-to-noise ratio (Lambert *et al.* 1991). However, as thermal instability limitations in conventional media became more apparent, patterned media appeared to offer a route to higher density recording. Despite this promise, significant development of patterned media did not occur until the 1990s when high resolution lithography became widely available for fabrication of arrays of magnetic elements (Chou *et al.* 1994, Chou 1997, White *et al.* 1997).

The fabrication requirements for patterned media are challenging. To make a structure consisting of 250 G particles in$^{-2}$, an array of elements with a period below 50 nm is needed. The lithography method used must therefore be capable of resolving 25 nm features or better over an area several centimeters or greater in diameter. This is well beyond the capabilities of the optical lithography currently used in semiconductor device fabrication, so higher resolution patterning techniques are necessary. Early studies of small, patterned structures used optical lithography to make arrays with micron-scale features, but the most common method now used to make submicron arrays with features of 10 nm and above is electron-beam

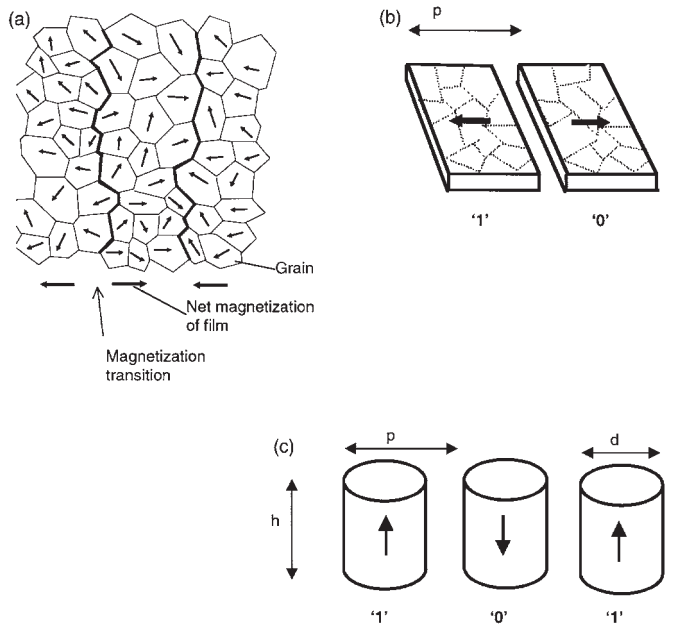

***Figure 1***
Schematic of (a) conventional thin film medium, consisting of single-domain grains. Bits are represented as transitions between regions of opposite net magnetization. Each bit occupies an area of tens to hundreds of grains. (b) Patterned medium with in-plane magnetization. Now the bits are defined lithographically and have period $p$. The bits can be polycrystalline (indicated by dotted lines) or single crystal, but magnetically they act as single domains. (c) Patterned medium with out-of-plane magnetization. The period is $p$, height $h$ and diameter $d$. Binary one and zero are indicated. (Reprinted with permission *J. Vac. Sci. Technol. B***17**, 3168; © American Institute of Physics 1999.)

lithography (e.g., Chou *et al.* 1994, New *et al.* 1996, O'Barr *et al.* 1997). However, this is a serial method in which each element is exposed sequentially, so it is too slow for economic patterning of large areas. Other lithography methods have therefore been explored, including x-ray nanolithography (Rousseaux *et al.* 1995), nano-imprint lithography (Wu *et al.* 1998), and interference lithography (Fernandez *et al.* 1996, Haast *et al.* 1998, Ross *et al.* 1999), all of which are capable of patterning large areas. Self-assembly processes have been proposed as an alternative patterning route. In these methods, the self-assembly of, for instance, pores in anodized alumina (Bao *et al.* 1996) or domains in block copolymers (Zhu *et al.* 1997, Cheng *et al.* 2001) are used as templates for the patterning of magnetic arrays. Magnetic particles can also be made by chemical synthesis and assembled onto a surface to form a regular array (Sun and Murray 1999). Self-assembly techniques can pattern large area structures with good short-range order, but have the drawback that long-range order is often poor. High resolution lithography processes and self-assembly methods have been successfully used to make large area magnetic arrays on a laboratory scale for media prototypes, and scaling up of many of these methods is under development. A promising avenue for patterned media formation is the combination of top-down lithography with self-assembly (Naito *et al.* 2002, Cheng *et al.* 2004).

The magnetic materials themselves are formed using a variety of methods. Commonly, a mask is defined by lithography or self-assembly processes, consisting of an array of holes in a layer made of photoresist or other material. Magnetic material is then electrodeposited through the mask to form an array of pillars, or evaporated over the mask followed by a lift-off process to leave an array of cones or pillars. Alternatively, a film of magnetic material can be initially deposited onto a substrate, then a template or etch mask is defined on top of the magnetic film by lithography. The exposed magnetic material is then etched away to leave an array of magnetic dots. Thin films can also be patterned using a focussed ion beam or other direct writing technique, or by imprint lithography (Lohau *et al.* 2001, Mc Clelland *et al.* 2002). A further method relies on the self-assembly of pre-formed magnetic particles on a surface. Examples of some of these structures are shown in Fig. 2. Each deposition method has its advantages. Electrodeposition is ideal for making

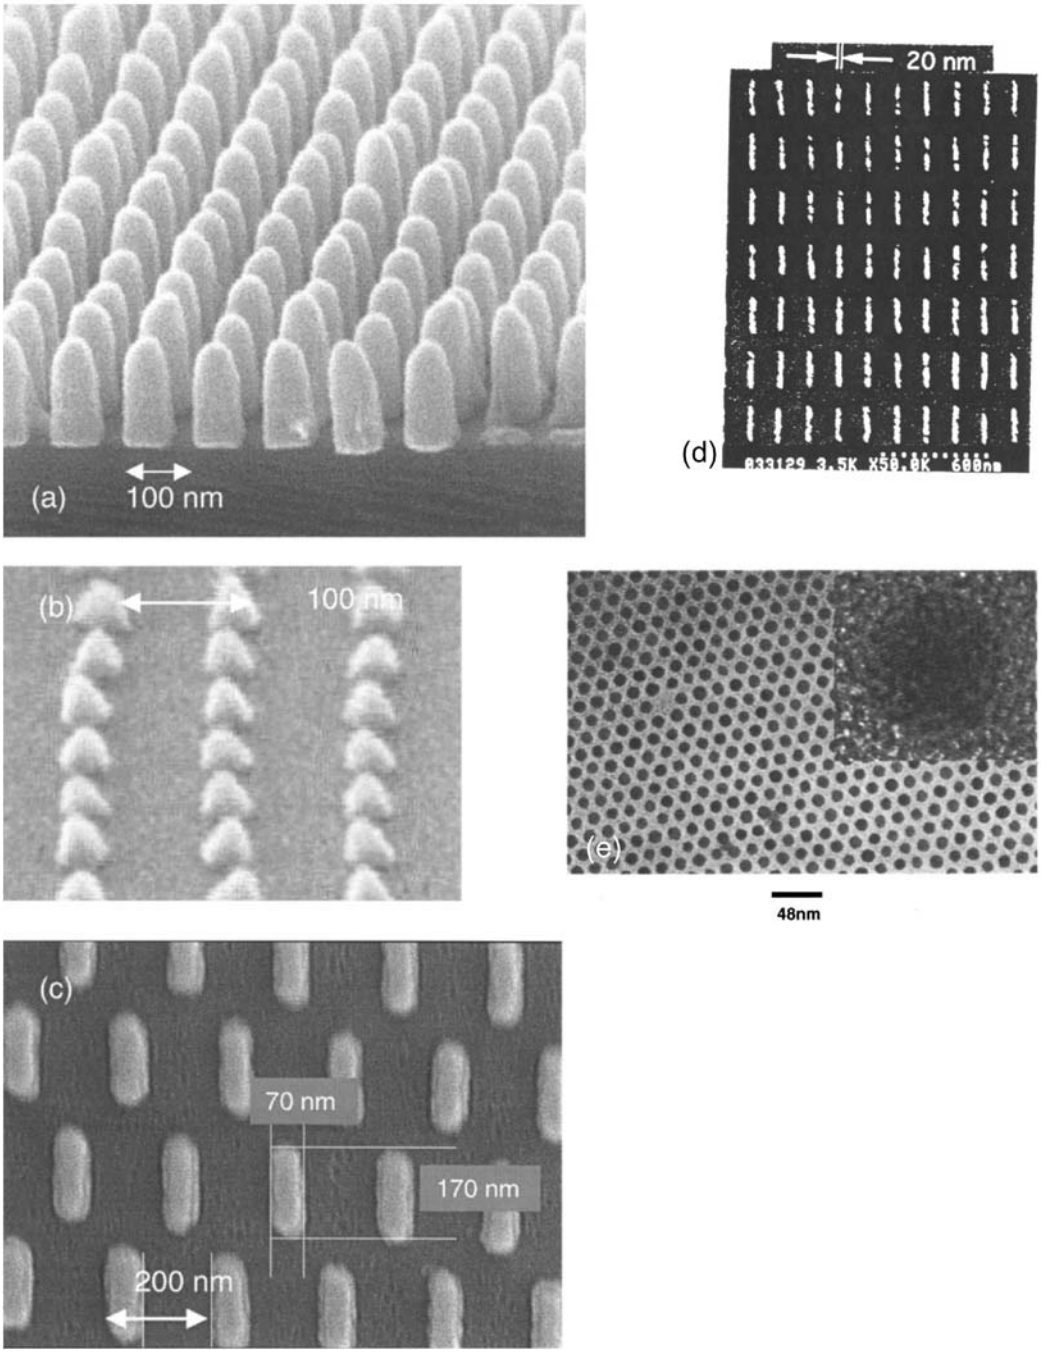

***Figure 2***

features with a large aspect ratio, but it is restricted to certain compositions. Evaporation and liftoff is convenient for flat or conical shapes but is also restricted in composition. Deposition of a film or multilayer structure by sputtering followed by etching offers the greatest range of compositions and magnetic properties, but etching of the material into dots is often difficult and the thickness of the films is limited. The methods chosen will depend on the desired geometry and composition of the array.

## 2. Magnetic Properties of Patterned Media

The optimum magnetic properties of patterned media (the magnetic anisotropy, coercivity or switching field, and magnetic moment) are not as clearly understood as the properties of hard disk or flexible media, and will depend on the specific recording device in which the medium is incorporated. However, some general considerations apply to all patterned media. Most importantly, the elements need to be single-domain particles with a number (usually two) of well-defined stable magnetization states to represent the data bits. For common ferromagnetic materials, single-domain behavior occurs in sub-100 nm particles because it is energetically unfavorable for domain walls to form in very small particles. Hence for a practical patterned medium with sub-100 nm period, the elements will automatically be single-domain as depicted in Fig. 1(b) and Fig 1(c).

A single-domain particle can be characterized by its total magnetic anisotropy $K$, its switching field $H_{sw}$, and its saturation magnetization $M_s$. The anisotropy $K$ controls the direction and number of the preferred magnetization axes. A uniaxial anisotropy defines a single preferred magnetization direction. $K$ includes two major contributions, one arising from the particle shape, $K_s$, and the other from its magnetocrystalline anisotropy, $K_c$ (Cullity 1972). Needle-shaped particles have a uniaxial $K_s$ with magnitude that increases with the particle aspect ratio and with $M_s$; the preferred magnetization direction is parallel to the long axis of the particle. $K_s$ can therefore be controlled by choice of particle shape. In contrast, the magnetocrystalline anisotropy $K_c$ depends on the material composition and crystal structure, and quantifies the preference for the magnetization to lie parallel to certain crystallographic directions within the crystal. Some materials such as cobalt have a strong $K_c$, which in cobalt causes the magnetization to lie parallel to the [0001] direction. By choice of materials, microstructure (amorphous, polycrystalline, or single crystal) and particle shapes, the total anisotropy can therefore be controlled over a wide range. Most patterned media structures rely on shape anisotropy, though magnetocrystalline anisotropy has been used to control magnetization in arrays of iron rectangles (New *et al.* 1996).

The total anisotropy $K$ is important because it governs the switching field $H_{sw}$, which is the magnetic field required to change the magnetization of an element from one direction to the other. This is the most important magnetic parameter in terms of the writing process because the recording system must apply a field of at least $H_{sw}$ to write data on the medium. $H_{sw}$ is determined both by $K$ and by the mechanism of magnetization reversal. In the simplest case, the magnetization of a single domain particle reverses in a uniform manner known as coherent reversal (Stoner and Wohlfarth 1948) and the switching field is simply given by $H_{sw} = 2K/M_s$ when the field is applied parallel to the anisotropy axis. However, measured switching fields are often smaller than this due to nonuniform magnetization reversal processes in which the magnetization reversal might occur by curling (Frei *et al.* 1957), or it might start in one region and propagate through the entire particle (Fredkin *et al.* 1991, Gibson and Schultz 1993, Seberino and Bertram 1997). The switching field for nonuniform reversal depends on particle size and shape, but as the particles become smaller, coherent switching becomes the dominant reversal mode and the switching fields of particles increase (e.g., Chou 1997). Clearly, a lower $H_{sw}$ will make the medium easier to write, but it will also make it more vulnerable to thermal instability (superparamagnetism) and to accidental erasure. Most patterned media prototypes have switching fields of several hundred of oersteds.

In terms of reading data back from the medium, most recording devices are designed to detect the magnetic field surrounding each element. For single domain particles, the field approximates to a dipole field whose magnitude is proportional to $M_s$ and to the particle volume (Cullity 1972). This field decreases as the inverse cube of the distance from the element. A stronger field will make detection of the magnetization state of the element easier. However, if the field from an element is too strong, it may cause inadvertent reversal (writing) of neighboring particles, which is undesirable. If the nearest-neighbor interaction field is $H_i$, then in a square array of perpendicular magnetic dipoles, the maximum field experienced by one element due to all of its neighbors is $9H_i$. Thus a criterion for arrays such as Fig. 1(c) to support stable magnetization patterns is that $H_{sw}$ must exceed $9H_i$ (Ross *et al.* 1999). This limits how close together the elements can be placed. Arrays in which the element separation is similar to the element diameter are usually found to be stable.

## 3. Recording Systems

We have seen that a patterned medium can be designed by choosing the particle size, shape, and material to determine the switching field of the elements

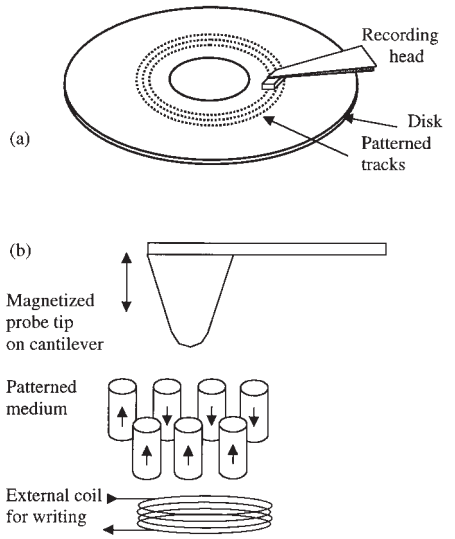

*Figure 3*
Recording schemes using patterned media. (a) A spinning disk. The disk is patterned with elements arranged in circumferential tracks. The medium is written and read using an ultra-narrow recording head. (b) A scanning probe. A probe tip detects the magnetic field from perpendicular patterned elements. An external field, plus the field from the probe tip, is used to write data.

and by choosing the array geometry so that the elements do not interact too strongly. A variety of lithographic and self-assembly processes combined with deposition and etching processes have been developed to make arrays with period of 100 nm and smaller. However, the development of practical recording systems has lagged behind the development of the media.

Development of patterned recording systems has followed two distinct paths as illustrated in Fig. 3. The first is a spinning-disk system, similar to a conventional hard disk system but using a patterned instead of a continuous hard disk medium. This has the advantage that much of the existing hard drive technology is applicable, including the basic design of the drive, actuators and other mechanical components, and signal detection circuitry. The major challenges for this device are to produce heads with extremely narrow widths, to follow accurately the lithographically-defined tracks, and to synchronize the writing process with the physical location of the lithographically-defined bits. In such a scheme the patterned elements may be designed with in-plane (longitudinal) magnetization directions such as Fig. 1(b), similar to a conventional hard disk, or alternatively the elements can have out-of-plane (perpendicular) magnetization directions such as Fig. 1(c). Modeling of the readback response of both types of media has

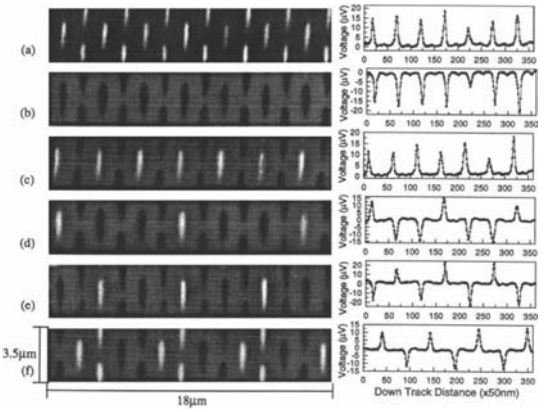

*Figure 4*
A set of images taken using a magnetoresistive recording head which was dragged across an array of nickel pillars with 2-μm spacing. The white and dark images represent up and down magnetizations of the pillars and the linescans show the readback signal from the head. Several different patterns have been written and read back. (Reprinted with permission from *Appl. Phys. Lett.* **74**, 2516; © American Institute of Physics 1999.)

been carried out (Nair and New 1998, Boerner *et al.* 1999), and the reading and writing of patterned media has been demonstrated (Todorovic *et al.* 1999, Zhu *et al.* 2000, Albrecht *et al.* 2003) as shown in Fig. 4, but a practical spinning-disk system has not been made.

A more radical departure from conventional recording is a probe-based system (Ohkubo *et al.* 1991, Mamin *et al.* 1995). In this case, a scanning probe tip similar to an atomic force microscope addresses an array of elements. The elements are perpendicularly magnetized as shown in Fig. 3(b). The probe tip is magnetic and is mounted on the end of a flexible cantilever. The probe detects the magnetization state of each element by responding to the force gradient exerted by the magnetic field emanating from the element, which causes a change in the resonant frequency of the cantilever. This is the same as the operation of a magnetic force microscope. To write data patterns on the medium, a magnetic field less than $H_{sw}$ is applied to all the elements using an external coil. The magnetic probe tip is then moved close to the target element, so that the sum of the field from the probe tip plus the external field is sufficient to reverse that one element but not its neighbors (Gibson and Schultz 1993, Kleiber *et al.* 1998). Variations on this theme are also possible, for instance using a separate tip for reading and writing (Chou 1997, Kong *et al.* 1997). An example of an array with written features is shown in Fig. 5.

These probe-based systems are inherently slow because they rely on moving the probe tip to specific

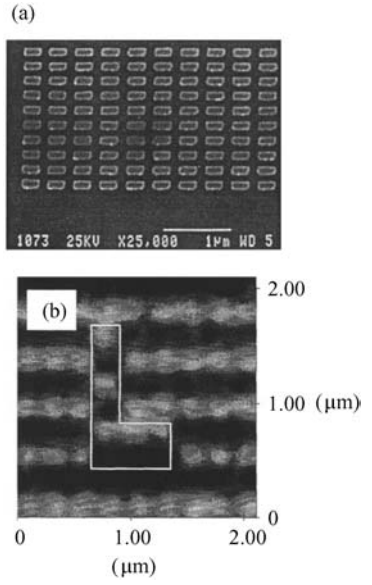

***Figure 5***

locations in the patterned medium. To increase the data rate, a large number of probe tips working in parallel is necessary (Pohl 1995, Minne *et al.* 1996, Binnig *et al.* 1999). In these devices, the challenges are to make the device compact and mechanically robust, and to design a reliable method for writing the underlying patterned magnetic media.

One other storage scheme that should be mentioned in relation to patterned media is the magnetic random access memory (MRAM) (e.g., Tehrani *et al.* 1999), which is described in more detail in the article *Random Access Memories: Magnetic*. These devices consist of an array of magnetoresistive elements, connected together by conductor lines. Each element stores one data bit, as in the patterned media systems described above, but the elements in a MRAM consist of more complex, multilayer films such as spin-valve or spin-tunneling structures such as the sample shown in Fig. 2(c). Many of the issues of inter-element interactions, thermal stability, and switching behavior, as well as the need for high resolution lithographic patterning, are common to both MRAM elements and patterned media.

## *4. Summary*

The onset of thermal instability (superparamagnetism) in conventional hard-disk media is driving the development of patterned media systems for areal densities exceeding hundreds of $Gbin^{-2}$. Patterned medium structures have already been fabricated using a range of lithographic and deposition techniques, and the switching field and interactions between the elements can be controlled by the choice of materials and array geometry. The development of practical storage schemes has lagged behind the development of media, but prototype systems have been demonstrated. Patterned media will most likely first appear in a spinning-disk system, but probe-based systems have also been explored.

# Magnetic Recording: Rigid Media, Preparation

Hard disks have various formats with diameters varying from 3.5 in (8.9 cm) for PCs to 2.5 in (6.4 cm) and to 1.8 in (4.6 cm) for laptop and notebook computer drives. The disk has a central hole for location on the spindle of the disk drive motor. The rotating disk is addressed by read/write head(s) ''flying'' within tens of nanometers of its surface. The disk substrate, on which the magnetic film is deposited, varies in thickness from about 1.25 mm for 3.5 in disks to 0.5 mm for the smaller format disks. Rotation speeds for the disk are continually increasing to decrease access times, and speeds approaching 10000 rpm are now used.

A cross-section of the structure on one side of a conventional disk is shown in Fig. 1. The first layer is often a thick, mechanically hard and nonmagnetic film on which is deposited one or more underlayers or seed layers that encourage a preferred microstructure and crystallographic texture in the magnetic layer. It can be seen that the magnetic film is relatively thin. The hard coating and the lubricating layer at the head/disk interface protect the magnetic storage layer in any contact stop–start phase of the head slider flight and also assist in that flight.

## 1. The Substrate

The most common disk substrate material is an Al–4% Mg alloy. The disk is prepared by stamping, and

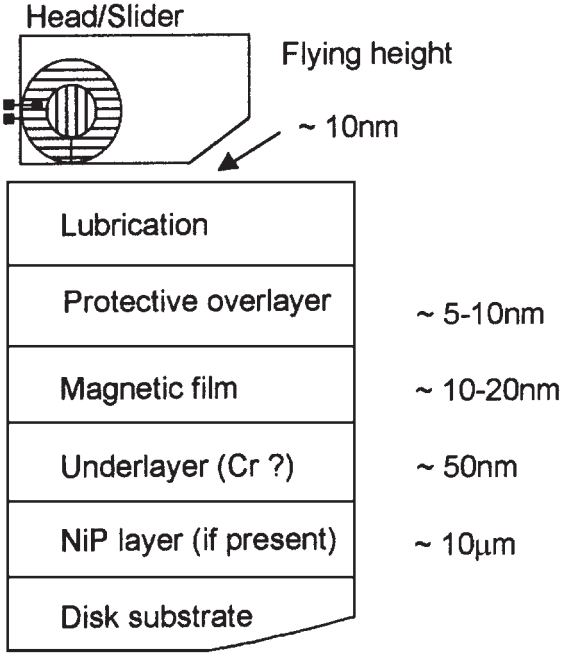

***Figure 1***
Schematic diagram showing a cross-section of one side of a typical thin-film hard disk.

a first coating is generally prepared by chemically plating the aluminum alloy disk with about 10 μm of a structurally amorphous and mechanically hard NiP alloy. This layer is then often mechanically textured on the micrometer scale and the resulting uneven surface of the finished disk reduces problems with stiction in the start and stop phases of the head slider flight in systems in which the head is "parked" on the disk at rest. However, the move to higher and higher storage densities requires smaller and smaller ($\sim$10 nm) flying heights.

This is leading to smoother finishes on the disk and the adoption of procedures such as locally focused ion beam and laser etching to produce relatively rough areas on which to land and park the head. Faster rotation rates, essential to reduce access times and increase data rates, require stronger, harder, stiffer, and lighter substrate materials. These are usually nonmetallic to avoid mechanically induced distortion and glass, glass ceramic, aluminum, boron, and silicon carbides, and silicon are being used or are being explored. However, the substrate material must be thermally stable and also process compatible. Also, the nucleation and growth of the several layers on the disk may very well depend on the substrate material.

The various layers, apart from the NiP layer, are now without exception put down by physical vapor deposition (PVD) methods, nearly always sputter deposition, at fairly fast rates of $\sim 10\,\text{nms}^{-1}$ onto variable temperature substrates. The use of PVD techniques offers the necessary control and reproducibility in the deposition process. The different forms of magnetron sputtering that may be used are variations on a technique that offers excellent control of deposition rate, film thickness, alloy composition, substrate conditions and environment, and efficient use of the target material.

## 2. *The Underlayer*

The magnetic layer is deposited on one or more chosen underlayers or "seed" layers (Figs. 1 and 2). The usual role of the underlayer(s) is to promote the growth of a particular crystallographic texture and grain size and morphology in the magnetic layer. The magnetic layer is, without exception, a polycrystalline, cobalt-based alloy film, typically CoCrTa,Pt that crystallizes with a hexagonal crystal structure. The magnetically preferred orientation of the grains is with their [001] *c*-axis in the plane of the film. As discussed below, there is an exception to this in media designed for the perpendicular recording mode in which the *c*-axis should be perpendicular to the film plane. However, commercial drives use "longitudinal" recording and in-plane magnetization is required.

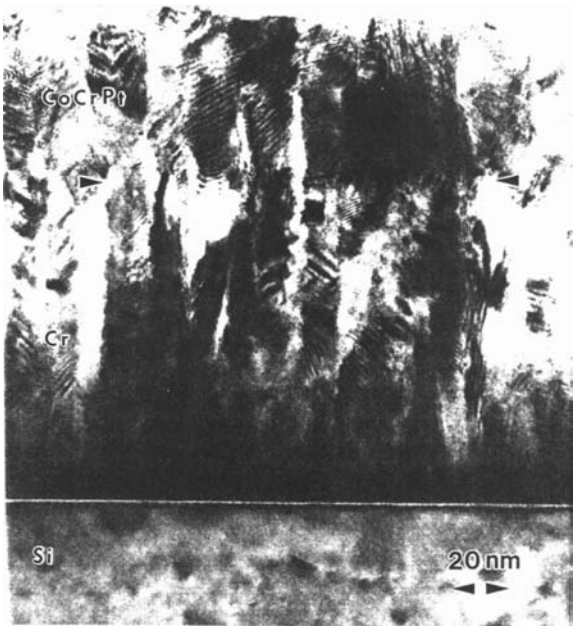

***Figure 2***
High-resolution transmission electron micrograph of a cross-sectional sample prepared from an experimental thin-film disk showing the silicon substrate, the chromium underlayer, and the CoCrPt magnetic layer.

The heteroepitaxy between the underlayer(s) and the magnetic layer, which is so apparently beneficial to recording performance, clearly must depend on the lattice spacings of the layers as well as their crystal structures. Important additions to the basic CoCr alloy in the magnetic layer are tantalum and platinum. The alloy is still hexagonally packed but there are subtle changes in the $c/a$ ratio on alloying. Chromium has been the usual underlayer but b.c.c. alloys based on chromium, such as CrV and CrTi, can be used (Shiroishi *et al*. 1993) to improve the crystallographic fit and perhaps also to produce elastic distortions in the magnetic layer that in turn may increase anisotropy and coercivity. Growth orientations of the cobalt alloy layer on the immediate underlayer that have been identified (Lee *et al*. 1995, Grundy 1998) are typically (10.0)Co//(112)Cr, (11.0)Co//(100)Cr.

The crystallographic texture, grain size, and morphology developed in the underlayer depend on the substrate type and process conditions. Important process conditions are base vacuum, substrate temperature, deposition rate, sputter gas pressure, and film thickness. Various strategies are used to promote oriented chromium or chromium alloy layers on glass and other substrates, including the initial deposition of special seed layers such as NiAl (Lee *et al*. 1995) under the chromium.

The requirements for the magnetic layer are that it has optimized magnetic properties and also that it provides the recording and replay performance required from the finished disk. The microstructure and many magnetic properties, such as magnetocrystalline and shape anisotropies and intergranular exchange, of the overlying magnetic layer depend on the microstructure of the underlayer(s) (Grundy 1998). Their crystallographic orientation, grain structure, crystal lattice parameters, and thermal and chemical properties control the growth of the magnetic layer. It is found that conditions restricting adatom mobility, such as low substrate temperature and high sputtering pressures ($\geqslant 1$ Pa), encourage unoriented films with a rough surface. Low deposition pressures and higher substrate temperatures ($\sim 200\,^{\circ}$C) favor increased mobility and oriented and smoother chromium and chromium alloy deposits.

## 3. The Magnetic Layer

The improved recording and replay performance required of magnetic disks has led to the development of CoCr-based ternary alloys, such as CoCrTa,Pt, quaternary, and, indeed, quinternary alloys and the deposition of polycrystalline films with small (20–50 nm), oriented but segregated grains (Fig. 2). The size distribution of the grains should be narrow, with a mean size as small as possible, but one that is greater than the so-called superparamagnetic limit so that the recorded signal is stable.

It is known that media noise, the dominant noise limiting recoverable signals in replay, is reduced when the magnetic medium is subdivided into isolated, noninteracting particles. However, smaller particles require a larger value of magnetic anisotropy for stability (Lu and Charap 1994). To satisfy this need, media with increased magnetocrystalline anisotropy are required.

Chromium was originally used to improve the corrosion properties of cobalt films but it was also found to help in increasing coercivity and reducing replay noise. This is achieved by segregation of chromium at the grain boundaries producing a nonmagnetic layer that interrupts exchange interactions between grains or clusters of grains (Doerner *et al*. 1993). There is also evidence that compositional gradients exist within grains (Hono *et al*. 1995). The tantalum and platinum additions substitute into the majority cobalt lattice and increase the magnetocrystalline anisotropy with a concomitant increase in coercivity. However, cobalt and its alloys can exist in other crystalline forms, notably a f.c.c. structure. The magnetization of the f.c.c. form of cobalt is not very different from that of the hexagonal phase but it has four easy axes of magnetization along the $\langle 111 \rangle$ directions and the magnetocrystalline anisotropy is much less than that of the h.c.p. phase. Cubic grains would have a deleterious effect on the recording behavior of the film (Dova *et al*. 1999).

In efforts to increase coercivity even further, what might be called the confusion principle is being applied in the investigation of even more complex quaternary and quinternary alloys such as CoCrPtXY (Akimoto and Shinohara 1998), where X and Y are tantalum, niobium, silicon, or boron. Boron enters the lattice interstitially and changes the $c/a$ ratio, as do the substitutional solutes. It is therefore probable that anisotropy will be changed and segregation effects made more complex.

## 4. Overlayers

The integrity of the thin-film disk in the drive is preserved by the application of a mechanically hard overlayer. This prevents wear of the magnetic layer in any stop–start action. Such wear would involve loss of the storage medium and the information it contains and it would also introduce debris into the drive mechanisms. Low friction in the system is ensured by a final coating of a high molecular weight polymer.

The most common hard overlayer is a thin (5–10 nm) film of modified carbon. Sputter or plasma beam deposition of carbon in atmospheres containing hydrogen or hydrocarbons can result in so-called diamond-like carbon (DLC) films (Cord and Scherer 2000). The presence of hydrogen in the films favors the formation of $sp^3$ bond orbitals at the expense of $sp^2$ orbitals that are characteristic of graphitic

bonding. The resultant density and hardness of the films is a function of the hydrogen content of the films and the relative proportion of $sp^3/sp^2$ bonding. Values in the literature are in the range 5–20 GPa. This compares with the hardness of, for example, tungsten carbide, WC, at 3 GPa.

Typical lubricants are the perfluoropolyethers, such as Fomblin, with molecular weights of 2000 and more. These lubricants have the necessary properties of thermal and chemical stability, low vapor pressure, and low surface tension (Bushan 1990). The coating is at a monolayer thickness and binds to the carbon overcoat by interactions between end groups in the linear polymer and the carbon surface. The strong binding ensures that lubricant remains between the head slider and the disk where contact occurs and also that it does not leave the disk when it spins at high speed. However, some mobility is needed so that areas from where lubricant is lost can be recovered.

## 5. Perpendicular Recording Media

The thin-film media discussed so far have in-plane magnetization and record information in the longitudinal mode. A second mode of recording has been proposed (Iwasaki and Nakamura 1977) in which the transitions separate regions magnetized perpendicularly to the film surface. This situation requires a magnetically uniaxial film in which a strong, perpendicular anisotropy, $K_p$, outweighs the demagnetizing energy, i.e., $K_p > \mu_0 M_s^2/2$, and supports magnetization normal to the film. Several types of material have been investigated, including particulate barium ferrite films and sputter-deposited crystalline films of cobalt alloyed with transition metals (Grundy and Ali 1983).

The media investigated mostly so far are cobalt alloyed with chromium at compositions round $Co_{81}Cr_{19}$ (Wright *et al.* 1985) A well oriented, columnar or equiaxed microstructure can be obtained by growth on a variety of substrates; including rigid substrates, such as glass, and glass coated with f.c.c. crystalline underlayers and NiFe (the NiFe acts as a magnetic closure layer) and amorphous underlayers such as germanium, and flexible substrates such as polyimide and melinex. The metallic underlayers are preferentially oriented with a $\langle 111 \rangle$ fiber texture, which encourages heteroepitaxy in the CoCr layer, whereas the amorphous plastics and germanium presumably favor the nucleation of the high surface energy basal planes in the cobalt alloy. The main advantage of the perpendicular scheme is that, in principle, the recording transition width is narrower than for the longitudinal mode and hence higher bit densities are possible. At the same time, the magnetic structure is resistant to demagnetization, even at high packing densities.

There is as yet no perpendicular recording disk drive on the market. There is no doubt of the potential of the scheme for very high storage densities. Calculations (Bertram and Williams 2000) have suggested that, although acceptable limits for longitudinal recording may be upgraded to $\sim 100\,\mathrm{Gbits\,in^{-2}}$ ($15\,\mathrm{Gbits\,cm^{-2}}$), perpendicular recording may support $\sim 500\,\mathrm{Gbits\,in^{-2}}$ ($75\,\mathrm{Gbits\,cm^{-2}}$). There have been problems in developing a fully integrated system, and the very rapid improvements in longitudinal media and associated GMR heads are providing strong competition. However, the great potential of the perpendicular mode in resisting demagnetization and thermal instability is rekindling a great deal of activity in the development of this technology. It may yet provide the transitional mode of magnetic storage between the longitudinal scheme and patterned media.

## 6. Fabrication

Commercial deposition equipment attempts to reproduce the precision of laboratory systems and yet operate with the cost effectiveness and reproducibility of mass production methods. They usually take one of two forms. The first is the in-line coater in which disks are unloaded from a cassette in a load-lock chamber and progress through a series of in-line process chambers in which the various layers are sequentially deposited onto the disk.

In this type of coater, such as the Leybold A400 system (Leybold AG, Hanau, Germany), the individual deposition chambers for, say, chromium, CoCrTa,Pt, and carbon depositions are separated by individually pumped buffer chambers with narrow-aperture slit load locks that allow continuous passage of the palates loaded with disks between large rectangular magnetron cathodes. The second system is the single-station system where most of the layers are deposited onto the disk from a cluster set of circular magnetrons. The Balzers CIRCULUS M12 or M14 (Balzers Process Systems, Balzers, Liechtenstein), have 12 or 14 process stations in a circular layout (Fig. 3). Each disk progresses round the circle of magnetrons from the input station to a holding cassette at the output. Each station is isolated and has its own pumping and cold trap system, gas supply, and measurement devices.

In both systems rapid processing demands sputter deposition at rates greater than $10\,\mathrm{nm\,s^{-1}}$, and substrate heating and cooling for the various deposition regimes. Layers are deposited with little interruption to avoid contamination and to achieve reproducibility. Uniformity across the disk can in principle be enhanced by using magnetrons with on-line adjustable magnet fields. The base vacuum standard in both systems is that of conventional high vacuum, i.e., $\leqslant 10^{-5}$ Pa, with partial pressures of $< 10^{-4}$ Pa, of $H_2O$ and $< 5 \times 10^{-5}$ Pa of $N_2$ and $O_2$, respectively. Disk production demands, of course, a clean room environment up to semiconductor fabrication

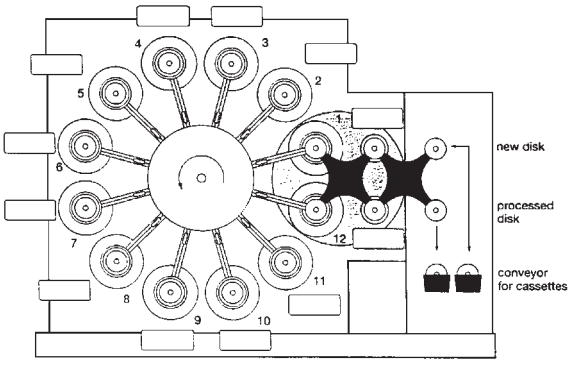

***Figure 3***
Schematic plan of the Balzers CIRCULUS M12 deposition system showing the disk input and output stage and the 12 magnetron positions.

standards in the initial presentation of the disks and in any subsequent testing and in packaging after fabrication. Commercial deposition systems can now produce fully coated disks at rates approaching 1000 per hour.

There are continuing efforts to improve processing procedures and to introduce new technologies in disk fabrication (Cord and Scherer 2000). For instance, research (Takahashi *et al.* 1997) has shown that improved properties, including larger magnetic coercivity, can be obtained in samples deposited in systems which have ultrahigh vacuum base pressures ($<5\times 10^{-7}$ Pa) and use very pure target materials and sputtering gas. This is thought to produce uncontaminated thin films with grains that are less faulted, which for a given composition should have an increased anisotropy field and greater coercivity. Any moves to adopt such preparation standards commercially will need to take account of increased costs of fabrication, although investment in plant is essentially a one-off expenditure. However, the required increases in storage densities discussed above will probably lead to more demanding standards in disk fabrication.

## Magnetic Recording: Rigid Media, Recording Properties

Rigid disk drive performances are being pushed ahead at such an enormous rate that disk recording has become the flagship for state of the art developments in digital recording. Other applications of recording benefit from and follow this lead but at a lesser pace. This article will describe briefly the theoretical background to digital recording and identify which properties of the recording media are important.

Recording media used in rigid disk drives are without exception of high coercivity and very thin. These requirements have been known for many years and have grown to be accepted as a result of early experimental and theoretical work completed largely in the

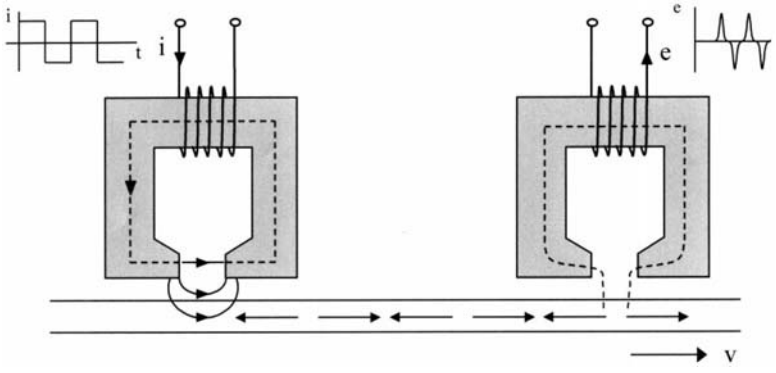

***Figure 1***
Schematic of the record and replay processes.

1960s and 1970s (e.g., Bertram 1994, Comstock 1999, Hoagland 1963, Hoagland and Monson 1998, Middleton 1987, Middleton 1989, Richter 1999). Since then, technology has marched ahead and so has the understanding of the nature of the record and replay processes. The values of the parameters involved have also changed dramatically but the basic requirements remain for thin media of high coercivity.

Figure 1 shows a simple diagram illustrating the complete digital record–replay cycle. A current into the record head is magnetizing a section of the medium to the right, whereas previously a current of the opposite polarity caused a magnetization to be written to the left. The magnetization transition between these states is used to represent a bit of stored information and a sequence of recorded transitions, or absences of them at particular locations along the track, is used to represent the recorded data. The width of a transition is indicative of the space needed to store a bit of information and so this is an important parameter ultimately determining the density at which bits are stored. When a transition moves under the replay head the stray field arising from its divergent magnetization couples into the head structure and generates an output voltage pulse. This article considers the nature of the recorded magnetization transitions and the corresponding output waveforms, and draws conclusions about the requirements for high-density recording.

## 1. The Recording of a Transition

In this theory (Middleton 1987, Middleton 1989), only components of magnetization in the plane of the recording medium, which have been assumed to arise from the influence of the planar components of the head field, will be considered. Figure 2 shows detail of how the head field magnetizes a medium to the right which had previously been magnetized to the left. The magnetization variation in the transition is determined

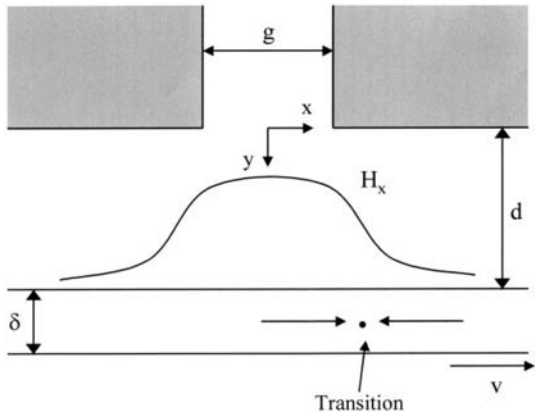

***Figure 2***
Close up of the head gap, the field distribution, and the recorded transition to the right of the gap.

by the hysteresis loop $M(H_t)$ of the medium and the total field $H_t$ it experiences. The latter is made up of head field $H_x$ plus any demagnetising field $H_d$ produced by the medium. The head field is given by:

$$H_x = \frac{H_g}{\pi}\left(|\tan^{-1}|\left(\frac{g/2+x}{y}\right)+|\tan^{-1}|\left(\frac{g/2-x}{y}\right)\right) \quad (1)$$

where $H_g = ni\eta/g$ is the field along the surface of the head ($y=0$) where $n$ is the number of turns, $\eta$ the head efficiency, $i$ the record current, $g$ the gap length, and $x$ and $y$ are defined in Fig. 2.

The recorded magnetization in the transition is assumed, for simplicity, to take the form:

$$M = -\frac{2}{\pi}M_r \tan^{-1}\left(\frac{x-x_o}{a}\right) \quad (2)$$

where the center of the transition is at $x=x_o$, near to the trailing edge of the gap, and the magnetization varies smoothly from a value of $+M_r$ on one side to

$-M_r$ on the other. $M_r$ is the remanent magnetization of the medium and $a$ is proportional to the transition width and is known as the transition width parameter. Using Eqn. (2) the demagnetizing field arising from a thin medium of thickness $\delta$ is:

$$H_d = \frac{M_r \delta (x - x_o)}{\pi((x - x_o)^2 + a^2)} \tag{3}$$

The gradient of the magnetization in the transition is given by:

$$\frac{dM}{dx} = \frac{dM(H_t)}{dH_t}\frac{dH_t}{dx} = \frac{dM(H_t)}{dH_t}\frac{d(H_x + H_d)}{dx} \tag{4}$$

where $dM(H)/dH$ is the slope of the hysteresis loop and $dH_t/dx$ is the total field gradient. The head field gradient in a medium spaced $y = d$ from the head is given by $dH_x/dx = \alpha H_c/d$ where the quantity $\alpha$ has values, in the literature, ranging from $(2/\pi)$ to 1 depending on the size of the head gap and the magnitude of the head current. Here $\alpha = \sqrt{3}/2$ corresponds to maximization of head field gradient for a narrow gap head. At the center of the transition, where $x = x_o$, $M = 0$, and $H_t = H_c$, the slope of the hysteresis loop is $\chi$ and so, using Eqns. (3) and (4), it is easily shown that:

$$\frac{2M_r}{\pi a} = \chi\left(\frac{\sqrt{3}H_c}{2d} - \frac{M_r\delta}{\pi a^2}\right) \tag{5}$$

Solving this equation leads to a transition width of:

$$a = \left(\frac{2M_r d}{\sqrt{3}\pi\chi H_c}\right) + \sqrt{\left(\frac{2M_r d}{\sqrt{3}\pi\chi H_c}\right)^2 + \frac{2M_r\delta d}{\sqrt{3}\pi H_c}} \tag{6a}$$

When the hysteresis loop is steep sided and $\chi$ is large:

$$a = \sqrt{\frac{2M_r\delta d}{\sqrt{3}\pi H_c}} \tag{6b}$$

This is the transition width in the presence of the head field but as the medium moves away from the record head, and the influence of its field wanes, the transition demagnetizes to a greater width. When the transition then moves to the vicinity of the replay head it induces within it magnetic charges which image those within the medium. The net reduced pole strength reduces the demagnetizing fields and narrows the transition widths to values approaching those given by Eqn. (6). Thus Eqn. (6) is a reasonable first approximation of the final transition width.

When the head field gradient is large, it can, according to Eqns. (6) and (3), lead to a transition sufficiently narrow as to give rise to a demagnetizing field which is larger than the coercivity of the recording medium. Such a field cannot be consistent with a hysteresis loop and so the transition widens to reduce the field to less than or equal to the coercivity. The minimum possible transition width is when the demagnetizing field is equal to the coercivity. Thus equating the maximum of the demagnetizing field, given by Eqn. (3) at $(x - x_o) = a$, to the coercivity, the minimum value for the transition width is:

$$a = \frac{M_r\delta}{2\pi H_c} \tag{7}$$

This is sometimes known as the self-demagnetizing limited transition width.

The transition width occurring in a recording medium is the larger of the write- or self-demagnetizing limited values given, respectively, by Eqns. (6) or (7), and these are plotted in Fig. 3 as a function of $(M_r\delta/H_c)$. Experimental results confirm these relationships and in each case the important ratio in determining recording performance is $(M_r\delta/H_c)$ which should, obviously, be kept small.

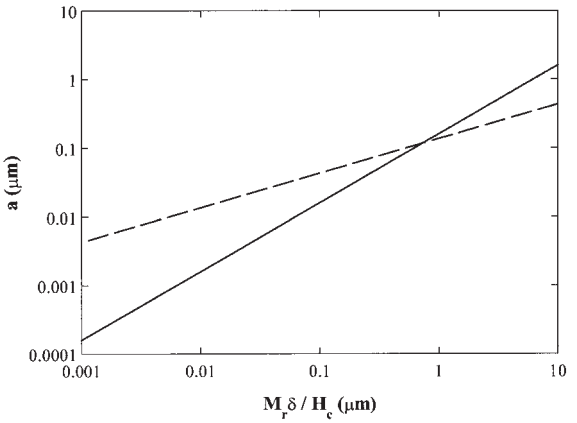

***Figure 3***
The broken line shows the write limited transition width, from Eqn. (6b) with $d = 40$ nm and $\chi = \infty$, while the solid line shows the demagnetizing limited case from Eqn. (7).

## 2. *The Replay Process*

During the replay process (Middleton 1987, Middleton 1989) transitions pass under the replay head which is sensitive to their presence. The variation of sensitivity with position under the head can be represented by a sensitivity function which has the same mathematical form as the field distribution per unit current, $H'_x$, obtained from Eqn. (1). The replay head voltage generated as the magnetization gradient moves through the sensitive region of the head is:

$$e(\bar{x}) = -\mu_o v w \delta \int_{-\infty}^{+\infty} \frac{dM_x(x - \bar{x})}{d\bar{x}} H'_x(x, d)dx \tag{8}$$

where $\mu_o$ is the permeability of free space, $v$ the medium velocity, $w$ the track width, $\bar{x} = vt$ and $t$ is time. Substitution of Eqn. (1) for the head sensitivity function along with the magnetization from Eqn. (2), into Eqn. (8) and evaluation leads to the output pulse shape:

$$e(\bar{x}) = \frac{-2\mu_o vwn\eta M_r\delta}{\pi}\left(|\tan^{-1}|\left(\frac{g/2-\bar{x}}{d+a}\right) + |\tan^{-1}|\left(\frac{g/2-\bar{x}}{d+a}\right)\right) \quad (9)$$

This pulse shape is identical to that of the sensitivity function of the head except that the spacing $d$ is replayed by $(d+a)$. Three pulse shapes are shown in the inset of Fig. 4, where the amplitude $e(0)$ and width $p_{50}$ are shown on one of them. From Eqn. (9) these quantities are given by:

$$e(0) = \frac{-4\mu_o vwn\eta M_r\delta}{\pi}\,|\tan^{-1}|\left(\frac{g/2}{d+a}\right) \quad (10a)$$

and

$$p_{50} = 2\sqrt{(a+d)^2 + (g/2)^2} \quad (10b)$$

It is easily seen from Eqns. (10a) and (10b) that maintaining a narrow transition width keeps the pulse amplitudes high and the pulse widths narrow, in line with the requirement for high density recording.

At high densities when the transitions are close together, the total voltage can be predicted using linear superposition. This says that the total waveform $e_t(\bar{x})$arising from a sequence of transitions is given by the sum of the isolated pulse shapes as:

$$e_t(\bar{x}) = \sum_{n=-\infty}^{n=+\infty} (-1)^n e(\bar{x} - n\lambda/2) \quad (11)$$

where $\lambda/2$ is the spacing between the transitions.

Figure 4, inset, shows three overlapping pulses, their sum, and the consequent reduction of output. The variation of normalized output voltage with packing density, for a long sequence of pulses, is shown in Fig. 5 for a typical thin-film recording medium. This type of graph is often referred to as a roll-off curve and is one of the standard measurements of recording performance. The full line represents theoretical predictions and the points represent experimental values. Their coincidence shows the validity of linear superposition but such agreement is not found in all circumstances (Richter 1999) because intertransition interactions can cause their widths and/or shapes to change with a consequent loss of agreement.

The summation, Eqn. (11), of pulse shapes, Eqn. (9), can be represented in closed form and at short wavelengths approximates to:

$$e_t(0) \propto e^{-2\pi(a+d)/\lambda} \quad (12)$$

Now the transition width appears in an exponential term and its role in causing a fall of output becomes very strong. This re-emphasizes the need to keep $a$, and therefore $(M_r\delta/H_c)$, small so as to keep the output high at high recording densities.

The simplified recording theory given here has, in its full exposition, had much success in explaining

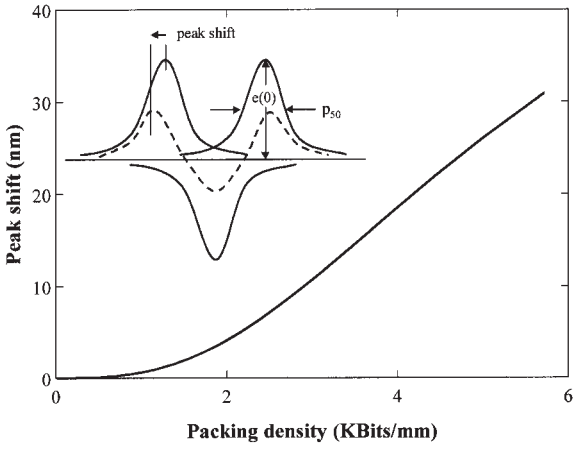

*Figure 4*
Inset: overlapping pulses and their sum showing a reduction of output and the occurrence of peak shift. Main graph: peak shift as a function of packing density for pulses calculated using Eqn. (9) with $a = 50$ nm, $d = 40$ nm, and $g = 220$ nm.

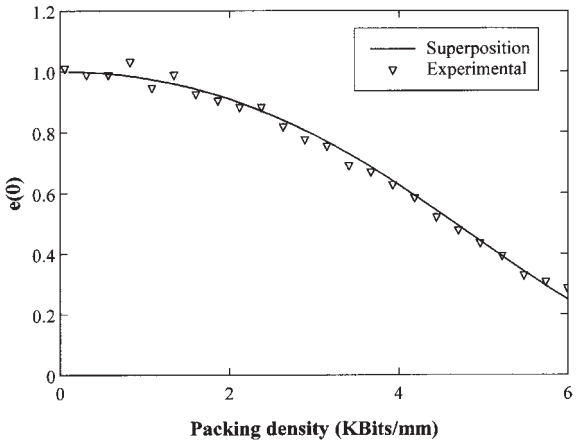

*Figure 5*
A roll-off curve showing normalized output voltage as a function of packing density. The solid theoretical curve is by linear superposition and the points are for a thin film medium with $M_r\delta = 20$ mA, $H_c = 159$ kA m$^{-1}$, $a = 50$ nm, and with $d = 40$ nm and $g = 220$ nm.

practical experience and guiding the way forward with prediction of future performances. While this theory has shortcomings with the simplicity of its basic assumptions and analysis, more sophisticated numerical modeling has not altered the basic media requirements.

The requirement for narrow transitions for high density operation has led to the widespread adoption of thin film media with high coercivity. Other requirements include media with steep sided hysteresis loops, small to medium head spacings and heads with narrow gaps. Practical media satisfying these requirements are now around 20 nm or less in thickness, and are reaching over 250 kA $m^{-1}$ in coercivity. They are invariably of alloys of cobalt or cobalt–nickel with small additions of tungsten, platinum, or other metals. Future media suitable for the predicted very high storage densities are expected to rise to around 400 kA $m^{-1}$.

## 3. Recorded Magnetization Transitions

Direct observation of recorded magnetization distributions in thin media obtained by either bitter colloid techniques or electron microscopy reveal, in plan view, a transition structure which varies in the cross track direction as shown in Fig. 6. This is known as a ''saw-tooth'' pattern whose nature is not indicated by Eqn. (2). Early interpretations of these patterns were that they came about to spread the magnetic poles over longer transitions, thereby reducing demagnetizing fields and self-demagnetizing energies. This may be so in wider transitions where bitter colloids have shown the presence of demagnetizing fields around the saw-teeth, and some record theories have followed this interpretation.

However, micromagnetic modeling of narrow transitions in higher coercivity films has shown that the saw-tooth like structures arise as a result of part of the magnetization distributions forming flux closure patterns. These do not contribute fields which influence the recording process, and subtraction of them from the total magnetization shows the resulting charge carrying transition to have little cross track structure, not unreasonably represented by Eqn. (2). Indeed, micromagnetic calculations carried out on self-demagnetization limited transitions found that cross track average magnetizations, where flux closure components sum to zero, have distributions not unlike Eqn. (2) and transition widths which are close to Eqn. (7). This goes some way to explaining why record theory based on such simple assumptions, as used here, continues to apply even when the detailed structures of transitions appear so complicated.

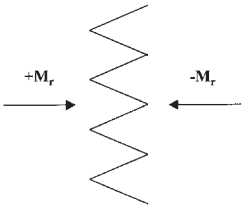

***Figure 6***
Diagrammatic representation of the plan view of the appearance of a ''saw-tooth'' transition.

## 4. Practical High Density Recording

It has been shown above that at high densities the output voltage is significantly reduced and therefore so is the signal to noise ratio. At high densities there is also a loss of timing accuracy in the replayed waveforms because the superposition of pulses leads to a total waveform where the peaks are shifted in position. This phenomenon, known as peak shift, increases rapidly as densities increase and this is illustrated in Fig. 4. These timing shifts, in concert with the reduced signal to noise ratios, lead to increased error rates in the recovered data.

## 5. Conclusions

This chapter has concerned itself with basic record theory to identify those properties of recording media, thinness and high coercivity, which are needed to allow high-density recording to take place. It has discussed these findings in view of the rather complicated magnetization distributions which are found in practice, and which appear at first sight not to be consistent with the theory quoted.

# Magnetic Recording: Rigid Media, Tribology

Magnetic recording disk drives are generally designed so that the slider flies over the disk during steady-state operation of the drive. The flying of the slider is based on the formation of a thin air bearing which separates the slider and the disk. If the disk drive is shut down, the slider is in contact with the surface of the disk. During start/stop of the drive, sliding motion between the slider and the disk occurs until the air bearing is formed and the slider is supported completely by hydrodynamic pressure forces.

The design of a magnetic recording slider during steady-state operation is a problem of hydrodynamic lubrication, requiring the solution of the compressible Reynolds equation. However, during start/stop of a drive, contacts between the slider and the disk occur, requiring the understanding of boundary lubrication and wear. Since a magnetic disk drive may be turned on and off more than 50 000 times during its life, great care has to be taken in the design and implementation of the head/disk interface in order to guarantee reliable operation of the disk drive.

In order to obtain maximum signal resolution and highest recording density, it is important that the spacing between the slider and the disk be as small as possible. In fact, from a magnetics point of view, the spacing between disk and slider (or "head") should be zero. This situation, generally described as "contact recording", causes problems with friction and wear. Thus, a compromise must be made so that the spacing between the slider and the disk is small enough to give adequate signal strength, but is large enough to establish a strong air bearing to enable flying of the slider over the disk. Flying heights of typical magnetic recording sliders are of the order of 20 nm.

## 1. Reynolds Equation

The equation governing the hydrodynamic flying of a magnetic recording slider is the compressible Reynolds equation, given by

$$\frac{\partial}{\partial x}\left(Q(Kn)ph^3\frac{\partial ph}{\partial x}\right)+\frac{\partial}{\partial y}\left(Q(Kn)ph^3\frac{\partial ph}{\partial y}\right)=6\mu U\frac{\partial ph}{\partial x}+6\mu V\frac{\partial ph}{\partial y}+12\mu\frac{\partial ph}{\partial t} \quad (1)$$

where $p$ is the pressure, $h$ is the spacing between slider and disk, $\mu$ is the viscosity of the lubricant film, and $U$ and $V$ are the disk velocity components in the $x$- and $y$-direction, respectively. The factor $Q$ is a function of the local Knudsen number, $Kn$ (ratio of mean free path and local spacing), and is an indication of the deviation of the air flow between slider and disk from continuum flow theory.

The Reynolds equation is a nonlinear partial differential equation which can be solved numerically using finite difference and finite element methods (Hu and Bogy 1996, Wahl *et al*. 1996). Two of the most important considerations in the design of magnetic recording sliders are the requirements for a slider to fly at constant flying height from the inner to the outer disk radius, and the need of a slider to be independent of altitude changes.

## 2. Slider Design

A typical air bearing slider is shown in Fig. 1(a). The slider consists of two side rails, a leading edge bridge, and a subambient cavity. Also shown is the positive pressure buildup over the slider rails and the subambient pressure region over the cavity portion (Fig. 1(b)).

## 3. Disk Characteristics

For flying heights of the order of 20 nm, the roughness of a disk has to be well controlled. The peak-to-valley roughness of a typical disk is of the order of

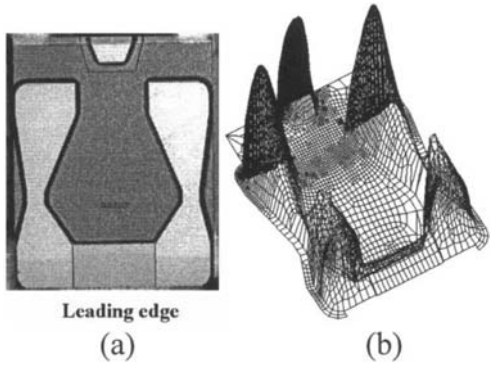

***Figure 1***
(a) Typical magnetic recording subambient pressure slider and (b) the pressure distribution over the slider.

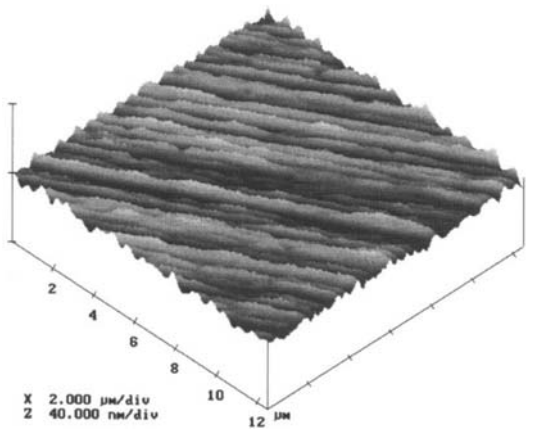

***Figure 2***
Surface roughness of hard disk measured with atomic force microscopy.

10–20 nm. A roughness plot for a hard disk measured by atomic force microscopy is shown in Fig. 2. The substrate of choice for 65 mm laptop disk drives is glass, while the substrate for 95 mm disk drives is aluminum. In the case of aluminum substrates, a 10–15 µm thick layer of nickel phosphorous is first deposited on the disk, followed by a 10–50 nm thick layer of magnetic alloy. On top of the alloy is a thin carbon film that, in turn, is coated with a 1–2 nm thick lubricant film.

## 4. *Tribology of the Head/Disk Interface*

### *4.1 Friction and Stiction*

During shutdown and startup of a disk drive the slider is in contact with the disk, resulting in friction and wear at the interface. The variation of the coefficient of friction is shown in Fig. 3 as a function of the number of start/stop cycles (CSS) between slider and disk. In general, the coefficient of friction is found to increase with the number of start/stop cycles and is influenced by environmental conditions such as temperature and humidity (Zhao and Talke 1999a).

The coefficient of friction shows, in general, a sharp increase during startup with a well-defined peak approximately 100–200 ms after motion starts. This peak in the friction force is generally described as ''stiction''.

The stiction force, $F_s$, encountered at the startup of a disk can be expressed as follows:

$$F_s = \mu(W_s + F_m) + F_v \qquad (2)$$

where $\mu$ is the coefficient of friction, $W_s$ is the suspension load of the slider, $F_m$ is the meniscus force, and $F_v$ is the viscous force in the lubricant film.

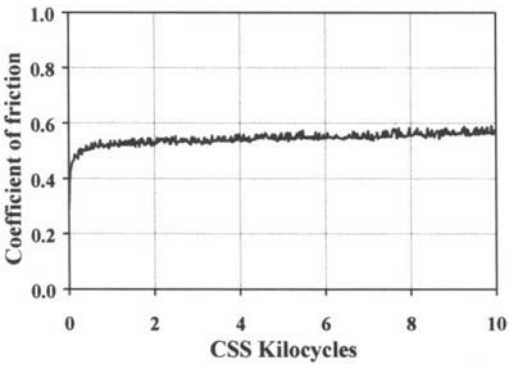

***Figure 3***
Coefficient of friction as a function of contact start/stop cycles.

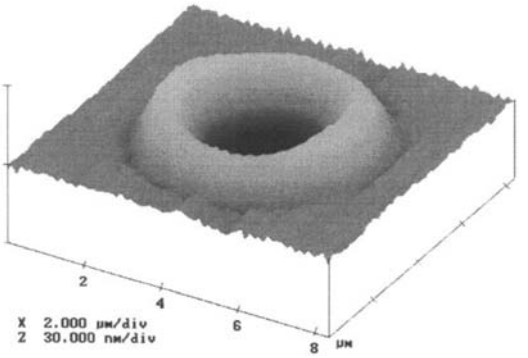

***Figure 4***
Crater-shaped laser bump.

The meniscus force, $F_m$, is related to the presence of lubricant films or adsorbed water films on the disk surface. A number of models have been developed to predict stiction as a function of design parameters and environmental conditions (Gui and Marchon 1995, Zhao and Talke 1999b).

### *4.2 Laser Zone Texturing of Disks*

A large stiction force can prevent the motor from starting the disk drive after shutdown of the drive. In order to prevent failure of the head/disk interface owing to excessive stiction, texturing of the disk surface in the start/stop region of a magnetic disk has been implemented using laser texturing. Laser texturing is performed by focusing a laser beam onto the disk surface and creating a number of small and evenly spaced ''bumps'' in the ''landing'' zone of the disk by localized melting of the disk surface (Fig. 4). The height and size of the individual laser ''bumps''

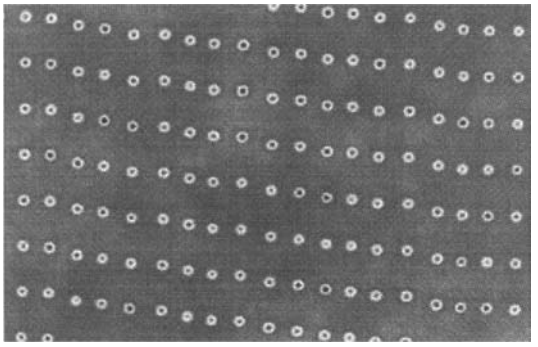

*Figure 5*
Array of laser bumps with bump spacing between rows of 40 μm.

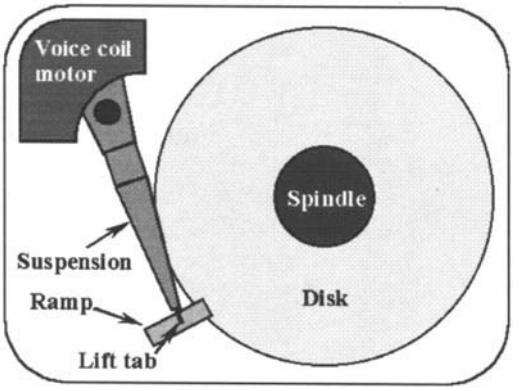

*Figure 6*
Ramp load/unload mechanism.

can be adjusted by the energy level and pulse duration of the laser pulse, resulting in a well-controlled surface roughness of the landing zone (Baumgart *et al*. 1995). During contact of the slider on this landing zone, the formation of meniscus areas is restricted to the areas around the "bumps." Thus, the stiction force is controlled by the number and shape of the laser bumps. Because of this, stiction of laser-textured disks is much less sensitive to changes in the environmental conditions or the number of CSS cycles. An array of laser bumps with a pitch distance of approximately 40 μm between rows is shown in Fig. 5.

### *4.3 Load/Unload*

Laser zone texturing becomes ineffective if the height of the laser bumps is required to decrease to less than 10 nm. To avoid high stiction of the head/disk interface in the latter case, ramp load/unload has been introduced as an alternative to laser texturing. In the case of ramp load/unload, the slider is loaded onto the disk during startup of the drive using the ramp mechanism shown in Fig. 6. During shutdown of the drive, the slider is lifted from the disk surface using the ramp mechanism. The use of a ramp load mechanism avoids stiction completely during start/stop. Ramp load/unload is difficult to implement, however, because of severe tolerance requirements during assembly. Ramp load/unload mechanisms are used mainly in laptop computers, but have begun to appear also in 95 mm hard disk drives.

## *5. Wear*

Wear of the head/disk interface occurs on both the slider and the disk as the result of head/disk interactions during CSS or steady-state operation. Wear of sliders and rigid disks can occur as adhesive wear, abrasive wear, impact wear, or tribochemical wear. Intermittent slider/disk impacts during steady-state operation lead to impact wear. In addition, tribochemical wear occurs if oxygen from the atmosphere absorbs chemically on the surface of the carbon layer, leading to the formation of surface oxides. Thermal desorption of these species leads to the formation of CO and $CO_2$, which depletes the surface of carbon. For lubricated disks, the lubricant film tends to act as a chemical barrier, thereby reducing the occurrence of tribochemical wear in favor of other types of wear (Talke 1995).

Disks and sliders are typically coated with a thin layer of carbon to protect the magnetic materials from wear and corrosion. Carbon overcoats used for rigid disks and sliders are typically diamond-like carbon (DLC), amorphous DLC (a-C), hydrogenated DLC (a-C:H), and nitrogenated DLC (a:$CN_x$) (Grill 1997). Hydrogenated carbon films (a-C:H) show generally improved wear performance over a-C films. The hardness and the elastic modulus of DLC increase with hydrogen concentration in the DLC because hydrogen tends to increase $sp^3$ bonds in DLC (Lee *et al*. 1992). Incorporation of nitrogen in DLC also improves the wear resistance of DLC films. Nitrogenated films have gained wide application as thin-film disk and slider overcoats.

## *6. Lubricants and Additives*

In general, perfluorinated polyethers (PFPE) are used for disk lubrication since they have good load carrying capability and exhibit a very low vapor pressure. Sliding contact between a slider and a disk tends to remove the lubricant in the sliding track. To prevent lubricant depletion, a disk lubricant should have good mobility so that it can recoat areas of the disk depleted from lubricant. However, since high mobility

***Table 1***
Molecular structures of typical commercial disk lubricants.

| Tradename | Molecular structure | End group |
|---|---|---|
| Fomblin Y | $CF_3O[CF(CF_3)CF_2O]_n$–$(CF_2O)_m$–$CF_3$ | –$CF_3$ |
| Krytox AD | F–$[CF(CF_3)CF_2O]_m$–$CF_2CF_3$ | –F,–$CF_3$ |
| Fomblin Z | $CF_3O(CF_2CF_2O)_n$–$(CF_2O)_m$–$CF_3$ | –$CF_3$ |
| Demnum | F–$(CF_2CF_2CF_2O)_n$–$CF_2CF_3$ | –F,–$CF_3$ |
| Fomblin Z-DOL | HO–$CH_2CF_2O$–$(CF_2CF_2O)_n$–$(CF_2O)_m$– $CF_2CH_2$–OH | –OH |
| Fomblin AM2001 | P–$CH_2OCH_2CF_2$–$(CF_2CF_2O)_n$– $(CF_2O)_m$–$CF_2CH_2OCH_2$–P | –$CH_2$–phe$=$$(O)_2$$=$$CH_2$ |

increases lubricant spin-off, a compromise must be made between mobility and bonding. A number of commonly used disk lubricants is shown in Table 1 (Homola 1996).

Most disk lubricants exhibit thermal degradation problems when exposed to elevated temperatures. Furthermore, PFPE are susceptible to catalytic decomposition when in contact with $Al_2O_3$, a common slider material component. To reduce the degradation of disk lubricants caused by $Al_2O_3$ it is customary to eliminate the exposure of disk lubricants to $Al_2O_3$ by coating the slider surface with a thin carbon film. Another option is to use additives in the lubricant such as X-1P (Perettie *et al*. 1999). However, difficulties with phase separation have been observed with phosphazine additives at high temperature and humidity owing to the fact that these additives are insoluble in PFPE-based oils (Kang *et al*. 1999).

## 7. *Future Trends in Tribology of Rigid Media*

To increase the recording density to 100 Gbits in$^{-2}$ (15.5 Gbits cm$^{-2}$), it is anticipated that the flying height of the slider must be of the order of 5 nm, that the carbon overcoat on the slider and the disk should be reduced to less than 2–3 nm, and that the root mean square surface roughness be approximately 0.2 nm.

Owing to the complexity of these requirements, the question arises as to whether it would not be better to implement contact recording, in which case the air bearing between the slider and the disk would be eliminated completely. Although the latter situation is highly desirable, contact recording would require an extremely lightly loaded slider/disk interface in order to keep wear of the slider and the disk within acceptable limits (Talke 1995). Furthermore, a lightly loaded interface is prone to stick/slip and friction-induced vibration, making this approach all but technically unfeasible. However, the trend towards reduced flying heights will continue and lower and lower flying heights will be implemented in future disk-drive products. Thus, even more difficult tribology problems will be encountered.

# Magnetic Recording: VHS Tapes

The home video market is massive and is the dominant form of magnetic media sold in the world market. Estimated world sales for VHS (Video Home System) media for 1988 were equivalent to 2686 million E180 cassettes shipped at a total factory gate price of $3335 million. Figure 1 shows a comparison of VHS sales to other media. Originally used primarily for recording of TV programs for later viewing, use has now extended to home viewing of prerecorded film, camcorder applications, and is making inroads into multimedia PC programs.

Although VHS is the most popular video system, its technology has been overtaken by other formats. However, because of the large number of video machines in homes and the considerable investment in prerecorded film for sale and rental, it is likely to remain the dominant system until replaced by digital technology. There have been some additions to the format that allow stereo sound to be recorded, a long-play facility with slower tape speed, a compact cassette version for use in camcorders which can then be played in a standard video cassette recorder (VCR) using an adapter, and a super VHS (S-VHS) with improved performance quality. S-VHS requires a special machine and tapes to take advantage of the improved quality but is backward compatible with standard VHS tapes.

VHS tape sales are very competitive and prices have fallen dramatically over time. This has reduced profit margins so that many of the large media producers have withdrawn from the business to concentrate on more profitable "high-tech" media applications or have transferred production to low-cost regions of the world such as China and the East Asian Pacific Rim countries.

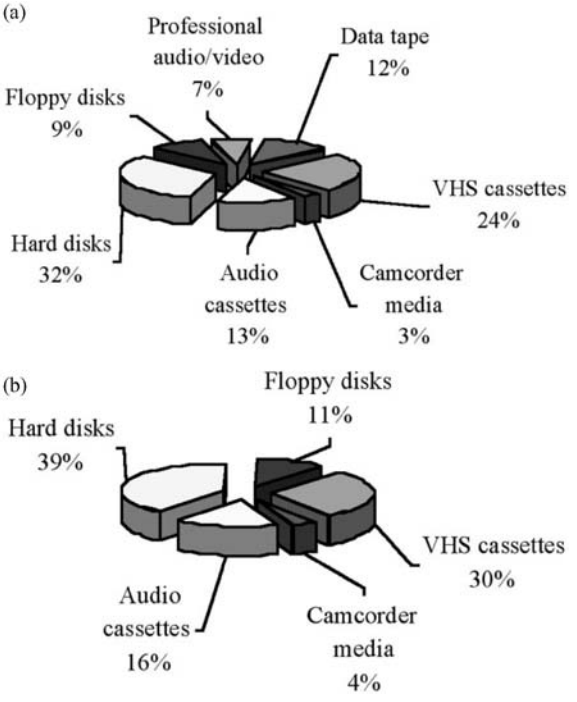

***Figure 1***
Chart of total sales of VHS media compared to other major magnetic storage media for 1988. Because some sales are in the form of prerecorded tape, estimates of VHS sales have been converted into the form of E180 cassettes (estimates by the Magnetic Media Information Service). (a) Total sales for 1998 as a percentage of total value ($13.833 billion.) (b) Total sales for 1998 as a percentage of total units (10.627 billion units.)

## *1. The VHS Format*

VHS is a helical scan system with the record/replay heads mounted on a drum that rotates at an angle to the tape transport direction. This produces recorded data tracks at an angle to the tape direction. This angle is dependent on the TV format and allows a relatively high head speed across the tape surface at a slow tape speed producing an efficient use of the recording area for the serially recorded signals (for the 625 line–50 field TV system, the angle of scan is $5^\circ\,57'\,50.3''$ at a head speed of $3.92\,\mathrm{ms}^{-1}$ and a tape speed of $23.39\,\mathrm{mms}^{-1}$ (EN 60774 1994)). For a detailed description of helical scan recording see Mee and Daniel (1996).

With all removable media systems it is important that exact standards are applied to the media to allow writing and replay in different machines and maintenance of replay quality under a range of changing conditions. Standards were originally established by JVC, the manufacturer who developed VHS, but detailed specifications are now incorporated into international standards (e.g., European Standard EN60774-1). Many of the details are mechanical, such as the dimensions of the cassette ($104\,\mathrm{mm} \times 188\,\mathrm{mm} \times 25\,\mathrm{mm}$), the reel dimensions (62 mm diameter), and the tape winding path and its control. The tape has a specified width of $12.65\,\mathrm{mm} \pm 0.01\,\mathrm{mm}$ (0.5 in) and a maximum thickness of 20.0 μm including the magnetic coating. Playing times are specified as 30 min, 60 min, 90 min, 120 min, and 180 min, which are determined by the length of tape in the cassette. Modern VCRs usually have a long-play facility that doubles the playing time by reducing the tape speed. This does produce some loss of quality but modern head technology minimizes noise levels.

The magnetic coating has to be of a high resolution, longitudinally oriented, and with a coercivity of approximately $50 \times 10^3\ \mathrm{Am}^{-1}$ (628 Oe). Invariably the magnetic coating consists of acicular oxide

particles, usually cobalt-modified iron oxide ($\gamma$-$Fe_2O_3$) although chrome dioxide ($CrO_2$) can be used. The latter is reputed to have a better high-frequency response, but the cost is generally higher than for iron oxide. Most $CrO_2$ tapes on the market now contain a mixture of $CrO_2$ and cobalt $\gamma$-$Fe_2O_3$ to limit price.

## 2. Magnetic Particles

The properties of magnetic particles determine the final magnetic properties of the manufactured tape. Magnetostatic interactions between particles play an important role in determining properties such as coercivity, and the measured values for individual particles, pigments, and tapes can be very different (McConochie *et al.* 1996). Magnetic properties of particles are described in detail in *Magnetic Recording Materials: Tape Particles, Magnetic Properties*. Ideally all particles should be single domain with identical magnetic properties. In practice this is not possible, but particles are manufactured so that parameters such as volume and aspect ratio have as narrow a distribution as possible. Typically particles have a length of about 600 nm and an aspect ratio of 6:1. Ferric oxide particles are the most commonly used, but basic $\gamma$-$Fe_2O_3$ has a coercivity controlled primarily by shape anisotropy and can only be used to make tapes with coercivities up to about $25 \times 10^3$ $Am^{-1}$ ($\sim$300 Oe). To increase this further, particles are surface doped with cobalt. $CrO_2$ has a higher intrinsic coercivity partly associated with crystal anisotropy and is suitable for VHS applications in its basic form.

## 3. Media Production

The magnetic tape coating consists of small magnetic particles dispersed in a nonmagnetic polymer matrix with additional nonmagnetic particles for other important functions. A wet dispersion of all the components is produced which is then coated onto plastic film and dried. The tape formulation is proprietary and each tape manufacturer will have its own choice of components. Manufacturers of precursors often have test formulations that are freely available to customers and produce an acceptable final product. All dispersions have essentially the same components that serve the same specific general functions as follows:

(i) Magnetic particles—see above.

(ii) Wetting agents—usually a surfactant whose function is to coat the magnetic particles and prevent agglomeration after dispersion. Some part at least can be replaced by "wetting" polymer resins, which have functional groups effective in wetting. This reduces the final wetting agent content of the tape to the advantage of wear and friction. Although originally developed for advanced particulate media manufacture, they are in common use for commodity products such as VHS.

(iii) Polymer resins—to produce the final solid matrix and generally comprising a mixture of several types which can be classified as soft, such as polyurethane, and hard, such as vinyl. The correct combination determines the final mechanical properties of the tape, e.g., stiffness and temperature resistance characteristics, which are important for controlling properties such as magnetostriction associated with changing magnetic properties, as particles are stressed and the matrix is strained during tape flexure.

(iv) Cross-linking agents—added just before final coating of the tape to strengthen the polymer matrix and to ensure that particles are strongly bound.

(v) Solvents—to dissolve the resins and the wetting agents.

(vi) Carbon black—to reduce static electricity in the tape.

(vii) Lubricants—additional surfactants and other lubricants which are incorporated into the matrix. These leach out during the life of the tape to lubricate the surface and ensure smooth transit across the heads and guides during record and replay.

(viii) Abrasives—such as aluminum oxide particles, which help to clean debris and deposits from heads and other parts in contact with the tape during use.

Magnetic particles are supplied by pigment manufacturers in a clustered form to aid handling of what, individually, would be a very fine and hazardous powder of particles with the dimensions of smoke grains. The main function of the wet dispersion process is to separate these particles without damaging them to produce a slurry of monodispersed magnetic particles which can be coated and oriented. This dispersion is very important in determining the final quality of the tape. Not only does it affect the ability of particles to be oriented by application of a magnetic field during production, but poorly dispersed particles will increase the roughness of the tape surface and affect noise characteristics (Clarke *et al.* 1991). A detailed discussion of wet dispersions can be found in *Magnetic Recording Media: Particulate Dispersions* but the essential processes of tape manufacture are as follows:

(i) Premixing—some of the components including the magnetic particles, wetting agents, and a portion of the solvents are mixed at high shear to wet the particle surfaces and exclude any water adsorbed on the surfaces.

(ii) Milling—the components are mixed in a bead mill or similar device to generate shear and separate particles. Milling times and rates are important as "over milling" generates broken particles whereas "under milling" leaves agglomerates in the system. Broken particles will have a low switching field or may be superparamagnetic and are detrimental to the recording properties of the tape resulting in "print through" and a lower saturation remanence.

Agglomerates will cause an increase in the tape noise and poor orientation.

(iii) Let down—additional solvents are added to control the final viscosity of the slurry ready for coating. This stage has to be completed carefully to prevent solvent shock, which can cause flocculation of the particles.

(iv) Filtering—any remaining agglomerates or oversized particles are removed by passing through a fine mesh filter.

(v) Coating—the final wet dispersion is applied to a plastic substrate using a knife coater or gravure roller. This is part of the mass-production process. Coating is at high speed onto wide plastic webs.

(vi) Orientation—immediately after coating and before the film has dried, the web is passed through an arrangement of magnets that increases particle alignment along the tape axis.

(vii) Drying—the web is then passed through an oven where the solvents are driven off and collected for recycling. The dried web is then wound onto rolls and stored to allow further curing of the polymers.

(viii) Calendaring—the web is passed between heated rollers that have specially prepared paper-coated surfaces. High pressure is applied so that the combination of heat and pressure produces a smooth tape surface. This is important in maintaining a good head/tape contact in the record and replay processes to minimize asphericity and surface roughness noise.

(ix) Back coating—a nonmagnetic layer containing carbon black is coated onto the back surface of the web. This prevents slippage during use and also reduces buildup of electrostatic charge.

The large rolls of completed media, referred to as jumbos, are then slit to the final tape width, slitting debris is removed, and the tape is wound onto individual reels, called pancakes. In a separate process, tape is spliced to plastic leader tapes already attached to reels in cassettes and the appropriate length of tape is loaded ready for final labeling and packaging of the cassettes.

## 4. Media Properties

The performance of a tape is defined in terms of its recording and replay properties, and characteristics such as signal to noise ratio. These are specified in the international standards and comparison is made to a reference tape VRT-2, which can be provided by JVC. In practice, having established particle supply and the tape production process, quality can be controlled by static magnetic measurements using a vibrating sample magnetometer. The only static magnetic property identified in the standards is the approximate coercivity ($50 \times 10^3\,\mathrm{Am}^{-1}$). However, in general all tapes have very similar major hysteresis loop shape and characteristics. Figure 2 shows the major hysteresis loop for a typical proprietary VHS tape, measured in the tape direction and transverse to it. The effect of particle orientation can be clearly seen by comparison of the shape of the two loops. Listed below are some parameters that have been devised to characterize recording media and values measured for this sample.

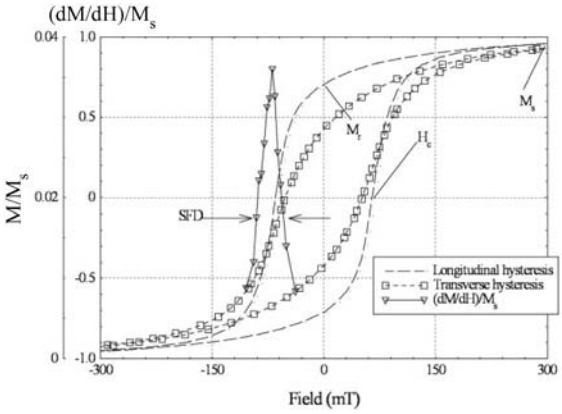

***Figure 2***
Hysteresis loops for a cobalt $\gamma$-$Fe_2O_3$ VHS tape measured along the tape axis direction and transverse to it. The differential of the hysteresis is also shown and indicates the switching field distribution measured at half height.

(i) Coercivity, $H_c$ ($52\,\mathrm{kAm}^{-1}$ (648 Oe))

(ii) Saturation magnetization, $M_s$, usually expressed as a moment per unit area ($490\,\mathrm{Am}^{-3}$ ($49\,\mathrm{memucm}^{-2}$))

(iii) Remanent magnetization, $M_r$ ($370\,\mathrm{Am}^{-3}$ ($37\,\mathrm{memucm}^{-2}$))

(iv) Squareness, $M_r/M_s$ (0.76)

(v) Orientation ratio, $M_{r[\text{in tape direction}]}$:$M_{r[\text{transverse}]}$ (1.67)

(vi) Switching field distribution (SFD), obtained by differentiating the hysteresis loop. This produces a peak around the coercivity. The SFD is defined as the peak width at half height ($27\,\mathrm{kAm}^{-1}$ (340 Oe))

(vii) Coercivity squareness, $S^*$, a measure of the steepness of the loop at the crossing point (0.68). It is defined by (Köster 1984):

$$\left(\frac{\mathrm{d}M}{\mathrm{d}H}\right)_{M=0} = \frac{M_r}{H_c(1 - S^*)}$$

## 5. Camcorder Applications

A major use of video tape is for camcorder recording. The standard VHS tape is far too cumbersome for this application and so a compact VHS cassette has been developed. This uses the standard 12.65 mm tape but in a cassette measuring $59\,\mathrm{mm} \times 92\,\mathrm{mm} \times 22.5\,\mathrm{mm}$, which is about a quarter of the volume of a standard cassette. The compact cassette can be inserted into an

adapter, which then allows it to be replayed or edited in a standard VHS VCR. There are rivals for analogue camcorders, the most notable being the 8 mm system, which like the later development of Hi8 use 8 mm wide tape in a much more compact cassette and an increased coercivity. The 8 mm tapes are based on metal particles, usually passivated iron, and the Hi8 uses either metal evaporated tape or advanced metal particles. The 8 mm systems have an improved response over VHS. However, in spite of taking a large part of the camcorder market, 8 mm VCR machines have failed to make much impact on the television-related use for time shifting and replay of prerecorded "videos." Digital camcorders are now available and these will replace the older VHS and 8 mm analogue systems very rapidly.

## 6. *Prerecorded Tape*

Much of the tape that is produced is sold with prerecorded films and other entertainment material. Making copies used to involve playing a master tape on one VCR that was re-recorded on a number of copy machines. This process is very slow, equipment intensive, and is not cost effective. A process of anhysteretic duplication has been developed that produces a magnetic image of a master tape in a high-speed process.

The principles of the technique are based on anhysteretic remanence. This process involves the application of a small d.c. bias magnetic field to a magnetic sample subjected to a saturating a.c. field which is then slowly removed. The d.c. bias field is then removed and a remanent magnetization is left. Figure 3 shows the anhysteretic remanent magnetization (ARM) as a function of d.c. bias field for a typical VHS tape.

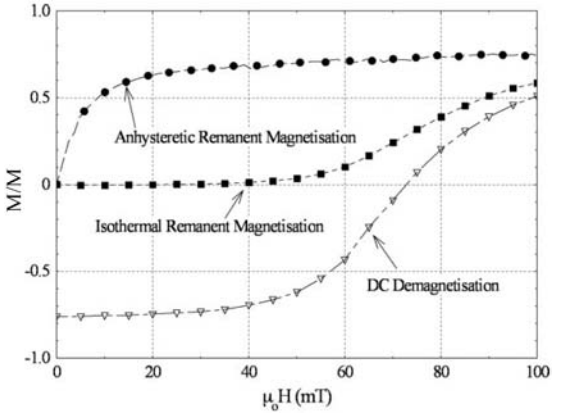

***Figure 3***
ARM for a cobalt $\gamma$-$Fe_2O_3$ VHS tape. Isothermal remanent magnetization and d.c. demagnetization curves are included for comparison.

For comparison, the isothermal remanence (IRM) and the d.c. demagnetization remanence (DCD) are also shown. The IRM curve is a plot of the remanence produced by the application of a d.c. magnetic field to an initially a.c. demagnetized specimen while the DCD curve is a plot of the remanence produced in an initially negatively saturated sample. The IRM and DCD curves are used extensively as an indication of the nature of interactions in recording media (Spratt *et al*. 1988, Kelly *et al*. 1989). The steep slope of the initial anhysteretic curve is evident in Fig. 3.

In anhysteretic duplication, a mirror image of the required video tape is produced on a master tape. When placed in contact with a blank VHS tape (magnetic surfaces together) and subjected to an a.c. field, the stray fields from the master tape magnetic recording are sufficient to produce an anhysteretic magnetic image imprinted on the VHS tape. It is clear that if the master tape is to withstand demagnetization in the process, the a.c. field must be sufficient to saturate the VHS tape but small enough so as not demagnetize the master tape, which must have a high coercivity (typically $160 \times 10^3\,\mathrm{Am}^{-1}$ (2 kOe)).

## 7. *Signal Loss and Archival Problems*

Tape replay is a dynamic process involving a magnetic interaction between the tape and the replay head. This produces a change in the magnetization of the tape that has to be reversible if the recorded signal is to remain unchanged. Magnetic changes do not affect the basic structure of the tape, unlike mechanical deterioration, which can result from replay in poorly maintained VCRs. Magnetic deterioration is not evident from visual inspection and re-recording restores the good quality video signal. First generation tapes did exhibit a signal loss with replay that was identified as being related to magnetostriction effects (Flanders 1976, Flanders *et al*. 1979). However, changes in formulation to reduce particle stresses improved tape performance. This effect was not evident in later generations of particles and this type of signal loss is no longer regarded as a problem in commercial tapes. However, some problems do still exist. All tapes are subject to dropouts associated with localized physical or magnetic defects where the recorded signal is defective or unstable. With replay, these dropouts increase in number resulting in a "snowy" TV image. Magnetic debris trapped on guides and heads can also cause signal loss, which is evident as missing lines on the TV image. With continual replay these can merge into bands and are referred to as magnetic scratching (S-Ararghi *et al*. 1992). Replay can also lead to a general increase in noise levels (McCann *et al*. 1999). This is believed to be a result of magnetostriction as identified in the signal loss of first generation tapes but at a much lower level so that it is only observed in the noise signal.

### 8. Conclusions

The VHS system has to be regarded as a commercial success story. Having been adopted as the preferred home video system, production of VCRs and video tape has produced one of the major volume storage media products. Although the technology has been surpassed by other systems, there is a tremendous inertia to change generated by the high domestic investment in machines and availability of prerecorded tapes. The VHS system is likely to remain the preferred medium for some time and will only be replaced with the move to digital recording.

## Magnetic Refrigeration at Room Temperature

Magnetic refrigeration, based on the magnetocaloric effect (MCE), has recently received increased attention as an alternative to the well-established compression–evaporation cycle for room-temperature applications. In the magnetic refrigeration cycle, depicted in Fig. 1, initially randomly oriented magnetic moments are aligned by a magnetic field, resulting in heating of the magnetic material. This heat is removed from the material to the ambient by heat transfer. On removing the field, the magnetic moments randomize, which leads to cooling of the material below ambient temperature. Heat from the system to be cooled can then be extracted using a heat-transfer medium. Depending on the operating temperature, the heat-transfer medium may be water (with antifreeze) or air, and for very low temperatures helium. Therefore, magnetic refrigeration is an environmentally friendly cooling technology. It does not use ozone depleting chemicals (CFCs), hazardous chemicals ($NH_3$), or greenhouse gases (HCFCs and HFCs). Another key difference between vapor-cycle refrigerators and magnetic refrigerators is the amount of energy loss incurred during the refrigeration cycle. The cooling efficiency in magnetic refrigerators working with gadolinium has been shown (Zimm *et al.* 1998) to reach 60% of the theoretical limit, compared to only $\sim$40% in the best gas-compression refrigerators. This higher energy efficiency will also result in a reduced $CO_2$ release. However, with most magnetic materials, this high efficiency is only realized in high magnetic fields, 5 T. Therefore current research aims at new magnetic materials displaying larger magnetocaloric effects, which then can be operated in lower fields, $\sim$2 T, that can be generated by permanent magnets.

The heating and cooling described above is proportional to the size of the magnetic moments and the

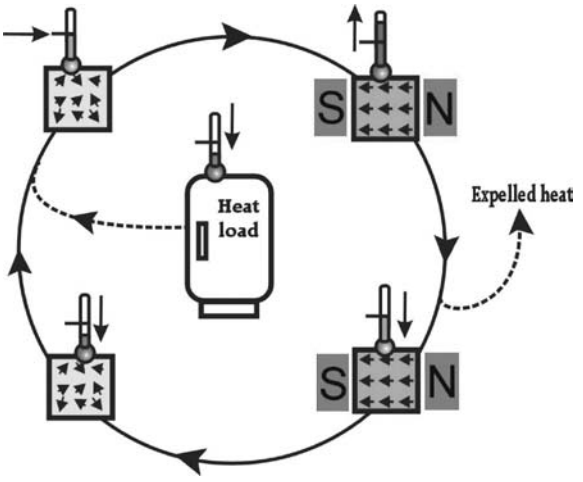

*Figure 1*
Schematic representation of a magnetic-refrigeration cycle, that transports heat from the heat load to the ambient. The lighter- and darker-shaded square containers depict material in low and high magnetic field, respectively.

applied magnetic field. This is the reason that, nowadays, research in magnetic refrigeration is almost exclusively conducted on super-paramagnetic materials and on rare-earth compounds (Tishin 1999). For room-temperature applications like refrigerators and air-conditioners, compounds containing manganese should be a good alternative. Manganese is a transition metal with high abundance. Also, there exist in contrast to rare-earth compounds, an almost unlimited number of manganese compounds with critical temperatures near room temperature. However, the magnetic moment of manganese generally is only about half the size of heavy rare-earth elements. Enhancement of the caloric effects associated with magnetic moment alignment may be achieved through the induction of a first order phase-transition or better, a very rapid change of magnetization at the critical temperature, which will bring along a much higher efficiency of the magnetic refrigerator. In combination with currently available permanent magnets, this will open the path to the development of small-scale magnetic refrigerators, which no more rely on rather costly and service-intensive superconducting magnets. Another prominent advantage of magnetocaloric refrigerators is that the cooling power can be varied by scaling from milliwatt to a few hundred watts.

Following the discovery of a sub-room-temperature giant-MCE in the ternary compound $Gd_5(Ge_{1-x}Si_x)_4$ $(0.2 \leqslant x \leqslant 0.5)$(Pecharsky and Gschneidner 1997), there is a strongly increased interest from both fundamental and practical points of view to study the MCE in Gd-based materials (Choe *et al.* 2000, Morellon *et al.* 2000). The common feature of these compounds is that they undergo a first-order structural and magnetic phase transition, which leads to a giant magnetic field-induced entropy change, across their ordering temperature. Many other materials have been studied with respect to their (magneto-caloric) properties, here we will mention only a few of them. The lanthanum–manganese–perovskite oxides $La_{1-x}Ca_xMnO_3$ show considerable MCE values (Zhang *et al.* 1996, Hueso *et al.* 2002). Transition metal pnictides such as $MnP_{1-x}As_x$ (Krokozinsky *et al.* 1982) and chalcogenites such as $Cr_3Te_4$ (Hashimoto 1981) have been studied. The nearly equiatomic alloy FeRh undergoes a magnetic and structural order–order transformation and exhibits giant MCE between 296 K and 316 K but its MCE is irreversible and disappears after the first application of the magnetic field (Annaorazov *et al.* 1992, 2002). The Heusler alloys Ni–Mn–Ga show large magnetic-entropy changes that are due to an abrupt change of the magnetization near the martensite–to–austenite structural transition (Hu *et al.* 2000, 2001a). The compound $La(Fe,Co)_{11.83}Al_{1.17}$ with a very low rare-earth content, also shows a considerable magnetocaloric effect (Hu *et al.* 2001b). The MCEs in most transition-metal-based alloys are lower than those in lanthanide-based alloys for the same temperature range, especially if one takes into account the fact that $\Delta T$ also depends on the specific heat of the compound (Pecharsky *et al.* 2001). This makes them unlikely candidates for use as magnetic refrigerant materials below room temperature. However, above room temperature there exist only a very limited number of rare-earth compounds exhibiting magnetic ordering, a prerequisite for showing large magnetocaloric effects. Fortunately, there exist many manganese compounds, such as MnAs (Pytlik and Zieba 1985), which display a variety of structural and magnetic phase transitions in the relevant temperature range. For a working material in a magnetic refrigerator it is however essential that the phase transition is also reversible.

## 1. *Theoretical Considerations*

When a material is magnetized in an applied magnetic field, the entropy associated with the magnetic degrees of freedom, the so-called magnetic entropy $S_m$, is changed as the field changes the magnetic order of the material. Under adiabatic conditions, $\Delta S_m$ must be compensated by an equal but opposite change of the entropy associated with the lattice, resulting in a change in temperature of the material. This temperature change, $\Delta T_{ad}$, is usually called the magnetocaloric effect. It is related to the magnetic properties of the material through the thermodynamic Maxwell relation

$$\left(\frac{\partial S}{\partial B}\right)_T = \left(\frac{\partial M}{\partial T}\right)_B \tag{1}$$

For magnetization measurements made at discrete temperature intervals, $\Delta S_m$ can be calculated by means of

$$\Delta S_m(T,B) = \sum_i \frac{M_{i+1}(T_{i+1},B) - M_i(T_i,B)}{T_{i+1} - T_i}\Delta B \tag{2}$$

where $M_{i+1}(T_{i+1},B)$ and $M_i(T_i,B)$ represent the values of the magnetization in a magnetic field $B$ at the temperatures $T_{i+1}$ and $T_i$, respectively. On the other hand, the magnetic entropy change can be obtained more directly from a calorimetric measurement of the field dependence of the heat capacity by integration:

$$\Delta S_m(T,B) = \int_0^T \frac{C(T',B) - C(T',0)}{T'}\,dT' \tag{3}$$

where $C(T,B)$ and $C(T,0)$ are the values of the heat capacity measured in a field $B$ and in zero field, respectively. It has been confirmed that the values of $\Delta S_m(T,B)$ derived from the magnetization measurement coincide with the values from calorimetric measurement (Gschneidner *et al.* 1999, Tegus *et al.* 2002b).

The adiabatic temperature change can be integrated numerically using the experimentally measured or theoretically predicted magnetization and heat capacity:

$$\Delta T_{ad}(T,B) = -\int_0^B \frac{T}{C(T,B')}\left(\frac{\partial M}{\partial T}\right)_B dB' \qquad (4)$$

Obviously, the MCE is large when $\left(\frac{\partial M}{\partial T}\right)_B$ is large and $C(T,B)$ is small at the same temperature. Since $\left(\frac{\partial M}{\partial T}\right)_B$ peaks at the magnetic ordering temperature, a large MCE is expected close to this magnetic phase transition.

Recently we discovered that $MnFeP_{1-x}As_x$ compounds exhibit a large magnetic entropy change (Tegus *et al*. 2002a), of a similar magnitude as the so-called giant MCE material $Gd_5Ge_2Si_2$, but whose optimum use temperature is at and above room temperature. This result is of significant practical importance, because it makes these compounds excellent working materials for magnetic refrigeration in household refrigerators or air-conditioning.

In the intermediate composition range ($0.15 \leqslant x \leqslant 0.66$), compounds in the $MnFeP_{1-x}As_x$ system crystallize in the hexagonal $Fe_2P$-type of structure. They have most interesting magnetic properties including a field-induced first-order magnetic transition (Zach *et al*. 1990). Polycrystalline samples can be synthesized starting from the binary $Fe_2P$ and $FeAs_2$ compounds, Mn chips and P powder mixed in the appropriate proportions by ball milling under a protective atmosphere. After this mechanical alloying process one obtains amorphous powder. To obtain dense material of the crystalline phase, the powders are pressed to pellets and sealed in molybdenum tubes under an argon atmosphere. These are heated at 1273 K for 120 h, followed by a homogenization process at 923 K for 120 h and finally by slow cooling to ambient conditions. The powder x-ray diffraction patterns show that the compound crystallizes in the hexagonal $Fe_2P$-type structure. In this structure the Mn atoms occupy the three(g) sites, the Fe atoms occupy the three(f) sites and the P and the As atoms occupy two(c) and one(b) sites statistically (Bacmann *et al*. 1994). From the broadening of the x-ray diffraction reflections, the average grain size is estimated to be $\sim$100 nm.

Figure 2 shows the change in critical temperature on the application of a magnetic field. As pointed out by Pecharsky *et al*. (2001), this change in critical temperature is a good indication for the temperature change induced by the application of a magnetic field. The inset of Fig. 2 shows the temperature dependence of the magnetization near room temperature of $MnFeP_{0.45}As_{0.55}$ and Gd (Alfa Aesar3N) as determined in an applied magnetic field of 1 T. It is obvious that the change in magnetization in $(Mn,Fe)_2(P,As)$ compounds at the ordering temperature $T_c$ is much larger, despite the fact that the magnetic

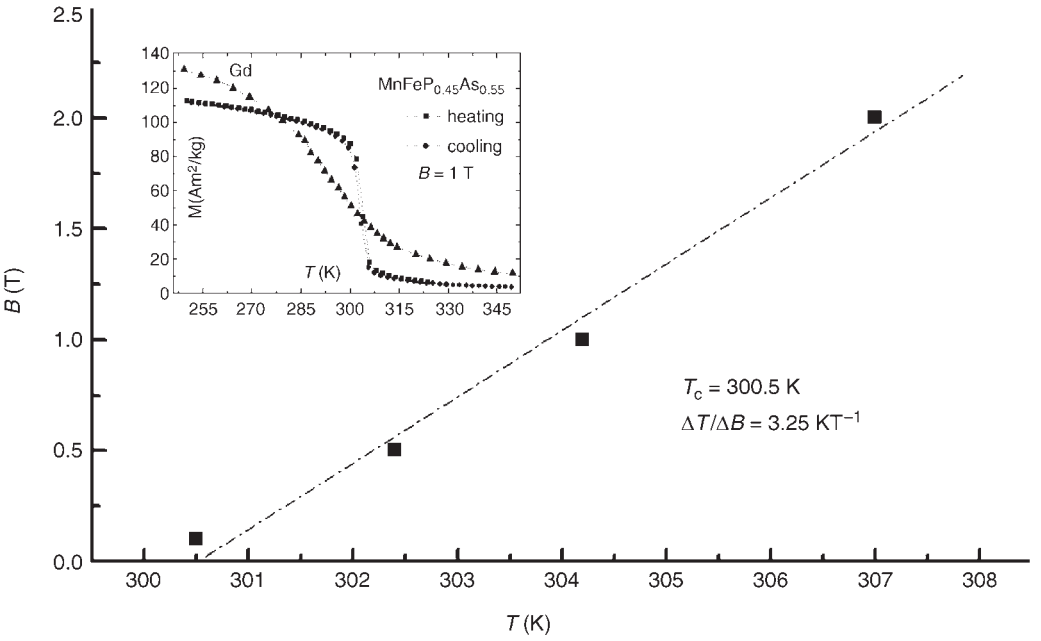

***Figure 2***
Variation of critical temperature with applied magnetic field, the line is a least square fit of the data. Inset: Temperature dependence of the magnetization for $MnFeP_{0.45}As_{0.55}$ and Gd measured with increasing (heating) and decreasing (cooling) temperature in a field of 1 T.

moment of Gd is much larger at low temperatures $248\,Am^2kg^{-1}$ compared to $125\,Am^2kg^{-1}$. Variation of the P/As ratio between 3/2 and 1/2 makes it possible to tune $T_c$ and the optimal operating temperature between 200 K and 350 K (−70 °C and 80 °C), without losing the large magnetocaloric effect. The inset shows the temperature dependence of the magnetization measured with increasing and decreasing temperature in an applied field of 1 T. The thermal hysteresis is signature of a first-order phase transition. Because of the small size of the thermal hysteresis (<1 K), the magnetization process can be considered as being reversible in temperature. From the magnetization curve at 5 K, the saturation magnetization was determined as $3.9\,\mu_B$/f.u. This high magnetization originates from the parallel alignment of the Mn and Fe moments, though the moments of Mn are much larger than those of Fe (Beckmann and Lundgren 1991). Variation of the Mn/Fe ratio may also be used to further improve the magnetocaloric effect.

We calculated the magnetic-entropy changes, $\Delta S_m$, from magnetization data by means of the Eqn. (2). The results are shown in Fig. 3. The calculated maximum values of the magnetic entropy change is $14.5\,J\ kg^{-1}K^{-1}$ for a field change from 0 T to 2 T. The maximum magnetic entropy in 3d materials depends on the spin moment $S$. Because there are two magnetic ions per formula unit, one has $S_m = 2R\ln(2S+1)$, where $R$ is the universal gas constant. From the saturation magnetic moment, we estimate the average $S$ value of the magnetic ions to be equal to $S=1$ thus $S_m = 18.3\,J\ mol^{-1}\ K = 117\,J\ kg^{-1}\ K$, which is about six times larger than the value obtained from the magnetization measurements. For comparison, the magnetic-entropy change of the compound $Gd_5Ge_2Si_2$ and Gd is also shown in the Fig. 3. It is evident that the MCE in $MnFeP_{1-x}As_x$ compounds is comparable with that of $Gd_5Ge_2Si_2$ though the Gd compound has a larger magnetic moment at 5 K. The origin of the large magnetic-entropy change should be attributed to the comparatively high three moments and the rapid change of the magnetization in the field-induced magnetic phase transition. In rare-earth materials, the magnetic moment fully develops only at low temperatures and therefore the entropy change near room temperature is only a fraction of their potential. In 3d compounds, the strong magneto-crystalline coupling results in competing intra- and inter-atomic interactions and leads to a modification of metal–metal distances which may change the iron and manganese magnetic moment and favors the spin ordering.

Bearing in mind the use of these materials in magnetic refrigerators, next to the magnetocaloric properties also the electrical and heat conductivity is of utmost importance. There is hardly any information on the electrical-transport properties of this system. The electrical resistance can also be useful for a more detailed investigation of the magnetic phase transition because it is very sensitive to changes in the interactions between magnetic ions. The availability of electrical-resistance data would make it possible to compare the critical magnetic fields derived from magnetic and electrical measurements and to understand the role of the electron–phonon and electron–magnon interactions in the magnetic phase transitions. The temperature dependence of the electrical

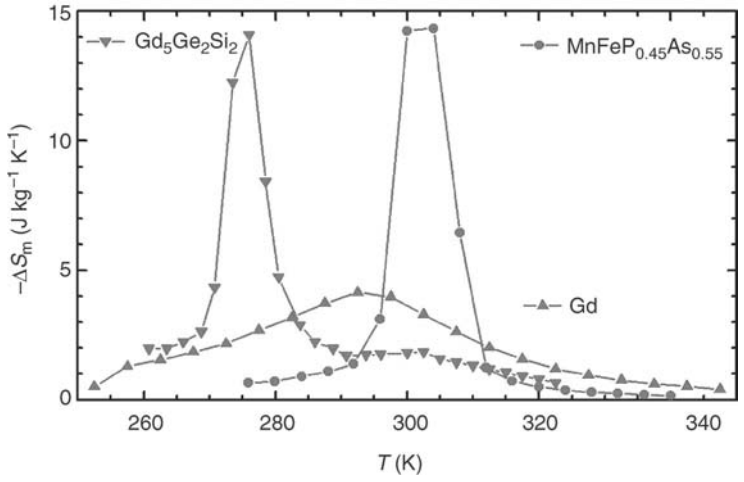

***Figure 3***

resistance of $MnFeP_{0.55}As_{0.45}$, measured during cooling of the sample, is presented in Fig. 4. It can be seen that there is an anomaly in the temperature dependence of the electrical resistance at $T_{cr} = 231$ K. Below $T_{cr}$, the electrical resistance increases with increasing temperature and has metallic character but, above $T_{cr}$, it decreases dramatically in a narrow temperature range and then recovers the metal-like dependence on temperature. The total contribution from both the electron–phonon scattering and the electron–magnon scattering in the paramagnetic (PM) phase is smaller than in the ferromagnetic (FM) phase which is contrary to normal ferromagnetic metallic materials. It is interesting to note that the transition at $T_{cr}$ is accompanied by a change in the $c/a$ ratio (Beckmann and Lundgren 1991), which may lead to a change in the Fermi-surface topology and may affect the electron–phonon scattering. Preliminary band-structure calculations indicate a strong shift of the Fermi level associated with the phase-transition (A. V. Antropov personal communication 2002).

The isothermal magnetic-field-dependent hysteresis loops of the magnetoresistance, defined as $\Delta\rho/\rho_0 = (R(B,T) - R(0,T))/R(0,T)$, in the temperature interval from 243 K to 265 K are shown in Fig. 5. The isothermal increase of the magnetic field leads to an increase of the electrical resistance of $MnFeP_{0.55}As_{0.45}$ beginning at a critical field $B_{cr1}$ and ending at $B_{cr2}$. Hence, between 243 K and 265 K in zero-field the sample is PM but application of a magnetic field exceeding $B_{cr1}$ brings it into the FM state. The field-induced PM–FM transition ends at $B_{cr2}$. During the reduction of the magnetic field, the reversible FM–PM transition begins at $B_{cr3}$ and ends at $B_{cr4}$. The behavior of the electrical resistance in a magnetic field reflects the presence of magnetic-field hysteresis for the complete PM–FM transition, which indicates that also the field-induced transition is first-order. Thus, the temperature and field dependence of the electrical resistance of $MnFeP_{0.55}As_{0.45}$ indicate that a PM–FM phase transition can be induced both by temperature and by magnetic field. The former type of transition takes place from a high-resistance ferromagnetic state at low temperature to a low-resistance paramagnetic state at high temperature. The latter type of transition leads to a positive magnetoresistance peak above $T_c$. The critical-magnetic-field diagram based on the electrical-resistance data shows that the FM–PM transition has a hysteresis of $\sim 1$ T.

In summary, we have observed a surprisingly large magnetocaloric effect in the compound $MnFeP_{0.45}As_{0.55}$, which is comparable with that of the giant-MCE material $Gd_5Ge_2Si_2$. The large MCE observed in $MnFeP_{1-x}As_x$ compounds originates from a field-induced first-order magnetic phase transition. The magnetization is reversible in temperature and in alternating magnetic field. The refrigerant capacity (Gschneidner and Pecharsky 1999) of the compound $MnFeP_{0.45}As_{0.55}$, calculated for a temperature span of 50 K, is larger than that of the well-known magnetocaloric material Gd and the ordering temperature of $MnFeP_{1-x}As_x$ compounds is tunable over a wide temperature interval (200–350 K). The excellent magnetocaloric features of the compound $MnFeP_{0.45}As_{0.55}$, in addition to the very low material costs, make it an attractive candidate material for a commercial magnetic refrigerator.

# Magnetic Steels

Iron is a major constituent in many ferromagnetic materials. Iron is abundant, cheap, and it has the largest elemental magnetic dipole moment, of 2.2 Bohr magnetons ($\mu_B$). Two defining intrinsic magnetic properties of a ferromagnet are (i) the *saturation magnetic induction* associated with the former, and (ii) the *Curie temperature*. Magnetic induction is the magnetic response to an applied magnetic field; magnetic exchange coupling persists to the Curie temperature. With few exceptions the average magnetic dipole moment and Curie temperature, $T_C$, of ferrous alloys are reduced as compared to elemental iron (Bozorth 1951) and most alloying additions are made to alter properties other than exchange and dipole moment. The distinction between *magnetically soft* and *hard materials* is understood in terms of the magnetic hysteresis curve, **B**(**H**), as discussed in *Magnetic Hysteresis*. *Magnetic Hysteresis* represents the energy consumed in cycling a *soft magnetic material* between a field **H** and $-$**H** and back (for a material with a square hysteresis loop this loss is equal to the saturation induction multiplied by the coercive field, $\mathbf{H}_C$) as well as the stored energy in a *hard* or *permanent magnetic material*.

## 1. Magnetically Soft Materials

Technical properties of interest for soft magnets include: (i) *high permeability* ($\mu = \mathbf{B}/\mathbf{H}$); (ii) *low hysteresis loss*, and (iii) *low eddy current* and *anomalous losses*. For soft magnets a small magnetic anisotropy (the barrier to switching the magnetization) is desired to minimize the hysteretic losses and maximize the permeability. A desire for small magnetocrystalline anisotropy guides the choice of cubic crystalline phases of iron, cobalt, nickel or alloys (FeCo, FeNi, etc., with small values of $K_1$) (Jiles 1991). In crystalline alloys, such as Fe–Ni, permalloy, or Hiperco, FeCo, alloy chemistry is varied so that the first-order magnetocrystalline anisotropy energy density, $K_1$, is minimized. Figures of merit for magnetically soft materials include the magnetic permeability and induction, as illustrated for premier soft materials in Fig. 1. Silicon steels, amorphous and nanocrystalline soft magnetic materials are discussed in *Nanocrystalline Materials: Magnetism*. Among other soft magnetic steels FeCo is prominent for its high induction and Curie temperature and FeNi (permalloy) for its large permeability.

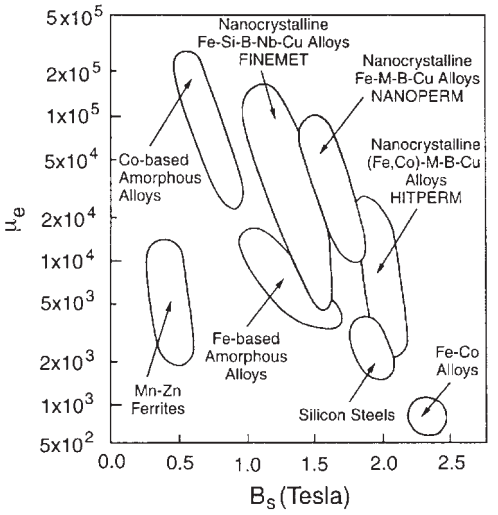

***Figure 1***
(a) Relationship between permeability, $\mu_e$ (at 1 kHz) and saturation polarization for soft magnetic materials (McHenry *et al*. 1999, reproduced by permission of from *Progress in Materials Science*, 1999, **44**, 291).

FeCo soft magnetic steels (Chen 1986) have evolved under the tradenames Permendur, Supermendur and Hiperco (Hiperco50 is a tradename of CarpenterTechnology). Fe–Co alloys exhibit the largest magnetic induction of any material, at composition near the peak in the well-known Slater–Pauling curve. Alloys near the equiatomic composition exhibit large permeabilities (Pfeifer and Radeloff 1980, Rajkovic and Buckley 1981, Boll 1994). This magnetic softness is rooted in a zero crossing of the first-order magnetic anisotropy constant, $K_1$, near this composition. Vanadium additions are made for metallurgical reasons and to increase alloy resistivity and decrease eddy current losses. The Fe–Co alloys undergo an order–disorder transformation at a maximum temperature of 725 °C at the composition $Fe_{50}Co_{50}$, with a change in structure from the disordered b.c.c.(A1) to the ordered CsCl(B2)-type structure. This ordering is important to the mechanical properties of this alloy and influences intrinsic magnetic properties slightly.

Permalloy refers to FeNi soft magnetic alloys of which three compositions are of technical interest (O'Handley 2000). These are a 78% nickel permalloy called supermalloy (Mumetal, Hi-mu 80), a 65% nickel permalloy and a 50% nickel permalloy (Deltamax). These are based on f.c.c. Fe–Ni with Curie

temperatures in excess of 400 °C. Owing to Fe–Ni pair ordering, these materials are quite responsive to field annealing, which is used to shape their hysteresis loops and to increase permeability.

## 2. *Magnetically Hard Materials*

Magnetically hard materials or permanent magnets are ubiquitous. Among the many applications of permanent magnets are small motors, loudspeakers, communications, electronic tubes and mechanical work devices. For a permanent magnet material, large amounts of magnetic hysteresis are desired, with figures of merit including the coercive force, the remnant magnetization and the energy product, $(\mathbf{BH})_{max}$. The remnant magnetization, $\mathbf{M}_r$, or induction, $\mathbf{B}_r$, represents the largest amount of magnetization possible in the absence of a field. The coercive field, $\mathbf{H}_c$, represents the amount of reverse field required to reduce the magnetization to zero after being saturated in the forward direction. For a material with a square hysteresis loop, the energy product, $(\mathbf{BH})_{max}$, is defined at the maximum demagnetizing field, in the demagnetizing quadrant of a hysteresis loop (Fig. 2(a)) (O'Handley 2000). The energy product is the most commonly used figure of merit for permanent magnet materials. (See *Hard Magnetic Materials, Basic Principles of*.)

There are a large number of iron-based and iron oxide-based permanent magnet alloys. Magnetite, $Fe_2O_3$, is named after the district in which it was first discovered, Magnesia in ancient Greece. Lodestone (magnetite) was mentioned in the writing of Greek philosophers and used in compasses guiding ancient mariners (Parker 1990). Technology for developing steel wires for compass needles (Coey 1996) was developed during the Sung period (960–1279) in China. Prior to 1917, permanent magnets made of plain carbon steels were weak and unstable with respect to demagnetization by self-fields. This led to geometric constraints (i.e., the horseshoe magnet) to exploiting these materials as permanent magnets. Steel magnets used prior to 1917 included plain carbon, tungsten and chrome steels (Cullity 1972).

A figure of merit for permanent magnet materials is their *energy product* defined above. Modern permanent magnets have progressed in several notable steps. In 1917 cobalt steels were discovered in Japan (see Honda and Saito 1920). This evolution continued with the later development of AlNiCo magnets. AlNiCo is a permanent magnet derived from the intermetallic $Fe_2NiAl$ Heusler alloy. AlNiCo magnets (see McCurrie 1994) derive their magnetic hardness from the shape of iron-rich particles which form on spinodal decomposition of the Heusler alloy into $\alpha$-Fe and $\alpha'$-NiAl phases. AlNiCo magnets are currently still a significant fraction of the permanent magnet market. Phases in the FePt and CoPt system were studied as early as 1936 by Jellinghaus, who observed them to have the highest energy products of any alloys known at that time (see Bozorth 1993). Important among these phases is the equiatomic FePt and CoPt, possessing the tetragonal $L1_0$ crystal structure. The specialty magnet, MnAlC, also has a tetragonal $L1_0$ crystal structure. (See *Magnetic Materials: Hard*).

Powdered iron and cobalt oxide magnets discovered in Japan by Kato and Takei (1933), and commercialized under the name Vectolite, were the forerunners of modern ferrite magnets. Synthetic hard hexagonal ferrites were developed by Philips

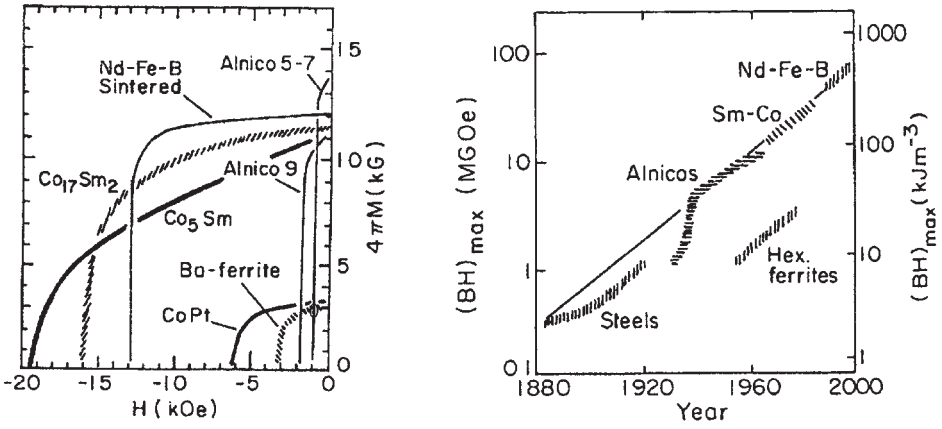

*Figure 2*
(a) Demagnetization curves for several premier hard magnetic materials and (b) historical progression of the magnetic energy product figure of merit for hard magnets (O'Handley 2000, reproduced by permission of Wiley from 'Modern Magnetic Materials, Principles and Applications,' 2000).

laboratories in the Netherlands during the 1950s. Went *et al*. (1952) first reported on isotropic barium hexaferrite magnets and Stuijts *et al*. (1954) reported on anisotropic strontium hexaferrites. While ferrite magnets have never held record energy products, because of their relatively inexpensive components and ease of fabrication, they constitute a large fraction of the permanent magnet market. (See *Permanent Magnets: Bonded*.)

A major development in the evolution of high energy permanent magnet materials has been the discovery of rare earth permanent magnet materials, REPMs. These materials are notable for their large magnetocrystalline anisotropies that are at the root of their large coercivities. Appropriate choice of the rare earth to transition metal ratios in REPMs results in large remnant and saturation magnetizations. The hexagonal, P6/mmm, structure of $CaCu_5$ is the prototype for the important permanent magnet material $SmCo_5$. $SmCo_5$ was first synthesized by Nassau, Cherri, and Wallace (1960), and Strnat and Hoffer (1966) are credited with first calling attention to its potential use as a permanent magnet material. It still has the highest uniaxial magnetic anisotropy ($K_u = 10^7$ J m$^{-3}$) of any known material. REPMs have evolved over the years and presently two families of permanent magnets have found commercial importance. The first of these are the $Sm_2Co_{17}$ (2:17) and the second the $Fe_{14}Nd_2B$ (2:14:1)-based permanent magnets. (See *Rare Earth Magnets: Materials*.)

The 2:17 materials have favorable intrinsic properties: remanent induction $\mathbf{B}_r = 1.2$ T (25 °C), intrinsic coercivity, ${}_i\mathbf{H}_c = 1.2$ T (25 °C) and $T_c = 920$ °C (e.g., in comparison to 750 °C for $SmCo_5$) . Higher 3d metal content leads to higher $T_c$ values. The 2:17 magnets currently in commercial production have a composition $Sm(CoFeCuM)_{7.5}$. Iron additions are made to increase the remanent induction (Huang *et al*. 1994); copper and M (zirconium, hafnium, or titanium) additions are made to influence precipitation hardening. Typical 2:17 Sm–Co magnets with large $\mathbf{H}_c$ are obtained through a low temperature heat treatment used to develop a cellular microstructure. Small cells of the 2:17 matrix phase are separated (and usually completely surrounded) by a thin layer of the harder 1:5 phase. The cell interior contains both a heavily twinned rhombohedral modification of the 2:17 phase and coherent platelets of the so-called z-phase (Fidler and Skalicky 1982), which is rich in iron and M and has the hexagonal 2:17 structure. Typical microstructures have a 50–100 nm cellular structure, with 5–20 nm thick cell walls.

Iron-based rare-earth intermetallic compounds were investigated by Das and Koon (1981), Croat (1981), and Hadjipaynias *et al*. (1983). Commercial $Fe_{14}Nd_2B$ permanent magnets were first synthesized in 1984 by sintering by a group at Sumitoma Metals (Sagawa *et al*. 1984) and by rapid solidification processing by a group at General Motors (Croat *et al*. 1984). Uniaxial magnetocrystalline anisotropy ($K_u = 10^7$ J m$^{-3}$) in these materials results from their tetragonal crystal structure. These materials are based on the cheaper more abundant iron transition metal. They have the largest room temperature energy products of any materials synthesized to date but their lower Curie temperatures as compared with Co-based magnets makes them unsuitable for high temperature applications.

# Magnetic Systems: De Haas–van Alphen Studies of Fermi Surface

Strongly correlated electron systems such as high-$T_c$ cuprates, cerium, and uranium compounds have attracted strong interest with respect to the non-BCS superconducting property. The *f*-electron systems of the rare-earth and uranium compounds have been studied in the context of Kondo lattice, heavy fermion, Kondo insulator, anisotropic superconductivity, RKKY interaction, and quadrupolar ordering. These are based on the hybridization effect between the conduction electrons with a wide energy band and the almost localized *f*-electrons. The Kondo effect, especially, is a basic phenomenon in the cerium and uranium compounds, consequently yielding a large electronic specific heat coefficient $\gamma$ of the conduction electron with an extremely large effective mass (Ōnuki *et al*. 1991, Ōnuki and Komatsubara 1987). It is a challenging study to detect the heavy conduction electron via the standard de Haas–van Alphen (dHvA) experiment.

## 1. De Haas–van Alphen Effect

The dHvA effect is caused when the Landau levels cross the Fermi energy as the magnetic field is increased. It provides a powerful tool for determining the topology of the Fermi surface, the cyclotron effective mass $m_{c^*}$ and the scattering lifetime $\tau$ of the conduction electron. This method of dHvA measurement is illustrated in this article with the strongly correlated electron systems of the transition, rare-earth and uranium compounds (Ōnuki *et al*. 1991, Ōnuki and Hasegawa 1995).

The dHvA voltage $V_{osc}$ is obtained in so-called $2\omega$ detection of the field modulation method:

$$V_{osc} = A\sin\left(\frac{2\pi F}{H} + \phi\right) \tag{1}$$

$$A \propto J_2(x) T H^{-1/2} \left|\frac{\partial^2 S}{\partial k_H^2}\right|^{-1/2} \frac{\exp(-\alpha m_c^* T_D/H)}{\sinh(\alpha m_c^* T/H)} \times \cos\left(\frac{\pi g m_c^*}{2m_0}\right) \tag{2}$$

$$\alpha = \frac{2\pi^2 k_B}{e\hbar} \tag{3}$$

and

$$x = \frac{2\pi F h}{H^2} \tag{4}$$

where $J_2(x)$ is the Bessel function, which depends on the dHvA frequency $F$, the modulation field $h$, and the magnetic field strength $H$. The dHvA frequency $F$ $(=(\hbar/2\pi e)S_F)$ is proportional to the extremal (maximum or minimum) cross-sectional area $S_F$ of the Fermi surface, and $T_D$ $(=\hbar/2\pi k_B)\tau^{-1}$ is the Dingle temperature, which is inversely proportional to $\tau$. The quantity $|\partial^2 S/\partial k_H^2|^{-1/2}$ is the inverse square root of the curvature factor $\partial^2 S/\partial k_H^2$. A rapid change of the cross-sectional area along the field direction diminishes the dHvA amplitude for this extremal area. The term $\cos(\pi g m_c^*/2m_0)$ is called the spin factor. When $g=2$ (free electron value) and $m_c^*=0.5\ m_0$, this term becomes zero for the fundamental oscillation, and the dHvA oscillation vanishes for all values of the magnetic field.

This is called the zero spin-splitting situation, in which the up and down spin contributions to the oscillation cancel out. The cyclotron mass is determined from the temperature dependence of the dHvA amplitude $A$ under a constant field, namely from the slope of a plot of $\ln A[1-\exp(-2\alpha m_c^* T/H)]/T$ vs $T$ at constant $H$ and $h$, by using a method of successive approximations. The Dingle temperature is also determined from the field dependence of the dHvA amplitude at constant temperature, namely from the slope of a plot of $\ln[AH^{1/2}\sinh(\alpha m_c^* T/H)/J_2(x)]$ vs $H^{-1}$ at constant temperature.

Three typical compounds $Sr_2RuO_4$, $CeRu_2Si_2$, and $UPt_3$, with extremely large cyclotron masses, will be discussed to demonstrate the use of dHvA effect studies.

## 2. Cylindrical Fermi Surfaces in $Sr_2RuO_4$

$Sr_2RuO_4$, with the same tetragonal crystal structure as the high-$T_c$ superconductor $La_{2-x}Sr_xCuO_4$, is a

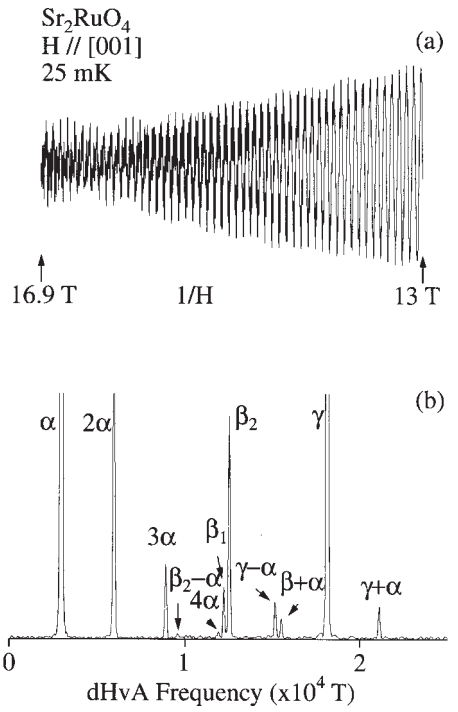

***Figure 1***
(a) De Haas–van Alphen oscillation; (b) its FFT spectrum in $Sr_2RuO_4$.

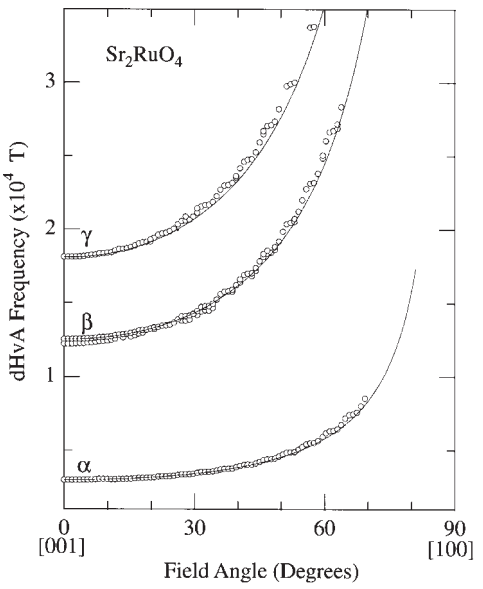

***Figure 2***
Angular dependence of the dHvA frequency in $Sr_2RuO_4$. The solid lines indicate the $1/\cos\theta$-dependence.

possible candidate for a *p*-wave (odd parity) pairing state (Ishida *et al*. 1997). The superconducting transition temperature $T_c$ is 1.5 K in $Sr_2RuO_4$, in contrast to 40 K in $La_{2-x}Sr_xCuO_4$ with a *d*-wave (even parity) pairing state, where the quasi-two-dimensional network of the $CuO_2$ plane is replaced by the $RuO_2$ one.

The electronic state is two-dimensional, reflecting the crystal structure; this was clarified by the dHvA measurement and the result of energy band structure calculations (Yoshida *et al*. 1999). Figure 1 shows the typical dHvA oscillation and its fast Fourier transform (FFT) spectrum for the magnetic field along the tetragonal [001] direction, or the c-axis. Three fundamental dHvA branches, named $\alpha$, $\beta$($\beta_1$ and $\beta_2$), and $\gamma$, as well as higher harmonics of $\alpha$, namely $2\alpha$, $3\alpha$, $4\alpha$, and the combined harmonics ($\beta_2 \pm \alpha$ and $\gamma \pm \alpha$), are presented in Fig. 1(b).

Figure 2 shows the angular dependence of the dHvA frequency. The solid curves for the fundamental branches represent the $1/\cos\theta$-dependence, where $\theta$ is a tilt angle from [001] to [100]. The $1/\cos\theta$-dependence means a cylindrical Fermi surface. For example, branch $\beta$ splits into two branches around [001], denoted by $\beta_1$ and $\beta_2$, which merge into one at $\theta \approx 30^\circ$. This angle corresponds to a so-called Yamaji angle, where all orbits on the cylindrical but slightly corrugated Fermi surface have the same cross-sectional area. The theoretical Fermi surfaces for branches $\alpha$, $\beta$ and $\gamma$ are shown in Fig. 3. They are mainly due to hybridized orbitals of Ru(4*d*) and O(2*p*).

From the temperature dependence of the dHvA amplitude A, namely the magnitude of the FFT spectrum in Fig. 1(b), we can determine the cyclotron effective mass $m_c^*$ for each Fermi surface. The cyclotron mass is 3.3 $m_0$ for branch $\alpha$, 6.9 $m_0$ for $\beta$, and 17 $m_0$ for $\gamma$. It is noted that the corresponding band masses are 1.0, 1.9, and 2.8 $m_0$, respectively. The largest cyclotron mass of branch $\gamma$ is six times larger than the band mass. The corresponding electronic specific heat coefficient is easily calculated, being 4.9, 10, and 25 $mJK^{-2}mol^{-1}$, respectively. The total $\gamma$-value is 40 $mJK^{-2}mol^{-1}$, which is in good agreement with the measured $\gamma$-value of 39.8 $mJK^{-2}mol^{-1}$ (Yoshida *et al*. 1999).

## 3. *Heavy Conduction Electrons in $CeRu_2Si_2$ Based on the Kondo Effect*

$CeRu_2Si_2$ possesses tetragonal crystal structure, with one molecule per primitive cell. Important properties of this compound are described in *Heavy-fermion Systems*. Figure 4 shows the typical dHvA oscillation for the field along the [100] direction and its FFT spectrum. Four dHvA branches named $\beta$, $\gamma$, $\psi$*, and $\psi$, as well as their harmonics, are presented in Fig. 4(b).

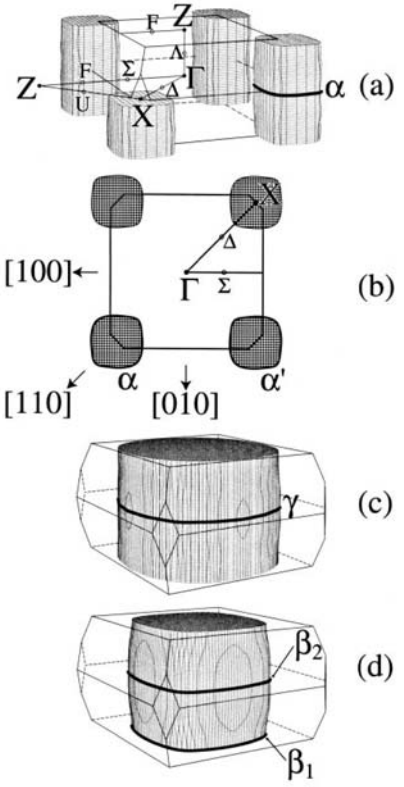

***Figure 3***
Fermi surfaces of (a) and (b) band-17 hole; (c) band-18 electron; (d) band-19 electron in $Sr_2RuO_4$.

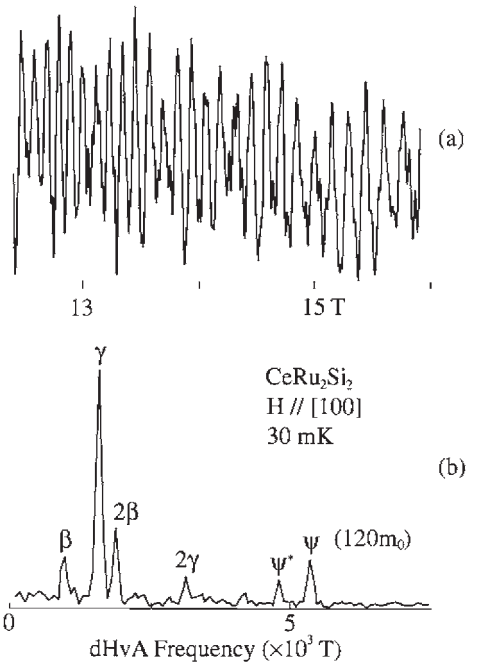

***Figure 4***
(a) De Haas–van Alphen oscillation and (b) its FFT spectrum in $CeRu_2Si_2$.

Figure 5 shows the angular dependence of the dHvA frequency (Takashita *et al.* 1996) and the result of energy band calculations (Yamagami and Hasegawa 1993). All dHvA branches are characterized as follows:

- branches $\psi$ and $\psi$*: band-14 hole
- branches $\kappa$, $\varepsilon$, and $\alpha$: band-15 electron
- branch $\gamma$: band-13 hole
- branch $\beta$: band-12 hole.

The theoretical Fermi surfaces are shown in Fig. 6. These Fermi surfaces are calculated by a relativistic augmented plane wave (APW) method with a local-density approximation (LDA), under the assumption that 4*f*-electrons are itinerant. The experimental result is in good agreement with the 4*f*-itinerant band model, although the calculated Fermi surface has a slightly larger volume than the experimental one.

On the other hand, the cyclotron effective mass, which was determined from the temperature dependence of the dHvA amplitude, is very different from the band mass, because the many-body Kondo effect is not included in the conventional band theory. The cyclotron mass of the branch $\psi$ is extremely large, 120

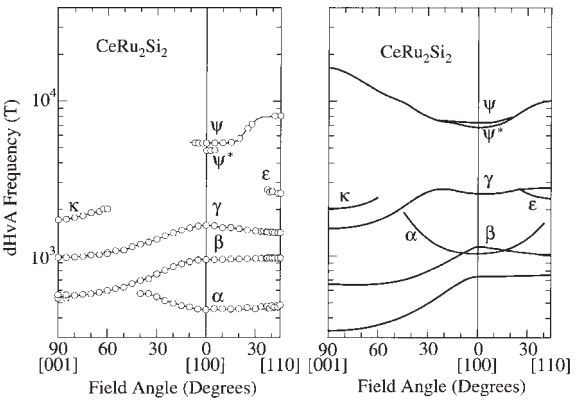

***Figure 5***

$m_0$ for the field along [100]. The corresponding band mass is 1.93 $m_0$. The experimental mass is about 60 times larger than the band mass. The dHvA branches $\psi$ and $\psi$* are not observed around [001]. This is because the metamagnetic transition occurs at about 8 T and the cyclotron effective mass is expected to

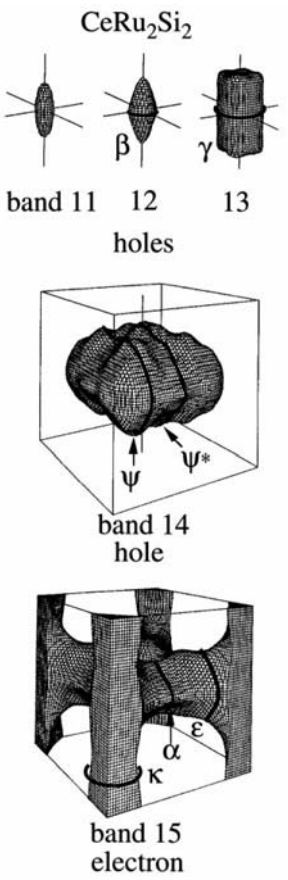

***Figure 6***
Theoretical Fermi surfaces in $CeRu_2Si_2$ (after Yamagami and Hasegawa 1993).

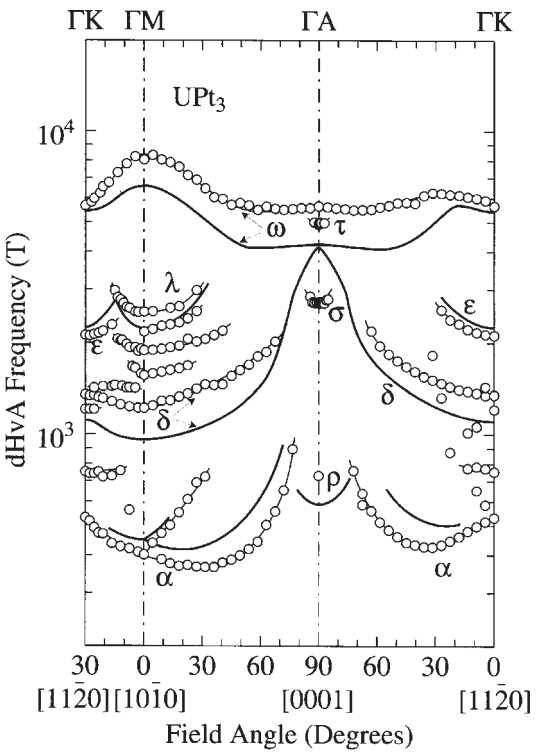

***Figure 7***

become much larger than 120 $m_0$. This transition is confirmed to be not of the first order (Sakakibara *et al.* 1995). The electronic state in fields above the metamagnetic transition is still under study.

In conclusion, the 4*f*-electrons in $CeRu_2Si_2$ are confirmed by the dHvA study to become itinerant at low temperatures. The conduction electrons, including the 4*f*-electrons, form a so-called "large Fermi surface." This Fermi surface is very different from the corresponding small Fermi surface of $LaRu_2Si_2$, in which the 4*f*-levels are far above the Fermi energy and do not contribute to the conduction electron states.

## 4. *Itinerant 5f-electrons in $UPt_3$*

$UPt_3$, with hexagonal structure, is a prime candidate for the unconventional pairing state to be realized (Tou *et al.* 1998). Superconductivity in $UPt_3$ coexists with antiferromagnetic ordering, with a Néel temperature of about 5 K. This ordering is, however, not static but dynamic. To understand the 5*f*-electron nature, it is vitally important to clarify the Fermi surface property (Kimura *et al.* 1998).

Figure 7 shows the angular dependence of the dHvA frequency. The origin of the detected dHvA branches will be identified on the basis of the 5*f*-itinerant band model. Figure 8 shows the theoretical Fermi surfaces. The branches are as follows:

- branch $\omega$: band-37 electron
- branch $\tau$, $\sigma$, $\rho$, $\lambda$, $\varepsilon$, and $\alpha$: band-36 hole
- branch $\delta$: band-35 hole.

The dHvA frequencies, shown by circles in Fig. 7, are in good agreement with theoretical results (the solid lines) of the 5*f*-itinerant band model. The branch $\omega$ possesses the largest cross-sectional area and cyclotron mass. The mass is determined as 80 $m_0$ in the field range of 15 to 17.5 T for the field along [0001], 105 $m_0$ in the field range of 18.2 to 19.6 T for [10$\bar{1}$0], and 90 $m_0$ in the field range of 17 to 19.6 T for [11$\bar{2}$0]. The corresponding band masses are 5.09, 6.84, and 5.79 $m_0$. The cyclotron masses are about 15 times larger than the corresponding band masses. It should be noted that all bands contain an *f*-electron component of about 70% and are flat in the dispersion.

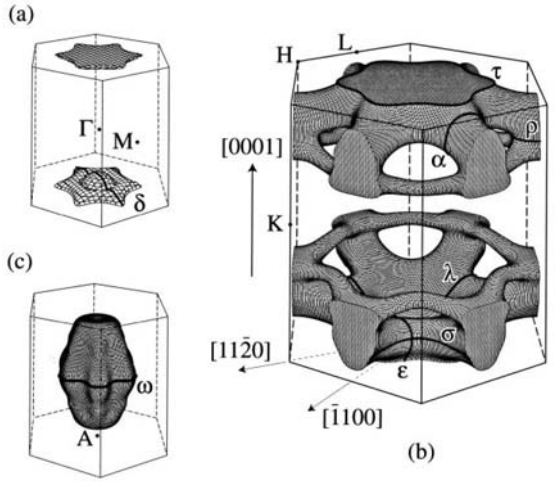

***Figure 8***
Theoretical Fermi surfaces in $UPt_3$: (a) band-35 (hole), (b) band-36 (hole), (c) band-37 (electron).

In theory, nearly spherical Fermi surfaces of a band-37 electron centered at the K point in the Brillouin zone, and band-38 and -39 electrons at the Γ point are present, but they are not observed experimentally. We suppose that they are not present. If these electrons are not present, the main Fermi surface named $\omega$ has to become larger than that in Fig. 8(c). In fact, the experimentally determined cross-section is larger than the theoretical one, as shown in Fig. 7.

Thus it can be concluded that the 5*f*-electrons in $UPt_3$ are of itinerant nature. Namely, the dHvA results are well explained by the 5*f*-itinerant band model, although a slight alteration is necessary. All branches are heavy, with cyclotron masses of 15–105 $m_0$, i.e., 10 to 20 times larger than the corresponding band masses. The mass enhancement is caused by magnetic fluctuations, where the freedom of charge transfer of the 5*f*-electrons appears in the form of the 5*f*-itinerant band, but the freedom of spin fluctuation of the same 5*f*-electrons reveals an unusual magnetic ordering and enhances the effective mass as in the many-body Kondo effect. These heavy conduction electrons, or quasiparticles, condense into Cooper pairs. To avoid a large overlap of the wave functions of the paired particles, the heavy-fermion state would rather choose an anisotropic channel, like a *p*-wave spin triplet, to form Cooper pairs in $UPt_3$.

## 5. Conclusion

We presented dHvA studies on the strongly correlated electron systems of $Sr_2RuO_4$, $CeRu_2Si_2$, and $UPt_3$. A low temperature of 20 mK and a high magnetic field of 20 T can be obtained with a commercial dilution refrigerator and a superconducting magnet, respectively. These are necessary conditions to detect a conduction electron with a large mass of 100 $m_0$ in the dHvA experiment for $CeRu_2Si_2$ and $UPt_3$. Moreover, a high-quality sample is vitally important: the band-37 electron with 100 $m_0$ in $UPt_3$ was not observed for the sample of the residual resistivity ratio ($RRR = \rho_{RT}/\rho_0$) of 300–400, but was observed for $RRR = 600$–$700$, where $\rho_{RT}$ and $\rho_0$ are the electrical resistivity at room temperature and the residual resistivity, respectively.

The topology of the detected Fermi surface is well explained by energy band calculations based on the density functional theory in LDA. The cyclotron mass is, however, very different from the corresponding band mass, because the many-body Kondo effect is not included in the conventional band theory. These Fermi surface properties should shed light on the basic understanding of strongly correlated magnetic materials.

# Magnetic Systems: Disordered

All real magnetic materials are imperfect to some extent; there are static structural imperfections either on the atomic level (impurity atoms substituted on host sites in an otherwise perfect lattice) or in the form of extended defects (dislocations, grain boundaries, or rough surfaces). The degree of imperfection can be very low, as in high-quality magnetic monocrystals or films, or it can be very high, as in certain concentrated alloys or in amorphous materials. "Disorder" in the present context can mean a wide distribution of magnetic couplings between local moments because of random environments. It can also mean random local crystal fields—broadly, the interaction between the effective electric charges on the atoms surrounding a magnetic site and the nonspherical charge distribution of the electrons on the site. Moderate disorder in ferromagnets has an essential influence on the hysteresis effects that are intrinsic to the technologically vital hard ferromagnets and magnetic memory materials.

Here we will first consider the limit of strong coupling disorder, which leads to behavior where the standard ferromagnetism or antiferromagnetism is replaced by "spin glass" ordering, with totally novel behavior. Such strongly disordered magnetic systems have no direct practical applications but they show fascinating thermodynamic behavior which poses conceptually tough problems. The models that have been developed to understand strongly disordered magnetism have been widely extended to provide paradigms for complex systems of all types–structural, biological, or sociological. Spin-offs resulting directly from the ideas arising from the magnetic problems include sophisticated numerical optimization methods and neural network computers.

## 1. Spin Glass Materials

Historically, the spin glass phenomenon was first discovered in the magnetism of dilute alloys; it is characterized by remarkable magnetic irreversibility and relaxation properties. In certain alloys such as AuFe or CuMn the transition metal atoms are distributed at random and have localized magnetic moments down to very low concentrations (van den Berg 1961). In these alloys the magnetic interactions between the local spins are through the Ruderman–Kittel (RKKY) polarization of the conduction electron band (for RKKY interaction see *Magnetism in Solids: General Introduction*). This polarization oscillates in sign as a function of the distance between the spins, so in a random dilute alloy some pairs of spins will be coupled ferromagnetically and others antiferromagnetically, meaning that the interactions are quasi-random with both signs present. There is therefore strong disorder in the couplings. If a sample of a few percent concentration of magnetic sites is cooled slowly and the low-field a.c. susceptibility is measured, there is a well defined sharp susceptibility cusp as a function of temperature at a critical temperature $T_g$, (Cannella and Mydosh 1972) (Fig. 1), while paradoxically there is no sign of any singularity anywhere in the specific heat (Keesom and Wegner 1976) (Fig. 2).

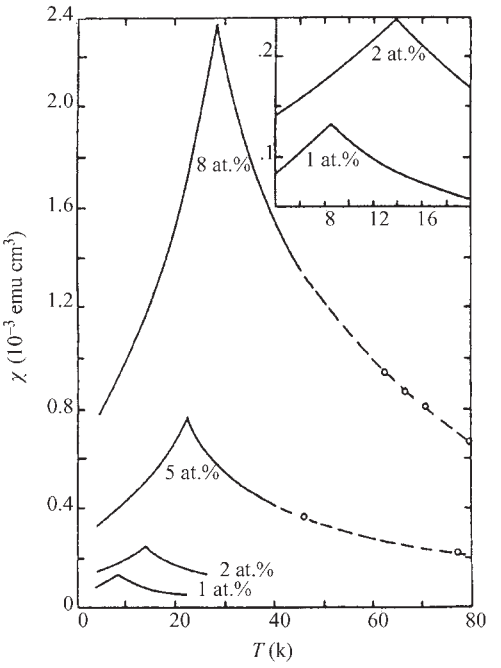

***Figure 1***
Low-field a.c. susceptibility of AuFe alloys 1–8 at.% Fe in a 5 gauss field at $\approx 100$ Hz frequency. The cusps are clearly defined. (Reproduced by permission of American Physical Society from *Phys. Rev. B* 1972, **6**, 4220.)

If the same sample is cooled slowly in a constant low magnetic field $H$ (field-cooled, FC), a temperature-independent magnetization plateau develops below $T_g$. If, instead, the sample is first cooled in zero field down to a low temperature (zero-field-cooled, ZFC), after which the same low field $H$ is applied as before and then the temperature is raised slowly, the magnetization is lower than the FC case until the two curves meet at $T_g$. Typically $T_g$ is of the order of 10 K for a sample with 1% magnetic impurities and is roughly proportional to the magnetic site concentration.

## 2. Dynamics and Critical Behavior

Over the whole range of temperatures above $T_g$ relaxation is paramagnetic; the sample has an induced magnetization in an applied field, and when the field

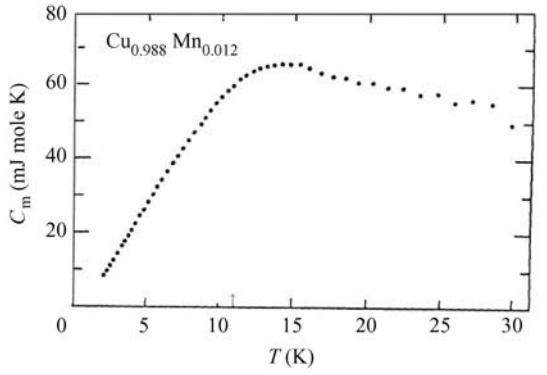

***Figure 2***
Magnetic specific heat for a Cu–1.2 at.% Mn alloy. The arrow at about 11 K indicates the susceptibility cusp temperature; there is no sign of any accompanying specific heat anomaly. (Reproduced by permission of American Physical Society from *Phys. Rev. B* 1976, **13**, 4053.)

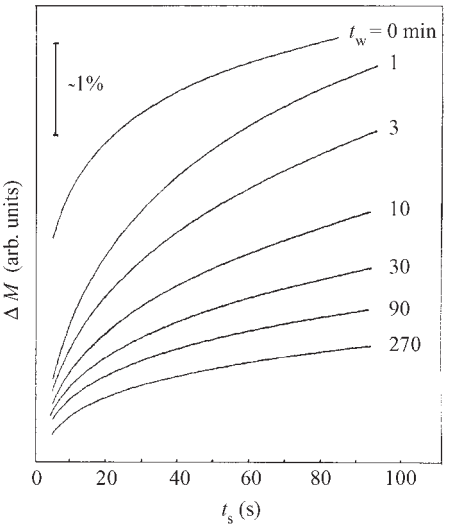

***Figure 3***
Relaxation in the frozen state of Cu–4 at.% Mn alloy. After cooling the sample in zero field to a temperature of 0.88 times the freezing temperature, a small field (1 gauss) is applied following a waiting time $t_w$. The relaxation of the resulting magnetization is measured for 100 sec after switching on the field. It can be seen that there is always a slow creep-like relaxation, and that this relaxation changes dramatically with the waiting time. (Reproduced by permission of American Physical Society from *Phys. Rev. Lett.* 1983, **51**, 911.)

is cut off the magnetization drops to zero in a short but finite time. The form of the relaxation decay becomes strongly nonexponential as $T_g$ is approached, and the relaxation times, while still much shorter than a second, become very long compared with atomic relaxation timescales which are of the order of a picosecond (Mezei and Murani 1979).

Things are very different below $T_g$. If the sample is cooled in field to a temperature $T$ below $T_g$ and the field is then cut off, there is a residual magnetization $M$ which decays slowly and quasi-logarithmically with time $t$, i.e.,

$$M(t) \sim M(0) - S \log(t) \qquad (1)$$

over many decades in $t$ (Guy 1978). This "magnetic creep" signifies that as time passes the relaxation becomes slower, and on all practical time scales (maybe even to millions of years) the residual magnetization will never decay to zero.

The difference between behavior above $T_g$ and below $T_g$ is dramatic. Just above $T_g$ relaxation is measured in microseconds while below $T_g$ there is a huge range of effective time scales, extending through years to infinity.

In fact, quasi-logarithmic relaxation below $T_g$ is simply a convenient approximation. $S$ is not a constant, and the form of the relaxation expressed in terms of $S(t)$ has been studied in great detail. There are striking aging effects in the low-temperature relaxation (Lundgren *et al.* 1983): if the sample is field-cooled to $T$ and then held at constant temperature for a "waiting time" $t_w$ before the field is cut off (or alternatively if the sample is zero-field-cooled and then a field is applied) the relaxation of the magnetization depends on how long the waiting time is, as shown in Fig. 3. There is a cryptic reorganization of the spins during the waiting. A related measurement is magnetic torque; if the sample is field-cooled to $T$ and then the field is rotated by a small angle, the magnetization does not follow the field but a torque signal appears. (A torque signal is equal to the vector product of magnetization and field). The origin of this torque is closely related to a local anisotropy, a specific spin glass characteristic. The fact that torque is observed is again a consequence of the memory of the spin system; if the spins could reorganize freely there would be zero torque.

Accurate measurements of the a.c. susceptibility in the region of the cusp show slight frequency-dependent effects: the smaller the frequency the lower the apparent cusp temperature. (Typically the change in the apparent $T_g$ is 0.1% for a decade change in excitation frequency, so this is a small effect). The change in $T_g$ could suggest that the cusp is not the signature of an onset of ordering but just an artifact related to a continuous and gradual slowing down of relaxation. However, careful experiments have shown that the static magnetization of the spin glasses has a critical behavior with well-characterized exponents (Bouchiat and Monod 1983, Lévy 1988), as in

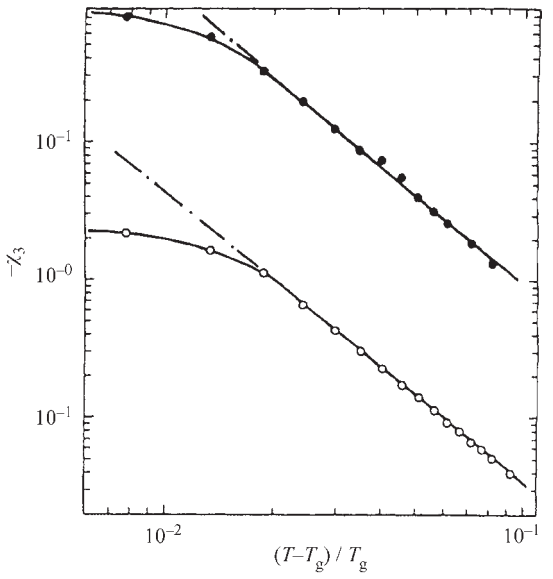

***Figure 4***
Temperature dependence of the nonlinear susceptibility $\chi_3$ in a AgMn–0.5 at.% sample above the freezing temperature. Measurements made at 0.01 Hz. Open symbols: zero static applied field; closed symbols: 90 gauss static applied field. The straight line on the log–log plot is the canonical signature of critical behavior at the approach to a transition temperature. The bend over very close to the ordering temperature is a critical slowing down effect. (Reproduced by permission of American Physical Society from *Phys. Rev. B* 1988, **38**, 4983.)

standard econd-order transitions (Fig. 4). Suppose we measure the reversible magnetization above $T_g$ and write the magnetization $M$ as a function of applied field $H$ in a Taylor expansion where there are only odd terms because of time reverse symmetry, the following expression is obtained:

$$M(T,H) = \chi_1(T)H + \chi_3(T)H^3 + \ldots \qquad (2)$$

Then the linear susceptibility$\chi_1(T)$ does not diverge at $T_g$ while the nonlinear susceptibility $\chi_3(T)$ does diverge, as $1/(T-T_g)^{\gamma}$. This important observation (where no time dependence is involved) demonstrates that $T_g$ is a bona fide thermodynamic transition temperature and not just a crossover temperature separating a rapid relaxation regime from a slow relaxation regime. The time dependencies observed in a.c. measurements arise because the response of the sample to a change of field has a very wide range of characteristic timescales when the temperature is close to the ordering temperature.

A remarkable fact is that despite the structural randomness (which implies that the effective concentration changes from one microscopic region to another) the freezing transition is sharp and therefore must be a long-range cooperative phenomenon.

The numerical values of the critical exponents (such as $\gamma$) are quite different from those seen at second-order transitions, magnetic or otherwise, in regular materials. Two examples are the critical exponent $\alpha$ for the specific heat, and the dynamic exponent $z$. In regular materials $\alpha$ is usually very near zero, which corresponds to a sharp maximum (or even a divergence) in the specific heat as the transition temperature is passed. In the spin glasses $\alpha$ is typically $-2$, which corresponds to a complete lack of singularity in the specific heat at the transition. Concerning the dynamics, in canonical systems $z \approx 2$ while in spin glasses $z \approx 6$. This means that there is an exceptionally wide regime of temperature above the transition in spin glasses where the dynamics are slowing down.

What is the physics behind the spin glass behavior? Because there is long time irreversibility below $T_g$ the material appears to be in an ''ordered'' state, as a paramagnetic state only has reversible behavior by definition. The question is: What does ''ordered'' mean? The spin glass ordering represents a freezing of the spins into a cooperative configuration that optimizes the overall energy by satisfying as many individual pair interactions as possible. Because there are many configurations which minimize global energy almost equally well, we have all the complicated dynamics both above and below the ordering temperature. The necessary condition for spin glass order to exist would appear to be a combination of a certain degree of randomness (the random positions of the spins in the dilute alloy case) and conflicting interactions (here due to the RKKY oscillations).

In practice the conditions of randomness and conflict appear to be quite commonplace in magnetic materials, as many hundreds of experimental materials, both metallic and insulating, show the same canonical behavior. As well as the dilute alloys AuFe, CuMn, AgMn, AuCr, or AlGd there are other alloys such as NiMn over an intermediate range of concentration, $Eu_xSr_{1-x}$, amorphous alloys such as NiFe(PBAl) or FeMnP, insulators such as $CdCr_{1.7}In_{0.3}S_4$, or semiconductors such as Cd(Mn)Te. Common signatures characteristic of all spin glasses are the magnetic irreversibility onset below $T_g$, a lack of any singular feature in the specific heat at $T_g$, and slow nonexponential relaxation of the residual magnetization, with aging, below $T_g$ (Mydosh 1993).

To understand what is happening it is useful to compare the results in model systems.

## 3. *Model Systems*

The simplest of all model systems for magnetic ordering is the pure Ising ferromagnet, originally studied

by Ising in his thesis in 1925, and solved exactly in dimension two by Onsager 15 years later (for the Ising model see *Magnetism in Solids: General Introduction*). Ising spins (the spin directions are restricted to be only up or down) are placed on a regular lattice with interactions of strength $-J$ between each pair of near neighbors. In the paramagnetic state the spins flip from up to down and there is no global magnetization. When the temperature is lowered through a critical temperature $T_c$ there is a spontaneous "symmetry breaking"; the spins all conspire to choose an overall magnetization direction, with a majority of spins pointing either up or down. When the same system is cooled down a number of times it chooses up or down at random each time, but for temperatures less than $T_c$, once the magnetization direction is decided after a given cooling it stays fixed. Temporary correlated clusters of spins of the same sign form and grow as $T_c$ is approached from above, and the timescale for magnetization fluctuations diverges as the temperature tends towards the critical temperature. All the thermodynamic and statistical properties of this system are now extremely well understood thanks to the renormalization group theory (Wilson 1975).

This is a pure ferromagnetic Ising system. But what about disorder? The simplest type of disorder that can be introduced is dilution. Suppose that some of the spins are taken away at random, leaving a fraction $p$ of occupied sites. It turns out that this does not affect the system in a very fundamental way. As could be expected the ordering temperature $T_c(p)$ drops as $p$ decreases, tending to zero at a critical value $p_c$ ; this corresponds to a "percolation" limit. When there is no longer a giant cluster of spins all linked together by near-neighbor interactions there will no longer be an ordered state even at zero temperature. However, the properties at the transition, such as the peak in the specific heat and the divergence of the susceptibility at $T_c$, remain very similar to those in the pure system from $p=1$ down to $p=p_c$.

Instead of dilution, the spin glass situation with both ferro and antiferro interactions can be mimicked by a regular lattice of Ising spins where the near-neighbor interactions are chosen randomly to be positive or negative ($-J$ or $+J$). This is much more drastic, as now half the pairs of spins want to be aligned parallel to each other and half antiparallel, giving strong frustration. It turns out that this model, the Edwards–Anderson model (Edwards and Anderson 1975), defined in a couple of lines, is extremely hard to solve theoretically, and for dimension three most of what is known comes from large-scale numerical simulations. (It is interesting to compare with the Japanese game of *Go*, which has trivially simple rules involving black and white pieces like up and down spins, and which is also of extreme complexity.)

The mean field limit (corresponding to an infinite space dimension where all spins are neighbors to all other spins) has been solved by Parisi (1983) thanks to a mathematical *tour de force*. It turns out that there is a huge number of inequivalent ground states, so the system must choose not just between two alternatives (global magnetization up or down) as in the ferromagnet case but between very many inequivalent complex arrangements of spins, all of which manage to minimize the total energy.

For spin glasses in finite dimensions (such as the real-world dimension three) it is still not clear if the physics is strictly the same as in the mean-field situation, but there are certainly huge numbers of either ground states or very long-lived metastable states, which are almost the same for practical purposes. The numerical data show that there is an ordered low-temperature state as in the experimental spin glass, where the word "ordered" has a special sense. In a standard ferromagnet or antiferromagnet the order parameter is the overall magnetization or staggered magnetization, respectively; for the spin glass there is no equivalent.

The order parameter is defined as the memory function averaged over time and over the spins:

$$q_{EA} = [\langle S_i(t) S_i(t') \rangle] \tag{3}$$

where $\langle \ldots \rangle$ means a time average for spin $S_i$ and $[\ldots]$ means an average over all spins. The difference between times $t$ and $t'$ is chosen to be arbitrarily long and the system contains many spins. If globally the spins have an infinitely long memory time for their individual orientations, at time $t'$ each spin $i$ has a probability of $>0.5$ to have the same orientation as it had at time $t$, however long is $[t'-t]$. The spins "remember"; this defines the system as being frozen and so "ordered", and $q_{EA} \neq 0$. The name "spin glass" coined in 1970 by Coles and Anderson (Anderson 1970) expresses the fact that the difference between the paramagnetic state and the ordered state is basically one of timescale, just as the difference between a liquid and a structural glass cannot be seen from the atomic position (there is no long-range atomic order in either case) but from the timescale of the atomic movements which is short in the liquid and infinitely long in the glass. This does not imply that the change in timescale is continuous as a function of temperature; at the ordering temperature the autocorrelation timescale diverges.

A great deal of information can be obtained from the numerical simulations, which are well adapted to the problem as Ising spins are good binary objects. As the spin ensemble is cooled down (according to standard numerical procedures) relaxation becomes slow and highly nonexponential, meaning that there is a very wide range of effective relaxation times (Ogielski 1985). The transition temperature can be defined by the divergence of the mean relaxation time, or through techniques using scaling rules applied to numerical samples of finite but progressively increasing size. Like in the experimental case there is

a well-defined transition with critical behavior, and again as for the experimental materials no visible singularity in the specific heat is observed at the transition. The frustration reduces the ordering temperature compared with the ferromagnetic case; for a three-dimensional ferromagnetic system with interaction strength $-J$ the ordering temperature is 4.51 kJ. For a spin glass on the same lattice with interactions randomly $+J$ and $-J$, the freezing temperature is near 1.2 kJ. In dimension two, the ferromagnetic ordering temperature is 2.27 kJ (Onsager 1944) while the spin glass does not order until zero temperature (Binder and Young 1986).

There are several experimental materials that are quasi-Ising. These systems have dilute, randomly distributed magnetic sites in a crystal structure with an axial symmetry such that there are strong local crystal fields acting on the spins, all parallel to the symmetry axis. If the local moments are all constrained to be parallel or antiparallel to the axis, then the material behaves essentially as an Ising spin glass. Examples are the three-dimensional mixed compound $Fe_{0.5}Mn_{0.5}TiO_3$ (Ito *et al*. 1986) and the two-dimensional layer compound $Rb_2Cu_{1-x}Co_xF_4$ (Dekker *et al*. 1988). Numerical and experimental values for properties such as the critical exponents can be compared, and good agreement has been found.

All the major features of the behavior of the experimental spin glasses are reproduced by the numerical simulations. For instance, the relaxation behaviors observed experimentally below and above $T_g$ are seen with essentially the same form in the simulations. The agreement between the experiments and the simulations (which, it must be remembered, are done on very simplified model systems) and the fact that experimental systems behave similarly to each other means that all these phenomena are intrinsic to the glassy type of ordering, and that the details of the interactions, the types of spins, and so on are fairly irrelevant. The numerical work can give access to parameters that are very hard to see experimentally such as the particular microscopic configuration taken up by the spins. Most remarkably, each time a large system is cooled down, it ends up in a microscopically different frozen state. There indeed appears to be a quasi-infinity of low-temperature configurations by which the spin ensemble can satisfy the frustrated interactions almost equally well. Instead of the system breaking symmetry by choosing between up and down global magnetization as in the ferromagnetic case, it breaks it in a fundamentally different way by choosing from among an enormous number of alternative complex inequivalent configurations.

Numerical studies of spin glasses are extremely time-consuming because of the long relaxations, and subtle difficulties appear. As a result, the ordering temperatures of the canonical models in dimension three are still not accurately determined even after more than 20 years of intensive numerical effort, and the correct description of the ordering process in finite dimensional spin glasses is still a hotly debated topic.

Finally, in the vast majority of experimental spin glass materials, the spins are Heisenberg (for a description of the Heisenberg model see *Magnetism in Solids: General Introduction*) rather than Ising, which means that the spin can take any orientation in space, not just up and down. Numerical simulations with this type of spin indicate clearly that if the mechanism of the ordering were the same as for Ising spins, then $T_g$ should be zero in dimension three. The most plausible explanation for this paradox (we certainly know from experiment that spin glasses with finite ordering temperatures exist in real-life three-dimensional materials) is that the ordering is fundamentally "chiral," which corresponds to a three-spin correlation function for Heisenberg spins rather than a two-spin exchange interaction. The numerous consequences of this model (Kawamura 1992) are still being studied.

The spin glass is not simply a thermodynamic curiosity. It should provide the most tractable example of the vast family of complex systems with disorder and frustration, which includes glasses of all kinds, and optimization problems such as the famous travelling salesman problem. Neural computing techniques are directly inspired by spin glass work. The spin glass has become a paradigm for the behavior of complex cooperative systems in general, from the stock market to the genetic code; however, it turns out that the physics of even the simplest model spin glass is extremely subtle and is not yet fully understood. An enormous experimental and theoretical effort has gone into the study of spin glasses over the last 30 years, but only a few definitive answers have been given in response to the many questions that arise.

## 4. Reentrant Magnetism

In certain alloy series, the nature of the ordering changes from ferromagnetic to spin glass as a function of concentration. AuFe alloys are ferromagnetic from pure Fe down to 15% Fe concentration, while for lower Fe concentrations they order as spin glasses. Clearly this behavior corresponds to a conflict between a ferromagnetic ordering tendency when the near-neighbor ferromagnetic interactions dominate and the random interaction spin glass case for dilute spins. There are many other experimental examples of this behavior (e.g., (Campbell and Senoussi 1992).

Very early on in the model calculations, the Ising system with near-neighbor interactions was studied for a fraction $p$ of ferromagnetic interactions and $(1-p)$ antiferromagnetic interactions ($p=0.5$ is of course the standard spin glass that is discussed

above). At a critical intermediate concentration $p_n$ the order passes abruptly from spin glass to ferromagnetic, much as in the experiments. However, the behavior seen in real materials where the spins are Heisenberg rather than Ising is subtler. There is again a critical concentration $p_n$ but on the ferromagnetic side of $p_n$ "reentrant" behavior is found. Suppose we have a sample on the ferromagnetic side of $p_n$. We cool it down slowly starting from high temperatures. We will first encounter an ordering temperature $T_c$ below which the order is conventional ferromagnetism. However, at some lower temperature $T_k$ "canting" sets in; i.e., each spin has a frozen component $M_z$ along the overall magnetization axis as in a ferromagnet, but it also has frozen components $M_x$ and $M_y$ in the plane perpendicular to the $z$ axis.

These perpendicular components are quasi-random, so the spin system has found a compromise between ferromagnetism and spin glass ordering by having a novel type of magnetic structure where ordering of both types is superimposed. In a sense the spins are ferromagnetic as far as their $z$ components are concerned but spin glass for their $x,y$ components. The onset of the canted state has important consequences for the macroscopic magnetic properties of the sample. The a.c. susceptibility can be high between $T_c$ and $T_k$ but drops drastically at temperatures below $T_k$ because the canting induces a blocking of the domain wall movements.

## 5. Random Anisotropy

Local magnetic moments are influenced not only by the exchange interactions with their neighbors but also by local effective crystal fields if their magnetism has an orbital component. In a perfect lattice there are already global anisotropies due to local crystal fields with the point symmetry of the lattice site (for crystal field and anisotropy see *Magnetism in Solids: General Introduction*, *Localized 4f and 5f Moments: Magnetism*). For instance, in a hexagonal site a local moment will generally prefer to align either parallel or antiparallel to the hexagonal axis, while in a cubic site there are higher-order anisotropy terms which favor specific crystal axes, for instance $\langle 111 \rangle$. If the crystal is made up of a random alloy of atoms A and B, individual atoms will have different local environments depending on how many of each type of neighbors it has and what neighbor sites they occupy. Atoms A and B have different effective charges, so each magnetic lattice site will have a local low-symmetry crystal field in addition to the regular crystal field arising from the crystal structure.

The orientation and strength of this local crystal field depends on the exact local environment created by the neighboring atoms; this situation is referred to as "random anisotropy." A given atomic moment can prefer to align along one space direction while another atom prefers a different direction. These anisotropy terms can be strong or weak, depending mainly on the type of magnetic atom as well as on the degree of disorder of the environment. Atoms such as Gd or Mn which have very small orbital moments are hardly influenced by the crystal fields, while other rare-earth atoms with strong orbital magnetism may be strongly affected in the same system. For a ferromagnetic alloy in presence of these random anisotropies, the local magnetic moments will be submitted to contradictory influences—the exchange interactions with the neighbors will tend to align the moments all the same way while the random anisotropies will try to force each moment to remain pointed along its local anisotropy axis.

Extreme cases are provided by amorphous alloys of rare earths. Because of the surrounding amorphous structure, rare-earth environments have very low symmetry. To a good approximation each rare-earth atom is submitted to a strong axial crystal field with the directions of the axes varying randomly from site to site. (The fact that the effective local crystal field is axial rather than planar can be shown to be a consequence of the high spins of the rare earths). When the exchange interactions between the magnetic sites are ferromagnetic, the moments freeze below an ordering temperature to form a "speromagnetic" structure: instead of all moments being aligned parallel, the moment directions fan out over a hemisphere (see *Amorphous and Nanocrystalline Materials*).

## 6. Random Fields

Model systems have been studied where each site is submitted to a random local magnetic field instead of a random anisotropy. A random local field does not have the same effect as a random axial anisotropy. With the latter the local moment has two equally favorable low-energy configurations, along the axis in the up or down direction. A random field favors one particular direction only. In the Random Field Ising Model (RFIM) (Imry and Ma 1975, Young 1997) random local fields of strength $+/-h$ act on each spin in an Ising ferromagnet. We know that Ising spins with ferromagnetic interactions on a two-dimensional lattice order ferromagnetically with a finite $T_c$. It can be demonstrated that for a large sample in dimension two, with ferromagnetic exchange interactions and random magnetic fields, the overall ferromagnetic order is destroyed even for weak $h$, as it is always energetically favorable for the system to break up into domains which organize themselves in such a way as to maximize the gain in energy from interaction with the field. For dimension three, ferromagnetism persists for small $h$, but is destroyed when $h/J$ passes a critical value. (It is clear that when the random field term is much stronger than the

spin–spin interaction term each spin will tend to align along its local field direction and so ferromagnetic order will be destroyed.) Extensive model calculations have been made on the dynamics of the RFIM.

At first sight it is not obvious that there is any physical system which could be considered to be of a random field nature, as it is not possible to apply external magnetic fields which change from up to down on an atomic scale. In practice a physical equivalent of the model is provided by a diluted Ising-like antiferromagnet in a uniform applied field. The canonical example is $Fe_xZn_{1-x}F_2$ (King *et al.* 1986). In the pure compound $FeF_2$ a large crystal field anisotropy means that the magnetic Fe moments have quasi-Ising character; they can point only up or down in the crystal field direction and the ordering is antiferromagnetic. When the system is diluted by the nonmagnetic Zn, in zero field its properties stay very much the same. However, when a uniform magnetic field is applied along the crystal field axis, because of the distribution of local exchange strengths, this leads physically to a situation which can be mapped precisely on to that of a ferromagnet in a random field. The critical behavior has been very carefully studied by a variety of techniques to check the RFIM predictions. As in spin glasses the critical dynamics at the RFIM are extremely slow, and in the ordered state are governed by pinning from the random field fluctuations or by vacancies.

## 7. *Disorder in Ferromagnets and Hard Magnetism*

In the previous sections the discussion has centered on the effects of very strong disorder, which tends to produce new classes of ordering. Weaker disorder also has important implications for the magnetic properties of the ferromagnets that are of extreme importance in today's technologies.

In zero magnetic field it has been considered above that a ferromagnet sample will order with all its spins parallel, either up or down. This is an idealized picture as a number of ingredients have been left out. An ideal theoretician's ferromagnet has only exchange interactions between spins and geometrical effects do not play a role; for a real-life ferromagnet it is important for instance also to take into account classical dipole energy terms. Although these are many orders of magnitude weaker than the exchange terms, they are long-range and strongly influence the overall magnetization arrangements in all but nanoscopic ferromagnetic samples. For general sample geometries the minimum energy magnetic configuration has a domain structure with domains of parallel spins having domain walls separating them.

The width of the domain wall depends on the interplay between exchange terms and anisotropy or magnetostriction terms. Consider a ferromagnetic monocrystal. Because of anisotropy (and to some extent magnetostriction) there are preferential crystal directions for the domain axes. We will discuss a particularly simple case. Imagine we have a single crystal with axial symmetry (e.g., hexagonal) and with the macroscopic anisotropy favoring magnetization either parallel or antiparallel to the $z$ axis. A typical magnetic configuration could be an up domain ($+z$ orientation) and a down domain ($-z$ orientation) separated by a single domain wall perpendicular to the $z$ axis. Within the domain wall the spin directions will turn progressively from $+z$ to $-z$, swinging through some direction in the $x$,$y$ plane at the center of the wall.

The width of the domain wall will depend on the ratio of anisotropy to exchange. When anisotropy is weak, the local magnetization direction can turn gradually so as to minimize the cost in exchange energy (neighboring spins within the domain wall will not be at a large angle with respect to each other if the wall is wide). We will have very broad domain walls, many hundreds of atoms thick. On the contrary, when the anisotropy is strong, the domain wall must stay narrow; the spins must turn within a short distance so as to incur as small a cost as possible in the anisotropy energy corresponding to the spins in the center of the wall which are necessarily oriented in the $x$,$y$ plane, the unfavorable direction with respect to the anisotropy. The domain wall will be narrow, in extreme cases only a few atomic layers thick.

Now if a magnetic field is applied, the domain wall will tend to move so that the domain with its magnetization parallel to the field can grow. When the domain wall is wide, any local defects will have little effect as it is the average energy over the whole wall that counts, so the energy of the wall will depend little on its exact position. Local disorder on the atomic scale will have little influence on such a broad domain wall, as any energy terms will be averaged over the whole width of the wall. Soft magnetic alloy materials, with carefully tailored compositions chosen to minimize hysteresis, can be concentrated alloys (such as mumetal) or amorphous transition-metal ferromagnets, without the strong local disorder reducing significantly their high domain wall mobilities because it is a homogeneous disorder.

Mobility is reduced and the soft magnetic properties are adversely affected by more macroscopic forms of disorder such as dislocations, which can pin the domain wall efficiently as they influence the wall energy on a much larger spatial scale. As a consequence, structural damage (such as cold work) can spectacularly diminish the high permeability of soft magnetic materials.

However, when the wall is narrow a few defects (even very local defects such as vacancies) can have a strong influence on the wall energy. In a matrix with defects there will be optimal positions for the wall, or in other words the wall will tend to be "pinned." For a sample with wide walls that can move easily the

response to the applied field is almost reversible; the materials are magnetically soft, with low hysteresis and high permeability. On the other hand, when walls are narrow and can be easily pinned the material will have high hysteresis and a strong residual moment. These are just the characteristics required for permanent magnets, i.e., for ''hard'' magnetic materials.

The conditions of high anisotropy-to-exchange ratios and strong pinning are particularly favorable in rare-earth compounds. The rare earths (except for Gd) have exceptionally strong orbital moments, and excellent hard magnetic materials are formed by many rare-earth–transition-metal compounds, with interstitial atoms introduced so as to give extra local crystal fields and to dilate the lattice, which has the effect of increasing the ordering temperatures. Special metallurgical techniques are used to produce materials with small grains and high dislocation densities, all in order to enhance pinning. Of course for engineering applications these materials have to satisfy many other criteria as well; for example, they must have a Curie temperature that is as high possible so as to have useful magnetizations at room temperature, and they must not corrode.

## Magnetic Systems: External Pressure-induced Phenomena

Most elements having magnetic moments as free atoms lose the moment after condensation into solids; magnetism is retained only in a few rare cases. In the competition between cohesive and magnetic interactions, the first one wins. Application of high external pressure to magnetic solids leads to a further decrease in interatomic distances and generally to a depression of magnetism. However, under a sufficiently high pressure, some electrons can be removed from a filled inner atomic shell and an appearance of new magnetism can reflect a momentary state of the electronic configuration. A good example of this phenomenon is metallic ytterbium, which only becomes magnetic under high pressure, when one electron is removed from the originally filled 4*f* shell (see *Intermediate Valence Systems*).

All interactions responsible for magnetism in solids are sensitive to interatomic distances. Application of an external pressure leads to variations in these distances and therefore offers a unique possibility to study these aspects of magnetism. Experiments

performed under external pressure provide intrinsic results. These results are not contaminated by parasitic effects accompanying the chemical substitutions, which are widely used to vary the interatomic distances. The changes of magnetic moments, their arrangement, and the magnetocrystalline anisotropy induced under pressure are very informative phenomena for both applied and basic studies in solid-state physics.

## 1. Theory and Experiments

### 1.1 Thermodynamic Relations

From the phenomenological point of view, the pressure-induced changes of magnetic properties can be considered as an inverse effect to the magnetostriction (see also *Magnetoelastic Phenomena*). Considering only the isotropic effects, the basic relations can be derived from the differential of the Gibbs function:

$$\mathrm{d}G = -S\mathrm{d}T - M\mathrm{d}H + V\mathrm{d}p \qquad (1)$$

where $M$ is the saturated magnetization of sample of volume $V$, parallel to the magnetic field $H$.

The relation between the magnetostriction and the pressure changes of the magnetization

$$\mathrm{d}M/\mathrm{d}p = -\mathrm{d}V/\mathrm{d}H \qquad (2)$$

directly follows from the exact differential $\mathrm{d}G$. Considering $M(T,p) = M_0(0,p)[f(T/T_\mathrm{C})]$, the pressure dependence of magnetization can be derived as

$$\mathrm{dln}M/\mathrm{d}p = \frac{[\mathrm{dln}M_0/\mathrm{d}p - T(\mathrm{dln}M/\mathrm{d}T)(\mathrm{dln}T_\mathrm{C}/\mathrm{d}p)]}{[1 + 3(\alpha/\kappa)(\mathrm{dln}T_\mathrm{C}/\mathrm{d}p)]} \qquad (3)$$

where $\alpha$ is the linear thermal expansion coefficient, $\kappa$ is compressibility and $T_\mathrm{C}$ is the Curie temperature. Using $\mathrm{dln}V = -\kappa\mathrm{d}p$ and the magnetic Grüneisen coefficient $\Gamma = \mathrm{dln}T_\mathrm{C}/\mathrm{dln}V$, the critical pressure $P_\mathrm{C}$ for the disappearance of the magnetic state in solids is given by the simple relation

$$P_\mathrm{C} \approx -T_\mathrm{C}(\mathrm{d}T_\mathrm{C}/\mathrm{d}p)^{-1} = (\kappa\Gamma)^{-1} \qquad (4)$$

To estimate the compressibility in the magnetically ordered state, the paramagnetic compressibility $\kappa$, as a material property connecting the theory and the experiment, has to be modified by a magnetic contribution $\kappa_\mathrm{m}$ depending on spontaneous magnetostriction $\omega_\mathrm{S}$:

$$\kappa_\mathrm{f} = \kappa + \kappa_\mathrm{m} \approx \kappa + \omega_\mathrm{S}/P_\mathrm{C} = \kappa(1 + \omega_\mathrm{S}\Gamma) \qquad (5)$$

Nonlinear effects can indeed be expected under conditions critical for the existence of magnetism where the simple linear approximations will not be valid.

### 1.2 Theoretical Models

The theoretical treatment of pressure effects on magnetic properties of solids has been performed within models of both localized and band magnetism (see also *Localized 4f and 5f Moments: Magnetism* and *Itinerant Electron Systems: Magnetism (Ferromagnetism)*).

The systems with localized magnetic moments are very stable and almost insensitive to a compression up to pressures that are capable of changing the electron occupation of the nonfilled inner atomic shells (e.g., in thulium) or of delocalizing the magnetic electrons (e.g., in cerium). Where the localized electrons occupy sharp atomic energy levels, the atomic spin moments $S$ are well defined and their interaction has been successfully described by the molecular field model with the Heisenberg exchange interaction. In the framework of this model, the Curie or Néel temperatures $T_\mathrm{C}$, $T_\mathrm{N}$, respectively, of many simple ferro-, ferri-, or antiferro-spin arrangements in solids have been explained as a function of the moment and the exchange interaction integral $J$, where $|J| = 3kT_{\mathrm{C,N}}/2zS(S+1)$, $k$ is the Boltzmann constant and $z$ is the coordination number, i.e., the number of nearest neighbors (see also *Magnetism in Solids: General Introduction*). Pressure-induced changes of $T_\mathrm{C}$ or $T_\mathrm{N}$ are mainly a result of the pressure effect on the exchange interaction integral $J$. A simple relation can be derived for this class of magnetic solids:

$$\mathrm{dln}J/\mathrm{dln}V = \mathrm{dln}T_{\mathrm{C,N}}/\mathrm{dln}V = \Gamma \qquad (6)$$

Nonintegral values of the atomic moments characterize a magnetic state in metallic systems with itinerant electrons. These partially delocalized electrons participate on magnetic as well as on transport—electric and thermal—properties of metals. The effective electron–electron interaction $J_\mathrm{f}$ and the density of states on the Fermi level $N(E_\mathrm{F})$ play a dominant role in the magnetism of itinerant electrons. Both, $J_\mathrm{f}$ and $N(E_\mathrm{F})$, are very sensitive to interatomic distances. In general, a decrease in distances between atoms in solids leads to an increase of both the electron interactions and the width $W$ of the electron energy band. However, the effects of an increase in $J_\mathrm{f}$ and a decrease in $N(E_\mathrm{F}) \sim 1/W$ under pressure can compensate each other in the Stoner factor $S_\mathrm{f} = [1 - J_\mathrm{f}N(E_\mathrm{F})]^{-1}$; this factor is crucial for the appearance of a magnetic state. Pressure derivatives of both $J_\mathrm{f}$ and $N(E_\mathrm{F})$ are strongly affected by many factors: by the crystal lattice symmetry and the coordination number or by the short-range order of atoms (namely in the case of amorphous metals and disordered alloys). In this respect, a variety of pressure effects on the itinerant electron magnets may be expected.

The models of band (itinerant electron) magnetism enable pressure-induced changes of $T_\mathrm{C}$ to be derived

in a form suitable for further characterization of the itinerant electron magnets. When $T_C$ is basically determined by the Stoner relation, then

$$T_C^2 = T_F^2[J_f N(E_F) - 1] \tag{7}$$

where $T_F$ is the degeneracy temperature (usually $T_F \gg T_C$) which depends on a fine structure of the single particle density of states $N(E)$ curve. Taking into account effects of electron correlation, the effective electron interaction $J_f$ in transition metals with a narrow energy d-band can be expressed by the relation

$$J_f = U/(1 - U/\gamma W) \tag{8}$$

where $U$ is the intra-atomic Coulomb energy of d-electrons and $\gamma$ is a constant (Kanamori 1963). Using the relations $d\ln W/d\ln V = -\lambda$ and $d\ln J_f/d\ln V = -\lambda(J_f/\gamma W) = -\lambda R$, the volume (or pressure) derivative of Eqn. (7) raises the possibility of two limiting cases of pressure dependence of $T_C$ in the transition-metal ferromagnets (Wohlfarth 1981). In the "strong itinerant ferromagnets" the effective electron interaction $J_f$ is comparable with the band width, $J_f \to \gamma W$, $R \to 1$, and $T_C$ increases with pressure. The parameter $dT_C/dp$ is proportional to

$$dT_C/dp \sim \lambda\kappa T_C \text{ and } \Gamma \sim -\lambda \tag{9}$$

The linear relation between $dT_C/dp$ and $T_C$ has also been derived on the basis of detailed theoretical calculations for crystalline NiCu alloys (Lang and Ehrenreich 1968). In the "very weak itinerant ferromagnets" with $J_f \ll \gamma W$, $R$ goes to zero and the pronounced decrease of $T_C$ with pressure is described by the well known Wohlfarth relation

$$dT_C/dp \sim -A_w/T_C \text{ and } \Gamma \sim +\lambda S_f \tag{10}$$

where $A_w$ is the Wohlfarth constant proportional to $+\lambda\kappa T_F^2$.

Calculations of the *s–d* interaction in transition metals are able to describe the volume dependence of the *d*-band width as $W \sim R^{-5}$ which leads to $\lambda = 5/3$ (Heine 1967). The pressure (volume) dependence of the band width $W$ given by the parameter $\lambda$ controls all the pressure-induced changes of the magnetic characteristics of the transition metal ferromagnets in the theoretical concept, where only single-particle excitations have been taken into consideration.

Since the late 1980s the band calculations based on the local spin density approximation (LSDA) (see *Density Functional Theory: Magnetism*) have revealed the instabilities of the transition-metal moments in the volume instability ranges (Moruzzi and Marcus 1988). The theoretically predicted existence of two ferromagnetic states, very close in energy, for iron in the f.c.c. crystal structure, and the verification of the Fe-moment stability in the more open b.c.c. crystal structure, explains the anomalous magnetovolume effects in Invar alloys (f.c.c.) as well as the almost total insensitivity of the b.c.c.-Fe to external pressures (see *Invar Materials: Phenomena* and references therein).

### *1.3 High-pressure Techniques*

Hydrostatic pressure enables the variation of interatomic distances in compressed matter to an extent similar to that achieved in the more widely used chemical substitution, but it retains the composition, purity, and shape of the sample. The pressure-induced volume and energy changes are dependent on the compressibility of a particular sample. Hence, the high pressures comparable in magnitude with the bulk modulus should be applied to obtain a sufficient effect. Routinely, volume changes of up to $\sim$1–5% per 1 GPa can be produced by hydrostatic pressure. (The pressure unit $Pa = Nm^{-2}$ is too small for this purpose, so the unit $GPa = 10^9$ Pa ($\sim$10000 atm) will be used in this article.)

An example of the hydrostatic high pressure cell used for measurements of magnetization is presented in Fig. 1. The cell is filled by a liquid pressure medium (mixture of oils, Fluorinert) which transmits pressure on to a sample (fixed on the plug) without shear stresses even during cooling of the cell down to liquid helium temperature. The pressure inside the cell can be increased easily up to 1.5GPa by a piston pushed inside by a clamping bolt. The miniature pressure cell is made from nonmagnetic CuBe bronze and can be used inside a standard SQUID magnetometer. The applied pressure can be measured inside the cell using the known pressure-induced shift of the critical temperature of the transition to the superconducting state of lead (Garfinkel and Mapother 1961).

Hydrostatic CuBe cells of larger dimensions (with an inner diameter of up to 12 mm) are widely used for measurements of magnetoresistance, magnetostriction, or magneto-optical properties of solids under

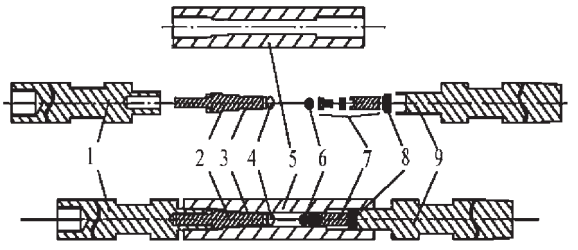

***Figure 1***
High pressure CuBe microcell for magnetic studies in a SQUID magnetometer, with inner diameter 2.5mm: **1, 9**—upper and lower pressure clamping bolts; **2**—plug; **3**—sealing; **4**—sample; **5**—pressure cell; **6**—Pb pressure sensor; **7**—piston; **8**—piston backup.

pressure up to 2.5 GPa in a wide temperature range from 4 K up to 400 K. In the vicinity of room temperature, accurate measurements of the pressures applied inside the cells are usually performed by Manganin pressure sensors (Bridgman 1958). A high-pressure diamond anvil cell (DAC) has been modified for magnetization and magneto-optical measurements in high and steady as well as in pulsed magnetic fields (Yamamoto *et al*. 1991). Extremely high pressures of up to 100 GPa can be reached using the DAC; however, the sample space in the DAC is extremely small, up to $10^{-3}$ mm$^3$. Detailed information on the high-pressure techniques and methods of measurements of material properties under pressure can be found in Bridgman (1958), Sherman and Stadtmuller (1987), or Eremets (1996).

## 2. *Magnetic Properties Under Pressure*

Extended experimental data on magnetic properties of solids under pressure are presented in several reviews (Bloch and Pavlovic 1969, Schilling 1981, Wohlfarth 1981). In the tables and figures below, typical and characteristic examples of the pressure changes of the magnetization, magnetocrystalline anisotropy, and temperatures of the magnetic transitions are presented.

### 2.1 *Magnetic Moment*

Direct measurements of the effect of high pressure on atomic moments $\mu$ have been very rare. The magnetostriction experiments and Eqns. (2) and (3) have been frequently used to determine the pressure parameter $d\ln\mu_0/dp$ at low temperatures. Using SQUID magnetometers and the pressure cells mentioned above, accurate values of the saturation magnetization $M_0$ at low temperature and under high pressure can be obtained (see, e.g., Mikulina *et al*. 1999). The data presented in Table 1 provide evidence of general trends.

In accordance with the discussion above, all three ferromagnetic transition elements iron, cobalt, and nickel with b.c.c., h.c.p., and f.c.c. crystal structures, respectively, exhibit a very stable magnetic moment with respect to the atomic volume. This is in good agreement with *ab initio* calculations (Moruzzi and Marcus 1988, Entel *et al*. 2000). On the other hand, a very pronounced decrease in the Fe-moment was observed under pressure in the Invar alloys $Fe_xNi_{1-x}$ ($0.7 \geqslant x \geqslant 0.6$) with f.c.c. crystal structure (see Table 1). This effect belongs to the Invar anomalies together with zero thermal expansion and the large spontaneous magnetostriction below $T_C$. This resolving effect of the crystal structure on the pressure-induced decrease of the Fe-moment correlates well with the theoretically described moment–volume instabilities in the iron-based alloys with f.c.c. crystal structure (for more details see *Invar Materials: Phenomena*).

The Invar-like magnetovolume phenomena were also observed in iron-rich RE–Fe intermetallics of the types $RE_2Fe_{17}$ and $REFe_{11}TM$, where RE is yttrium or a rare earth element and TM is a transition metal, e.g., titanium, vanadium, or molybdenum (Givord and Lemaire 1974, Buschow 1988). A much higher value of the pressure parameter $d\ln\mu_0/dp$ in $Y_2Fe_{17}$ than in $YFe_{11}Ti$ was predicted theoretically (Sabiryanov and Jaswal 1998) and observed experimentally (Mikulina *et al*. 1999) (see Table 1). The $Y_2Fe_{17}$ compound has a rhombohedral crystal structure, but the nearest neighbors of the iron atoms (and the calculated density of state curve) exhibit features of f.c.c.-iron. Thus, not only global but also local properties play a role in the magnetovolume effects. The pressure-induced decreases of Fe-moment in the individual $RE_2Fe_{17}$ intermetallics at 5 K differ from each other depending on the RE elements (see Fig. 2). However, a tendency of the parameter $d\ln M/dp$ to diverge in the vicinity of $T_C$ due to the relation in

***Table 1***

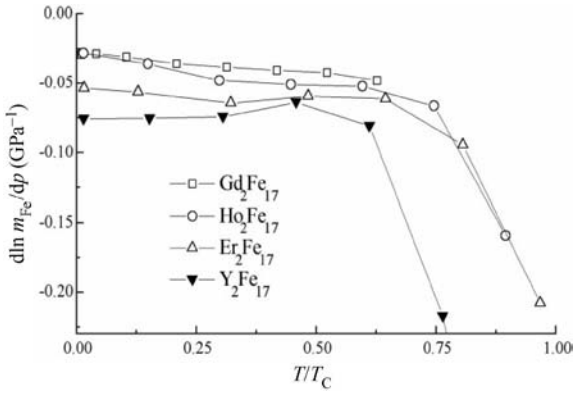

***Figure 2***
Temperature dependence of the pressure-induced changes of the Fe-moment $m_{Fe}$ in the $R_2Fe_{17}$ intermetallic compounds.

Eqn. (3) smoothes down these differences with increasing temperature (see Fig. 2) (Kamarad *et al.* 1999).

The localized moments in rare-earth elements have been observed to be pressure-independent. The pressure effect on the contribution of 5*d*-electrons to the RE-moment can be considered to be responsible for the very low values of $d\ln\mu_0/dp$ in gadolinium and dysprosium, presented in Table 1 (Bloch and Pavlovic 1969). The 5*f* electrons responsible for magnetism in the actinide metals are localized in the heavy actinide elements only. Their further delocalization can be enhanced by the effect of relatively moderate external pressures. Not only the magnetic but also the structural state of actinide metals and compounds are thus strongly affected by pressure (see Sechovsky and Havela 1988 and references therein). As an example, a very pronounced decrease in the U-moment in $UGe_2$ and $UGa_2$ intermetallics is presented in Table 1. Both the 5*f*–5*f* overlap and the 5*f*–ligand hybridization can be enhanced by external pressure. This leads to a very complex response in the magnetic properties of the uranium-based intermetallics—see the large initial decrease of the U-moment in $UGa_2$ accompanied by an increase in $T_C$ under pressure (Franse *et al.* 1985) in Table 2.

### 2.2 Magnetocrystalline Anisotropy

In magnetically ordered solids, atomic moments and the resulting magnetization $M$ are preferentially oriented into specific crystal lattice directions—easy magnetization directions (EMD)—due to magnetocrystalline anisotropy (see also *Localized 4f and 5f Moments: Magnetism*). Changes in the orientation of $M$ relative to the EMD by an external magnetic field are connected with relevant changes in the magnetocrystalline anisotropy energy. This energy $G_A$ can be expressed in uniaxial (hexagonal or tetragonal) crystals as

$$G_A = K_1\sin^2\theta + K_2\sin^4\theta + \cdots \qquad (11)$$

where $\theta$ is the angle between $M$ and the $c$ axis and $K_1$, $K_2$, … are the magnetocrystalline anisotropy constants. The materials listed in Table 1 represent ferromagnets with both axial (EMD along the $c$-axis, $K_1 > 0$) and planar (EMD in the plane perpendicular to the $c$-axis, $K_1 < 0$) magnetocrystalline anisotropy. A decrease in $|K_1|$ under pressure was observed for both types of magnetocrystalline anisotropy (Bloch and Pavlovic 1969, Mikulina *et al.* 1999). The effect of pressure on the magnetocrystalline anisotropy constant $K_1$ in the $Y_2Fe_{17}$ and the $YFe_{11}Ti$ intermetallics ($K_1 \gg K_2$) reflects the different local nearest-neighbor environment of the iron atoms and the difference in the parameters $d\ln\mu_0/dp$ in both intermetallics (see Fig. 3).

### 2.3 Magnetic Phase Transitions

The effect of pressure on the (isotropic) exchange interaction plays a dominant role in the pressure dependence of the Curie or Néel temperatures of magnetic systems with localized magnetic moments. An increase in $J$ with pressure was derived from measurements of the Kondo effect in "single impurity systems" as rare-earth elements or manganese diluted in noble metals (Schilling 1981). The Kondo temperature $T_K$ in such systems increases under pressure with an almost constant Grüneisen coefficient $\Gamma \sim -10/3$. The values of $\Gamma$ presented in Table 2 for antiferromagnetic FeO and the ferrimagnetic garnet $Fe_5Gd_3O_{12}$ were derived using Eqn. (6). They are very close to the characteristic values of $\Gamma$ for the single impurity systems and they confirm the localized character of the magnetic moments in these materials.

The very small pressure-induced changes of $T_C$ presented in Table 2 verify the above mentioned stability of the magnetic state in pure iron, cobalt, and nickel metals in the b.c.c., h.c.p., and f.c.c. crystal structures, respectively. However, a relatively low critical pressure $P_C \sim 10$ GPa for the disappearance of magnetism can be derived, Eqn. (4), for the Fe-based alloys with the f.c.c. crystal structure or the iron-based intermetallics with the f.c.c.-like near-neighbor arrangement of atoms. The compressibility values $\kappa_{300\,K}$ in Table 2 correspond to the ferro- or ferrimagnetic compressibility $\kappa_f$ in materials with $T_C > 300$ K and, hence, they comprise the magnetic contributions, $\kappa_m$, proportional to the spontaneous magnetostriction $\omega_S$, see Eqn. (5). The enhanced values of $\kappa_f$ in the iron-based alloy and intermetallics are almost twice those in pure iron and they reflect the pronounced magnetovolume phenomena in these

***Table 2***
Curie and Néel temperatures $T_C$ and $T_N$, $\Gamma = d\ln T_{C,N}/d\ln V$, compressibility $\kappa$, and spontaneous magnetostriction $\omega_S$ of selected magnetic materials under high pressure.

materials. The relevant anomalous decrease in $T_C$ under pressure belongs to the Invar characteristics (see *Invar Materials: Phenomena*).

The high negative values of the pressure parameter $dT_C/dp$, the spontaneous magnetostriction $\omega_S$, and the compressibility $\kappa_f$ in the $Fe_{65}Ni_{35}$ and $Fe_{72}Pt_{28}$ alloys and in the $Y_2Fe_{17}$ intermetallics presented in Table 2 are typical for Invar materials.

The model of "strong itinerant ferromagnets" was successfully used to describe the experimental pressure data for nickel and for many crystalline nickel-based alloys with a low content of Cu, Cr, Fe, V, Pd, and Rh, except for the NiMn alloy. The increase of $T_C$ with pressure, i.e., the pressure parameter $dT_C/dp$, is proportional to $T_C$, as seen in Fig. 4. Using Eqn. (9) the value of $\Gamma \sim -\lambda$ is close to Heine's result $\lambda = 5/3$ (Heine 1967). The same value of $\Gamma$ was derived also for $UGa_2$. However, the very pronounced decrease in its magnetic moment under pressure is inconsistent with the discussed model.

## 3. *Concluding Remarks*

The development of high-pressure experimental techniques extends the basic thermodynamic framework to the study of pressure-induced phenomena in magnetic systems. New miniature nonmagnetic, nonmetallic pressure cells will allow experiments to be carried out on bulk single crystals under multi-extreme conditions—in very high magnetic fields (including pulsed fields up to 100 T), under high

pressure (up to 100 GPa), and at low temperatures (down to mK range).

Studies of pressure-induced phenomena in magnetic systems have become an integral part of research into magnetism. Extraordinary efforts will undoubtedly be made to find a solution to the ''traditional'' problems and systems: the *f*- and *d*-electron systems, magnetic instabilities in mixed-valence systems (see *Intermediate Valence Systems*), and properties of two-dimensional magnetic structures (see *Bulk Magnetic Materials: Low-dimensional Systems*). There has been an enormous increase in the number of reports on high-pressure research, especially in the relatively new fields of study of the heavy fermions (see *Heavy-fermion Systems*) and non-Fermi liquid systems (see *Non-Fermi Liquid Behavior: Quantum Phase Transitions*).

## Magnetic Systems: Lattice Geometry-originated Frustration

Frustration of exchange interactions occurs in many magnetic systems owing to various microscopic mechanisms:

(i) Competing long-range exchange interactions (i.e., RKKY interactions) are known to stabilize helicoidal structures in several rare earth compounds.

(ii) Any crystallographic structure containing triangles (f.c.c., triangular lattices, etc.) is frustrated in the presence of nearest-neighbor antiferromagnetic interactions; the two-dimensional kagomé lattice (Fig. 1) and its three-dimensional analogue, the pyrochlore lattice (Fig. 2), are considered as the ''most frustrated'' structures among existing materials (Liebmann 1986).

(iii) In disordered magnetic systems competition between random ferro- and antiferromagnetic interactions leads to spin-glass (SG) behavior (Mydosh 1993).

Frustration in nondisordered systems has been intensively studied and there are many indications, both theoretical and experimental, that new types of ground states may occur in these systems owing to the large ground-state degeneracy. The main purpose of this article is to give an overview of the different possibilities.

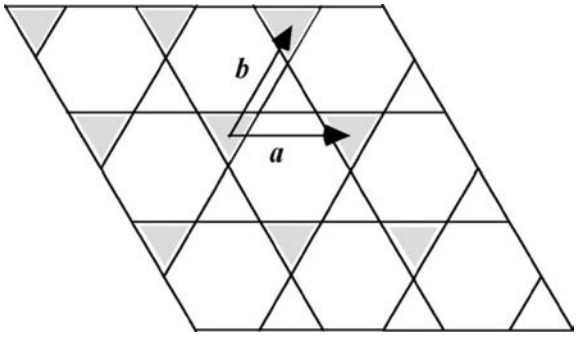

***Figure 1***
The kagomé lattice: a triangular lattice (generated by the translation vectors ***a*** and ***b***) with a triangular basis (indicated by the shaded triangles).

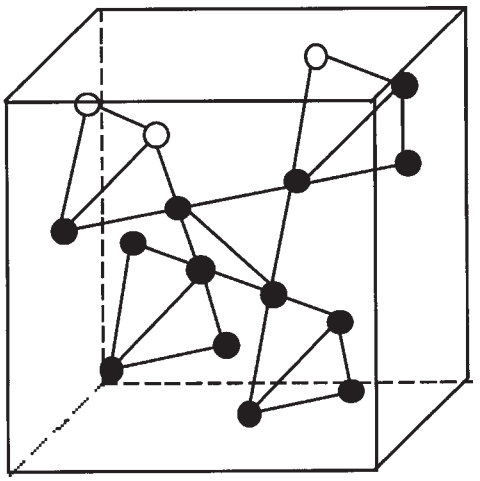

***Figure 2***
The pyrochlore lattice (f.c.c. lattice with tetrahedral basis).

In addition to the lattice geometry, the range and sign of the interactions and the number of degrees of freedom of local moments are important factors in frustrated systems. These systems are very sensitive to their microscopic characteristics: different behaviors are expected for metallic or insulating systems, as in $3d$ metallic systems where the size of magnetic moments can change, giving rise to an additional degree of freedom; other important parameters are the value of the spin ($S$) and the strength of magnetic anisotropy. For example, the triangular lattice with classical (equivalent to infinite $S$) or quantum $S=1/2$ spins is ordered, but with Ising spins it remains disordered with a finite entropy per site at $T=0$K.

Frustration can be measured for a given model by several parameters: e.g., when the entropy per site does not vanish at $T=0\,\mathrm{K}$ (which contradicts the third law of thermodynamics (Ramirez *et al.* 1999)), its value is a measure of the number of degenerate ground states; another measure is the constraint function, $F$, defined as the ratio between the ground-state energy, $E_g$, and the energy of the system if it would be possible to satisfy all pair interactions, $E_b$, i.e., $F=E_g/E_b$. For a nonfrustrated system, $F=1$, while in presence of frustration $-1<F<1$.

Many frustrated compounds order at low temperature and an empirical measure of frustration can be defined from experiments (Ramirez 1994) as the ratio of the paramagnetic Curie–Weiss temperature, $\theta_p$, which measures the strength of exchange interactions, to the ordering temperature, $T_c$ (which can be any cooperative transition temperature, e.g., Néel or SG transition): $f=|\theta_p|/T_c$. This definition is useful for classifying the frustrated compounds which exhibit any kind of transition; they all correspond to $f>1$. However, it is not appropriate to a disordered ground state. Values of $f$ larger than 100 are often observed in frustrated compounds. Clearly, a mean field approach cannot be valid for compounds with such large $f$ values.

## *1. Localized Moments Systems (Gaulin 1994, Harris and Zinkin 1996, Schiffer and Ramirez 1996, Reimers et al. 1991)*

### *1.1 Frustrated Classical Spins Systems*

The ground state of localized spin systems is usually well described by minimizing the classical exchange energy. For a Bravais lattice with one magnetic site per unit cell this energy can be written:

$$E=-\sum_{i,j} J(\vec{R}_i-\vec{R}_j)\,\vec{S}_i\,\vec{S}_j=-\sum_{q} J(\vec{q})\,\vec{S}_q\,\vec{S}_{-q} \quad (1)$$

where $J(\vec{q})$ is the Fourier transform of the exchange interactions $J(\vec{R}_i-\vec{R}_j)$. Thus the ground state is determined by the $\vec{q}$ value(s) which maximize $J(\vec{q})$. For non-Bravais lattices this procedure can be generalized in the following way. For $n$ magnetic sites per unit cell, the ground state is determined by the largest eigenvalue, $\lambda(\vec{q})$, of a $n\times n$ matrix. However, on the "fully frustrated" pyrochlore (Reimers *et al.* 1991) or kagomé (Harris *et al.* 1992) lattices, the largest eigenvalue, $\lambda(\vec{q})$, is independent of $\vec{q}$ over all the Brillouin zone. In these lattices the magnetic atoms are located on triangles (kagomé) or tetrahedrons (pyrochlore), in such a way that one site is shared by only two elementary clusters (triangles or tetrahedrons). All ground states satisfy the local constraint:

$$\left(\sum_{\text{cluster}} \vec{S}_i\right)^2=0 \quad (2)$$

for any elementary cluster. However, this constraint can be satisfied throughout the lattice without inducing any long-range magnetic order. In such a situation, the number of classical ground states increases as the number of sites, $N$.

It is important to point out that the energy landscape is quite different from that which occurs in an SG state, where the degenerate ground-state configurations are separated by energy barriers. Here, the energy landscape is flat, without any energy barrier between the different states. The thermodynamic properties of such systems are expected to be very different from both conventional ordered magnetic systems (where the ground state is nondegenerate) and SG. The absence of ordering in frustrated lattices is also different from that found in one- and two-dimensional systems, where magnetic correlations develop below the mean field transition temperature but no ordering occurs (or only at $T=0\,\mathrm{K}$) due to entropy effects.

Finally, in some lattices the highest eigenvalue is independent of $\vec{q}$ only along some lines of the Brillouin zone called "degeneration lines." In this case the number of ground states increases only as $N^{1/3}$ and fluctuations beyond mean field solution may induce a phase transition; it has been proposed that such a scenario applies for $\beta$-oxygen.

### *1.2 Possible Ground States in Fully Frustrated Systems*

In the mean field approximation, even at $T=0\,\mathrm{K}$, no conventional magnetic long-range order occurs in fully frustrated lattices. Several mechanisms have been proposed which could remove the degeneracy:

- The fluctuations around a particular mean field state contribute to the free energy beyond the mean field approximation. This contribution may change the energy landscape by introducing "valleys." In this case, one ordered state will be selected among all the degenerate states. This phenomenon, called "order by disorder," may occur owing to thermal disorder or to quantum zero point fluctuations or in the presence of a small concentration of impurities.
- Any additional interaction, such as anisotropy, deformations, and dipolar or further-neighbor exchange (Harris *et al*. 1992, Chandra and Coleman 1995), can play an important role in these systems and induce ordering, even if they are much smaller in magnitude than exchange. For quantum spins, more exotic ground states have been proposed, such as dimer, resonant valence bond, nematic, or chiral ordering (Chandra and Coleman 1995). No evidence for such ground states has been found.

Probably, the ground state is a spin-liquid (SL) state, i.e., a singlet state with short-range correlations and a nonzero spin gap. However, the excitation spectrum of these SL states would be different from nonfrustrated ones (e.g., one-dimensional integer spin chains). In the present case, the singlet–singlet excitations form a continuum starting at zero energy, while in the integer spin chains, the lowest energy excitations have a nonzero gap corresponding to singlet–triplet transitions.

### *1.3 Examples of Fully Frustrated Compounds*

A few kagomé compounds have been studied:

- In $SrCr_{8-x}Ga_{4+x}O_{19}$ (SCGO) (Schiffer and Ramirez 1996), the $Cr^{3+}$ ions ($S=3/2$) are located both on kagomé planes and on interplane triangular layers. This compound does not order despite its high negative paramagnetic Curie–Weiss temperature, $\theta_p \approx -500\,\mathrm{K}$. It exhibits an SG behavior below $T_f = 5\,\mathrm{K}$, which could be due to a partial covering of the kagomé planes.
- The chromium and iron jarosites (with $S=3/2$ and 5/2, respectively) are also two-dimensional kagomé compounds (Wills *et al*. 1998). Both systems order (antiferromagnetic or SG state) at temperatures quite low compared with the Curie–Weiss temperatures, $T_N/\theta_p \approx 0.03$ for chromium and 0.08 for iron jarosites. Moreover, below $T_N$ magnetization is strongly reduced by fluctuations.
- The only example of an integer spin ($S=1$) kagomé lattice is the organic antiferromagnet *m*-MPYNN.$BF_4$, which might have an SL ground state (Wada *et al*. 1997).

There are many more compounds exhibiting the three-dimensional pyrochlore structure: the oxides with general formula $A_2B_2O_7$; the spinels $AB_2O_4$ and $A_2B_2O_4$, where both A and B can be magnetic (rare earth or transition metal) ions; and the fluorides $ABCF_6$. Among these compounds, some exhibit noncollinear magnetic ordering which results from the competition between frustrated interactions and anisotropy. Examples are $FeF_3$ (Ferey *et al*. 1986), $\lambda$-$MnO_2$, $Nd_2Mo_2O_7$, and $Mn_2Sb_2O_7$ (Gaulin 1994), but many of them remain nonmagnetic and have unconventional low-temperature magnetic properties:

- SG-like behavior is observed in many pyrochlores in the absence of any structural disorder (Schiffer and Ramirez 1996).
- Strong, short-range magnetic correlations, as expected in an SL system, are observed in $CsCrNiF_6$ (Harris and Zinkin 1996) and $Li_2Mn_2O_4$.
- A "spin-ice" ground state has been proposed for $Ho_2Ti_2O_7$ and $Dy_2Ti_2O_7$ (Ramirez *et al*. 1999), where the exchange interactions are ferromagnetic but the presence of strong local Ising-like anisotropy leads to a disordered ground state analogous to common water ice.

Finally, the gadolinium gallium garnet $Gd_3Ga_5O_{12}$ (GGG) (Schiffer and Ramirez 1996) belongs to the same class of compounds: the $Gd^{3+}$ ions are located on two interpenetrating corner-sharing triangular

sublattices. It exhibits a complex field-dependent magnetic phase diagram, but there are indications that the zero-field ground state is a SL one (Petrenko *et al*. 1998). Dipolar interactions may also play a role in this compound.

Many of these compounds exhibit an SG-like behavior observed in magnetic response, but specific heat, which probes the low-energy spectrum, is different from normal SG ($T^2$ behavior instead of $T$). It is not yet clear whether this behavior is intrinsic to SL states or if it is due to a very small (even undetectable) amount of disorder.

## 2. *Metallic Compounds*

### *2.1 Mixed Magnetic Phases (Ballou 1998, Yoshimura* et al. *1986)*

In itinerant electron antiferromagnets, the amplitude of the magnetic moments can change with respect to external parameters (pressure, temperature, magnetic field, etc.) or to local environment (coordination, interatomic distance, etc.). This additional degree of freedom may lead to nontrivial magnetic phases.

Close to a magnetic–nonmagnetic (M–NM) instability, such amplitude variations occur more easily: frustration can then be lowered or even completely suppressed if some of the magnetic moments vanish. Such mixed phases, where magnetic and nonmagnetic sites coexist, have been observed in several compounds:

- The $RMn_2$ compounds crystallize in either the C15 cubic (for R = Y, Sm, Gd, Tb, Dy, or Ho) or the C14 hexagonal Laves phase, the first one being similar to the pyrochlore structure (shown in Fig. 2). The manganese magnetic moment depends strongly on the interatomic Mn–Mn distance. This allows stabilization of mixed magnetic phases in $DyMn_2$ (Yoshimura *et al*. 1986), $TbMn_2$ (Ballou *et al*. 1992), and $ThMn_2$, with the concentration of magnetic manganese atoms equal to 1/4 (dysprosium and terbium compounds) and 3/4 (hexagonal thorium compound). The stability of these mixed phases as well as their behavior with temperature or applied fields are well understood in the framework of an itinerant frustrated model close to an M–NM instability (see also *Alloys of 4f (R) and 3d Elements (T): Magnetism*).
- Mixed structures are also observed in a few cerium and uranium compounds. In CeSb (Rossat-Mignod *et al*. 1983) a large number of magnetic phases have been observed and several of them can be described by a stacking of ferromagnetic and nonmagnetic cerium planes. In the triangular $UNi_4B$ (Mentink *et al*. 1994) or kagomé-like CePdAl (Ballou 1998) compounds, the magnetic atoms form chains, one-third of which are nonmagnetic. These compounds are also close to a M–NM instability induced by the Kondo effect. Their observed magnetic structures can be well explained by a frustrated Kondo lattice model with intersite RKKY exchange interactions of the same order as the Kondo condensation energy $T_K$.
- A different kind of mixed phase occurs when the instability of the local moments is due to the crystal field scheme in non-Kramers ions. This occurs in $TbRu_2Ge_2$ owing to the small energy difference between the nonmagnetic singlet ground state and the magnetic excited states (Lacroix *et al*. 1998).

All these mixed phases can be modeled within the same pseudo-moment Hamiltonian which includes, in addition to the exchange interaction between the magnetic sites, the energy, $\Delta$, necessary for stabilizing a magnetic moment. In $TbRu_2Ge_2$, $\Delta$ is related to crystal field splitting; in the Kondo compounds, $\Delta \approx T_K$, while in the manganese Laves phase, $\Delta$ is the stabilization energy of a magnetic moment in an itinerant 3*d* band. Mixed structures are observed when $\Delta$ is of the order of the exchange.

### *2.2 Itinerant Spin Liquids*

In some itinerant systems the absence of magnetic ordering can be attributed to frustration, as in localized frustrated systems, rather than to the instability of band magnetism. This is the case for the cubic Laves phase compound $Y_{0.97}Sc_{0.03}Mn_2$, which remains paramagnetic at low temperature, and shows strong spin fluctuations with short-range magnetic correlations of the order of the interatomic distance. The observed spectrum can be described completely by a localized spin model on a pyrochlore lattice (Canals and Lacroix 1998) indicating that it is the crystal structure that plays the main role in the absence of ordering. Moreover, the signature of a singlet ground state has been observed directly in neutron experiments. The vanishing of the signal in the first Brillouin zone implies that:

$$\chi(\vec{q} = 0) \propto \left( \sum_i \vec{S}_i \right)^2 = 0 \qquad (3)$$

The same behavior occurs in $\beta$-manganese, which has a complicated frustrated crystallographic structure formed by corner-sharing triangles and remains paramagnetic at low temperatures (Nakamura *et al*. 1997).

These frustrated metallic systems exhibit large specific heat coefficients, $\gamma$ ($70\,mJK^{-2}mol^{-1}$ for $\beta$-manganese, $180\,mJK^{-2}mol^{-1}$ for $Y_{0.97}Sc_{0.03}Mn_2$), and they are considered as "3*d* heavy fermions." Much larger values have been measured in the spinel compound $LiV_2O_4$ where $\gamma = 420\,mJK^{-2}mol^{-1}$ (Kondo *et al*. 1997). However, unlike the usual 4*f* or 5*f* heavy fermion systems, the Kondo effect is not observed in these 3*d* materials. Thus, in the absence of any Kondo effect, such large $\gamma$ values indicate that the

density of low-energy excitations is large in these itinerant SL states (see *Heavy-fermion Systems*).

### 3. Summary

Strongly frustrated antiferromagnets may exhibit various unconventional ground states. An SL state can be stabilized in both localized and itinerant systems with frustrated crystallographic structure:

- The understanding of localized SL states has increased considerably, but several aspects need further study, especially the low-temperature dynamics and the difference with conventional SG states. It has been proposed that these systems belong to a new class of ''topological spin glasses.''
- For metallic SL states, static properties can be described satisfactorily within a localized model, but the dynamics are certainly different (''3*d* heavy fermions''). Also, in various materials close to a magnetic instability, mixed magnetic structures are stabilized.

## Magnetic Systems: Specific Heat

Historically, specific heat was defined as the heat ($\delta Q$) required to rise the temperature ($T$) of a unit of mass of a substance in a unit of degree, $C_y = \delta Q/\delta T$, where $y$ indicates the control parameters kept constant. This elementary definition worked hand in hand with the development of the thermodynamics because it is directly related to those parameters to be taken into account to describe the state of any physical system, i.e., its energy and temperature.

From the First Law, the heat absorbed by a system is distributed as, $\delta Q = \mathrm{d}U + \delta W$, where $U$ is the internal energy and $W$ the work done by the eventual expansion (compression), or by the change in the magnetization ($M$) under magnetic field ($h$). If only the thermal component of the system is taken into account (i.e., $\mathrm{d}V = 0$), the simple expression $C_v = \mathrm{d}U/\mathrm{d}T$ is obtained. However, the measurements are normally performed under vacuum (adiabatic) conditions, that implies at constant pressure ($C_p$). Therefore, $C_p = \mathrm{d}H/\mathrm{d}T$ is actually measured, where $H = U + pV$ is the enthalpy of the system, which includes the expansion of the system during the heating process. The difference between $C_p$ and $C_v$ is given by $C_p - C_v = TV\alpha^2/\kappa$, where $\alpha$ is the thermal expansion and $\kappa$ the compressibility (e.g., see Goodstein 1985). Provided that $\alpha$ and $\kappa$ are nearly temperature independent, this difference becomes negligible at low temperatures. But such is not strictly the case around phase transitions or when $T$ is comparable with the characteristic energy of the system. The same precautions have to be taken with other relations, like the Grüneissen parameter, $\Gamma \sim \kappa\alpha/C_v$, when $\kappa$ and/or $\alpha$ have significant $T$ dependence and consequently $C_v(T)$ differs from the measured $C_p(T)$.

The Second Law refers to the progressive access to the excited states with the increase of temperature. The measure of that process is evaluated by the entropy, $S(T)$, which is related to $\delta Q$ through, $\mathrm{d}S = \delta Q/T$. Then, specific heat can be expressed as, $C_p = T(\mathrm{d}S/\mathrm{d}T)_p$, and, therefore, the experimental knowledge of $C_p(T)$ provides a direct measure of the entropy evolution of the system, $S(T) = \int C_p/T \, \mathrm{d}T$, i.e., how the system accesses to its thermally excited levels. From this point of view, the specific heat works like a thermal spectrometer, where the excitation is given by $\delta Q$ and the response by $\delta T$. One of the most important aspects of the knowledge of $S(T)$ is that it provides information on the first term of the free energy variation ($\mathrm{d}G = -S\mathrm{d}T + V\mathrm{d}p - M\mathrm{d}h$). This is the reason why the access to the evolution of $C_p/T(T)$ constitutes one of the basic tools for the characterization of any new system.

## 1. Contributions to the Specific Heat

Since all allowed states of a system are equally likely, and each component contributes with its own entropy to the total value (i.e., $S(T) = \Sigma_i S_i(T)$), the specific heat provides simultaneous information on the full spectrum of excitations. Then from $C_p/T = \mathrm{d}S/\mathrm{d}T$ it is possible to compute the contribution of all the components of the system. To extract the information related to each of them requires finding at which range of temperature a specific contribution becomes dominant. According to their respective temperature range of importance, the following typical contributions can be enumerated: (i) nuclear for $T < 0.5\,\mathrm{K}$ which are usually recognized by a $C_\mathrm{n} \propto T^{-2}$ dependence, (ii) conduction electrons within the $0.5\,\mathrm{K} < T < 4\,\mathrm{K}$ range, (iii) when present, heavy fermion (*HF*) quasi-particles dominate the scene up to about 7 K, (iv) phonons for about $T > \theta_\mathrm{D}/30$, where $\theta_\mathrm{D}$ is the Debye temperature, (v) magnons, which are related to some magnetic transition and/or anomalies, are dominant up to about 20 K, and (vi) Schottky anomalies are well observed when their respective characteristic energies (or associated gaps, $\Delta$) are about $k_\mathrm{B}\Delta < 20\,\mathrm{K}$. Each of these contributions is related to different statistics, which describe the thermal population of the excited states. For example, Maxwell–Boltzman statistics applies to Schottky-type anomalies (like those originated by nuclear or crystalline electric field (CF) splitting), Fermi–Dirac statistics to the electrons in the band, and Bose–Einstein statistics to phonons, magnons, and other quasi-particles. Since many of these contributions are extensively treated in the literature (e.g., see Gopal 1966) only recent developments related to magnetic properties will be considered in this article.

Conduction electrons can be described as free electrons and their linear contribution to the specific heat, $C_\mathrm{el} = \gamma T$, is directly proportional to the density of states at the Fermi level, $N(E_\mathrm{f})$ (e.g., see Goodstein 1985). The factor $\gamma \propto N(E_\mathrm{f})$ is the Sommerfeld coefficient, which is constant within the experimental range of temperature. Interaction of band electrons with some quasi-particles (namely phonons, $\lambda_\mathrm{p}$ or magnons, $\lambda_\mathrm{m}$) dresses the measured $\gamma$ value, which is then corrected as, $\gamma = \gamma_o\,(1 + \lambda_\mathrm{p} + \lambda_\mathrm{m})$. Experimental values of $\gamma$ are extracted from a $C_p/T$ versus $T^2$ representation, as shown in Fig. 1, with $\gamma$ being the value at $T \rightarrow 0$. In pure metals, it ranges between $0.19\,\mathrm{mJ\,mol^{-1}K^{-2}}$ and $10\,\mathrm{mJ\,mol^{-1}K^{-2}}$ for beryllium and yttrium, respectively (Gopal 1966). These values are strongly enhanced by electron–electron interactions or magnetic correlations, as it occurs in intermediate valent compounds with $10 < \gamma < 80\,\mathrm{mJ\ mol^{-1}K^{-2}}$ (e.g., $CeIr_2$, Sereni 1991) or the system showing spin fluctuations with $50 < \gamma < 200\,\mathrm{mJmol^{-1}K^{-2}}$ (e.g., $UAl_2$, Stewart 1984). A further increase of this electronic term is observed in heavy fermions, where the $\gamma$ term becomes up to three orders of magnitude larger than that of a simple metal (e.g., $CeCu_6$, Löhneysen 1995).

Phonon contribution, $C_\mathrm{ph}$, is extracted from the slope of a $C_p/T$ versus $T^2$ representation (see Fig. 1) because $C_p/T = C_\mathrm{el}/T + C_\mathrm{ph}/T = \gamma + \beta T^2$, with $\beta = 12\pi^4 k_\mathrm{B} N/5\theta_\mathrm{D}^3$. This formula is valid up to $T = \theta_\mathrm{D}/24$. Some misuse of $\beta \propto N/\theta_\mathrm{D}^3$ causes an incorrect evaluation of $\theta_\mathrm{D}$ as it is strictly valid for pure elements or $N$ atoms of equal mass. This occurs, for example, when it is applied to systems involving components with different masses, where false variation of $\theta_\mathrm{D}(T)$ is extracted. A similar situation appears in solids containing a variable number of interstitial atoms without a concomitant change in the measured $\beta$. If it were included in $N$ a false variation of $\theta_\mathrm{D}(x)$ would be obtained.

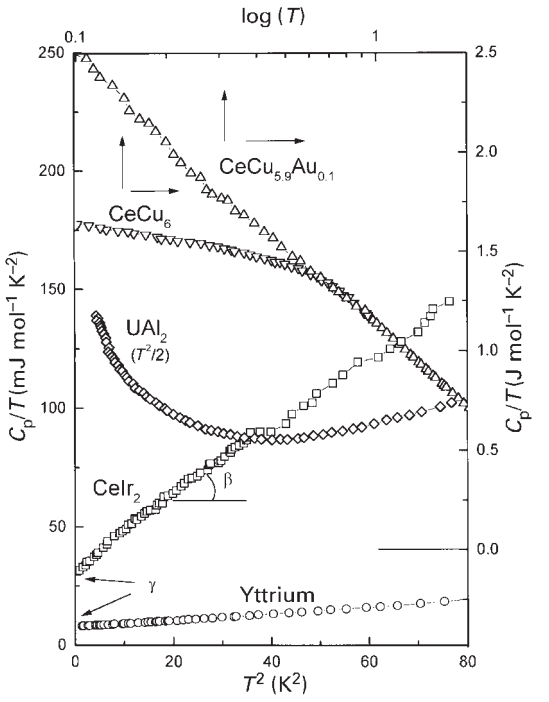

***Figure 1***
Electronic ($\gamma$) and phonon ($\beta$) contributions in a $C_p/T = \gamma + \beta T^2$ representation for different systems.

Magnetic contributions, $C_m$, include a large variety of contributions to $C_p(T)$, which are evaluated as $C_m = C_p - (C_{el} + C_{ph})$. In first glance, contributions related to a magnetically ordered phase and those arising from excitations which do not develop long-range order (LRO) can be distinguished. Others, like nearly or weak magnetic systems, are sometimes difficult to deal with because they appear at the verge of the ordered phase. Section 2 is devoted to magnetic contributions directly related to the ordering transition, followed by one describing the ordered phase itself. Afterwards, other types of magnetic transformations and excitations will be considered.

## 2. *Specific Heat at the Ordered Phase Boundary*

As the second derivative of the free energy ($C_p = T\partial^2 G/\partial T^2$), the specific heat defines the order of the phase transition at the critical temperature ($T = T_{ord}$). In the case of a first-order transition the discontinuity in $S(T)$ is reflected in $C_p(T)$ as a divergence at $T_{ord}$, and the latent heat ($L = T\Delta S$) can be evaluated as, $\int C_p(T)\mathrm{d}T$. Here, $L$ accounts the change of internal energy from one magnetic phase to the other, plus the eventual volume and/or magnetization changes ($L \propto \Delta H$). The Clausius–Clapeyron relationships, $\mathrm{d}T_{ord}/\mathrm{d}p = \Delta V/\Delta S$ and $\mathrm{d}T_{ord}/\mathrm{d}h = \Delta M/\Delta S$ give valuable information about the evolution of the phase transition as a function of the external control parameters.

In solids, most of these transitions are related to a sudden change of volume due to magnetostrictive effects or crystalline symmetry modifications, driven by some strong spin-phonon coupling. Examples of first-order transitions are those observed in dimerized systems, spin-Peirels chains, or quadrupolar splitting. Unfortunately, due to the limited knowledge of the elastic properties of these materials, a detailed description of the process involving a first-order transition can become quite difficult (Stanley 1971). The temperature dependence of $C_p(T)$ close to the transition provides useful information about the microscopic nature of the transition (e.g., dimensionality). The exponent describing the temperature dependence of $C_p(T)$ (with $t = |T - T_{ord}|/T_{ord}$) follows a power law, $t^{-\eta}$, where $\eta$ is the critical exponent with a value close to zero (e.g., see Stanley 1971).

In a second-order transition a jump in $C_p(T)$, $\Delta C_p$, (like the one shown in Fig. 2) is expected at $T = T_{ord}$ because of the change of the $\mathrm{d}S/\mathrm{d}T$ slope. According to the Ginsburg–Landau (GL) theory, an order parameter ($\zeta$) sets on at $T = T_{ord}$, with infinite initial slope and develops continuously till $T = 0$. Within the scope of the GL theory, the free energy ($G(\Phi)$) shows a minimum of $G$ at $\Phi = \zeta$ and then the variation of $\zeta(T)$ is reflected in $\partial^2 G/\partial T^2$ as a discontinuity or jump in the specific heat. Taking advantage that in ferromagnets $\zeta$ corresponds to the spontaneous magnetization $M_s(T)$, a direct observation of that parameter can be done as shown in Fig. 2. Furthermore, as $\Delta U_m \propto M_s^2$ then $C_m(T) \propto \mathrm{d}M_s^2/\mathrm{d}T$ is obtained. In broadened transitions, $T_{ord}$ can be experimentally determined as the temperature where

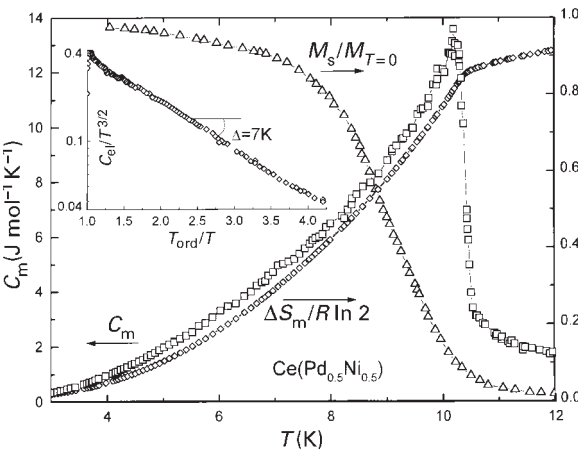

***Figure 2***
Ferromagnetic example for $\Delta C_m(T_{ord})$ and $C_m(T)$, $\Delta S_m(T)$ and $M_s \propto \zeta(T)$ evolutions. Inset: Arrenius representation for the magnon gap evaluation.

the maximum slope of the measured $C_m(T \simeq T_{ord})$ anomaly is observed, or more precisely by the entropy compensation criterion around $\Delta C_m(T_{ord})$ (e.g., see Stewart 1984).

Once $\zeta(T)$ develops, any discontinuity implies a jump in $U_m(T)$ and thus the occurrence of a first-order transition. Therefore, in magnetic systems presenting further transformations within their ordered phase, the second-order one is only expected at the paramagnetic phase boundary and first-order ones at lower temperatures, (as observed in $CeRu_2Ge_2$, Wilhelm *et al*. 1999). In some cases first- and second-order transitions occur simultaneously, as in the case of magnetostrictive effects. There, the change of volume (first-order) is triggered by the onset of magnetic order (second-order transition).

### 2.1 Morphology of the Magnetic Phase Transitions

In a mean field (MF) description of the magnetic transitions the value of $\Delta C_m(T_{ord})$ depends on the momentum $J$ according to, $\Delta C_m(T_{ord}) = 2.5\, R[(2J+1)^2-1]/[(2J+1)^2+1]$, with a related entropy given by $\Delta S_m = R \ln(2J+1)$. For $J = 1/2$ the respective values are, $\Delta C_m(T_{ord}) = 12.5\,\mathrm{J mol^{-1}\,K^{-1}}$ and $\Delta S = 5.7\,\mathrm{J mol^{-1}\,K^{-1}}$, as shown in Fig. 2 for the exemplary compound $Ce(Pd_{0.5}Ni_{0.5})$. Thus, a first-order transition can be recognized when $\Delta C_m(T_{ord})$ clearly exceeds the predicted MF value, as in $CeRu_2Ge_2$ (Wilhelm *et al*. 1999). Concerning the entropy, if it is only due to a discontinuity in $\zeta(T)$, the total entropy will not exceed $\Delta S_m = R \ln(2J+1)$. But, if the first-order transition corresponds to another contribution (e.g., $\Delta V \neq 0$), there is an extra contribution to be taken into account, because $\Delta S_{tot} = \Delta S_m + p\Delta V/T_{ord}$.

### 2.2 Effects of Magnetic Field, Pressure and Alloying

External magnetic field can be used to distinguish the nature of the magnetic order. In a ferromagnet, the presence of field broadens the transition because of the enhancement of magnetic correlations above $T_{ord}$. As a consequence $\zeta(T)$ (or $M_s(T)$) does not set on with infinite but with finite slope and from higher temperatures. In an antiferromagnet, the effect of $h$ is quite different because up to a critical field ($h_{cr}$), where a spin flip is inducted by the applied field, no significant effect should occur and $\Delta C_m(T_{ord})$ is only weakly shifted to lower temperatures. Above $h_{cr}$, the system will behave like an induced ferromagnet and $C_m(T)$ looks like a Schottky anomaly (see below), which corresponds to a two-level system with the respective parallel and antiparallel spin projection with respect to $h$. Field effect becomes an important tool in anisotropic systems, because $T_{ord}$ and $\Delta C_m(T_{ord})$ depend on the relative direction between field and magnetic axes.

In view of the mechanical energy involved, the application of external pressure is not expected to produce drastic changes in a magnetic transition by itself, aside from the increase of $T_{ord}$, due to the reduction of the interatomic distances. However, its effect can be strongly enhanced by other mechanisms such as the hybridization of the local and conduction electron states related to the Kondo effect (e.g., see Sereni 1995). The variation of $T_{ord}$ with pressure is related to $\Delta C_m(T_{ord})$ by the Ehrenfest relation, $dT_{ord}/dp = VT_{ord}\Delta\alpha/\Delta C_m$.

The effect of alloying may produce more important variations in a transition because the chemical potential itself is affected in the substitution process. Local structural pressure and disorder are also typical effects of atomic substitution, with the obvious consequence of the broadening of $\Delta C_m(T_{ord})$. Although pressure and doping are expected to produce similar effects, there are cases showing remarkable differences in $C_m(T)$. Such is the case of the alloyed compound $CeCu_2(Si_{1-x}Ge_x)_2$, where $T_{ord}$ decreases with $x$, whereas the $C_m/T$ ratio is practically not affected. On the contrary, the application of pressure on the $x = 0.1$ sample does not affect $T_{ord}$, whereas $C_m/T$ changes significantly (Sparn *et al*. 1998). This different dependence between pressure and doping indicates that the magnetic interaction (i.e., $T_{ord}$) does not change hand in hand with the amount of condensed degrees of freedom. Knowing $C_m(T,p)$, it is possible to relate this parameter with $\alpha$ through the Maxwell relation, $\partial S/\partial p = -\partial V/\partial T = -\alpha$, as verified in $CeCu_2(Si_{0.9}Ge_{0.1})_2$.

### 2.3 Low Dimensionality and Anisotropies

It is well known that 1D systems do not develop LRO and their $C_m(T)$ is described as an anomaly. The exact solutions for apparently elementary cases, like those described by Ising (IS) or Heisenberg (HS) models for chains, triangular, or quadratic cases, are not simple and have to be presented as numerical approximations. Nevertheless, the morphology of the phase transition provides some useful information regarding the characteristics of the ordered phase. For example, a 2D-IS lattice is expected to exhibit a logarithmic singularity, $C_m = A \ln t$ on both sides of the transition, with the proportionality factor, $A$, depending on the type of magnetic lattice (de Jongh and Miedema 1974). The systems approaching the 2D-HS magnetic configuration can be recognized from the evolution of their $\Delta S_m(T)$ because it is predicted that $\Delta S_m(T < T_{ord}) \approx \Delta S_m(T > T_{ord})$. A good complement is to also evaluate $\Delta U_m(T)$ and to compare its distribution above and below $T_{ord}$. For example, in a 3D-f.c.c. lattice with spins $\frac{1}{2}$, the values are, $(S_\infty - S_{ord})/(R \ln 2) = 0.27$ (HS) or 0.10 (IS) and $(U_\infty - U_{ord})/U_\infty = 0.44$ (HS) or 0.15 (IS), respectively (e.g., see Fisher 1967, Fig. 3).

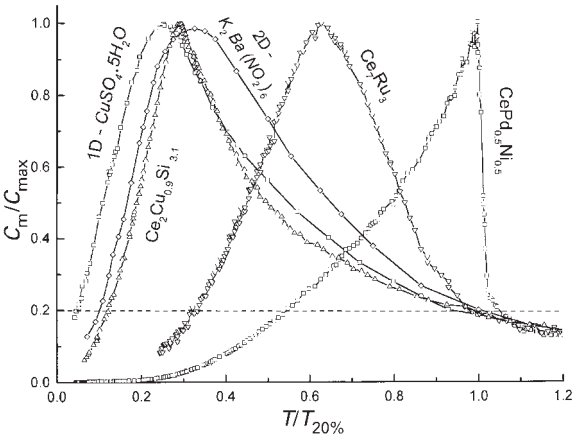

***Figure 3***
Normalized $C_m/C_{max}$ versus the temperature at which $C_m(T) = 0.2C_{max}$, $T/T_{20\%}$, to compare the evolution of magnetic correlations in 1D, 2D ($s = 1/2$ Heissenberg) and 3D magnetic systems.

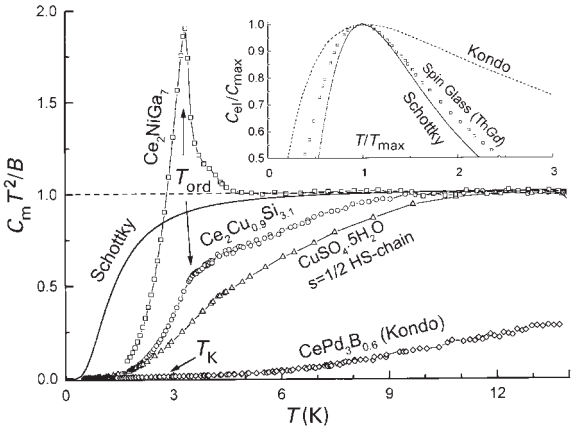

***Figure 4***
Normalized evolution of different systems to their respective paramagnetic states where $C_m T^2 \rightarrow B$, after subtracting phonon and excited CF-levels contributions. The Schottky type curve represents the $C_{RF}(T)$ of $Ce_2NiGa_7$. Inset: comparison of different anomalies around $C_{max}(T_{max})$.

In metallic systems, the anisotropy plays an important role in the magnetic behavior of rare earth compounds because of the CF effect. In these cases the $\Delta S_m(T)$ evolution tends to resemble the one expected for systems with lower symmetry, though the anisotropic $\zeta(T)$ develops in 3D. It is observed for example, that $C_m/T$ versus $T$ is symmetric with respect to the temperature of the maximum of $C_m/T$. Such a $\Lambda$-type transition fulfills the condition for a 2D-HS pattern, $\Delta S_{mag}(T < T_{ord}) \approx \Delta S_{mag}(T > T_{ord})$, despite the 3D behavior which is expected in compounds such as $Ce_7Ru_3$ or $CeCu_{0.45}Si_{1.55}$ (see Fig. 3). Indeed, for a strict definition of $T_{ord}$, it must be taken into account that in an antiferromagnet $\Delta U_m(T)$ is proportional to the magnetic correlation strength between spins, $\langle s_i * s_j \rangle^2 \propto \mu_{eff}^2$ (the effective moment). As $\Delta U_m(T) \propto \mu_{eff}^2 \propto \chi(T)T$, the following relation is obtained, $C_m(T) \propto d(\chi T)/dT$ (de Jongh and Miedema 1974). Then, because $T_{ord}$ is defined by the temperature of the maximum variation of $U_m(T)$, it corresponds to the maximum of $C_m(T)$, not to the maximum slope (as in MF transitions).

### *2.4 Tails ($T > T_{ord}$)*

The ideal phase boundary between an LRO phase and the paramagnetic (P) phase is not always well defined in real systems because magnetic fluctuations and/or correlations set on well above $T_{ord}$. The region where these precursors of the LRO dominate the scenario can be considered as quasi-paramagnetic (QP). From $\chi(T)$, the boundary of such a QP region can be recognized as a deviation from the Curie law, $\chi \propto T^{-1}$. This criterion can be transferred to the specific heat by using the Maxwell relation, $\partial S/\partial h = \partial M/\partial T \rightarrow \gamma/\partial h = \partial^2 M/\partial T^2 = h\partial^2 \chi/\partial T^2$ (Stanley 1971), from which a $C_m \propto T^{-2}$ dependence is deduced for the paramagnetic phase where $\partial M/\partial h = \chi \propto T^{-1}$. Therefore, the $C_m T^2 = B$ condition can be used to define the boundary between P and QP regions. Some selected examples of how the $C_m(T)T^2$ reaches this condition are shown in Fig. 4.

This way of approaching the P-phase can be used to compare the strength of the correlations above $T_{ord}$ in different systems. In Fig. 3, the temperature is normalized to that at which $C_m(T)$ is 1/5 (= 20%) of its maximum value. As shown in Fig. 3, the evolution of quite different magnetic systems at high temperatures nearly coincides in their $C_m \propto T^{-2}$ tendency, though the way they reach their respective $C_m^{max}$ value is very different.

In disordered or frustrated systems or those with low lying spin excitations, LRO may not develop at finite temperature. Nevertheless, the magnetic correlations accounted by the $C_m(T)$ tails can be considered as precursors of a magnetic transition. However, if it orders, the condensed degrees of freedom are taken from the QP state, where magnetic correlations are developing and then $C_m(T > T_{ord})$ can be used as a reference function ($C_{RF}$). Frequently, these tails are well described by a $C_{RF} \propto -T \ln(T)$ function, which can be independent of doping and pressure (e.g., see Sereni 1998 and references therein).

## *3. The Magnetically Ordered Phase ($T < T_{ord}$)*

The description of the ordered state in a magnetic system is given by the spin wave theory (e.g., see

Akhieza *et al*. 1968). Within this theory there are well defined $C_m(T)$ dependencies, as for example:

(i) ferro- and ferrimagnets with a quadratic ($q=2$) magnon dispersion-relation, $C_m(T) \propto T^{3/2}$

(ii) antiferromagnets with linear ($q=1$) magnon dispersion-relation, $C_m(T) \propto T^3$ (note that in these two isotropic cases, the temperature exponent, $T^\eta$, is given by $\eta = D/q$, see Gopal 1966)

(iii) under applied or anisotropic molecular fields, an activation energy for the spin waves arises, and then $C_m(T)$ increases exponentially at low temperatures, with an associated gap ($\Delta_M$) in the magnon spectrum. For $h$ applied on the easy axis of anisotropy of a ferromagnet $C_m(T)$ is $\propto T^{1/2} \exp(-\Delta_M/T)$, and for one with easy plane and $h$ perpendicular to it, a $T^{-1/2} \exp(-\Delta_M/T)$ dependence is expected

(iv) In the case of an antiferromagnet, with an easy axis of anisotropy one also gets $C_m(T) \propto T^{-1/2} \exp(-\Delta_M/T)$, whereas for the field perpendicular it is $C_m \propto T^3$

Experimental examples of most of these cases can be found in Sundström (1978) and the inset of Fig. 2.

### 3.1 Microscopic Character of the Dispersion Relation

The concept of specific heat as a thermal spectrometer is confirmed by its ability to recognize different microscopical dispersion relations (including gaps) in the magnon spectrum. Two illustrative examples are $Ce(Pd_{0.9}Ag_{0.1})$ and $CePd_3Ga_2$. The first shows antiferromagnetic behavior in its $\chi(T)$ macroscopic signal, despite the ferromagnetism of the CePd matrix. Experimentally, $C_m(T) \propto T^{3/2}$ indicates ferromagnetic interactions, in agreement with the positive Curie–Weiss temperature ($\theta_W > 0$). In this case, the disorder introduced by doping makes the reduced ferromagnetic domains to order randomly among them, behaving macroscopically as an antiferromagnet. A mirror-like case is provided by $CePd_3Ga_2$, which orders ferromagnetically at 6 K (Bauer *et al*. 1993) regardless of its Kondo character (Coqblin *et al*. 1996). Nevertheless, $C_m(T) \propto T^3$ is observed for $T < T_{ord}$ indicating the presence of antiferromagnetic interactions, in agreement with the $\theta_W < 0$ value. In this case, frustration effects due to the hexagonal symmetry of the magnetic lattice may explain the difference between the microscopic interaction and the actual type of order. These examples, and those related to the gap detected in the magnon spectrum, confirm the skill of this technique in providing microscopic information within a range of energy of a fraction of degrees (i.e., $\propto 1 \times 10^{-5}$ eV).

## 4. Transformations and Related Anomalies

Every physical phenomenon has an associated characteristic energy, which leads it to manifest within a certain range of the control parameters. Once that energy scale is identified, a comparative analysis with other effects can be performed. For this purpose, a distinction between phase transition and transformation has to be made. In the first case, the ordering energy ($k_B T_{ord}$) defines a critical value, whereas for the second (e.g., $k_B T_K$ in the Kondo screening or $k_B T_{sg}$ in a spin glass) it only gives a scale of energy where it competes with the thermal-energy $k_B T$. This implies that the condensation of the degrees of freedom occur within an extended range of temperature.

### 4.1 Kondo Effect

In a diluted magnetic system, where magnetic moments behave as single impurities, there is a spin-spin interaction between the local moment ($f$) and the conduction electrons ($s$). This $s$–$f$ exchange is antiferromagnetic and leads to the formation of a singlet ground state (GS) due to the spin compensation below the Kondo temperature $T_K$. Such as process is not a phase transition, but a continuous transformation occurring in a logarithmic temperature scale. A consequence of that interaction there is a significant increase of the density of states $N(E_f)$ due to the formation of a virtual-bound state, which is observed in thespecific heat measurements as a strong enhancement of the $\gamma$ coefficient. The height of this resonant state ($\sim\gamma$) is inversely proportional to its width and, therefore, $\gamma \propto 1/T_K$. The temperature dependence of the Kondo contribution to the specific heat ($C_K$) is linear at low temperature, has a maximum at $T/T_K = 0.45$ and reaches the $T^{-2}$ dependence at high temperature (e.g., see Bredl 1978). Once the GS is fully formed $\chi(T \to 0)$ becomes Pauli-like (i.e., $\sim N(E_f)$) and, therefore, $\sim\gamma$. The electronic scattering is also strongly enhanced, producing the characteristic logarithmic increase of the resistivity at low temperature. The problem of the Kondo effect in transport properties is extensively discussed in the chapter *Kondo Systems and Heavy Fermions: Transport Phenomena*.

### 4.2 Spin Glasses

Magnetic interactions do not develop LRO when randomness distribution inhibits the propagation of the order parameter. In any case, the presence of a mean molecular field at each magnetic moment site is able to freeze a magnetic configuration at a certain temperature, $T_{sg}$, below which the system behaves in a cooperative manner. This is a simplified picture for a spin glass that becomes more complex when microscopic aspects are considered (e.g., see Mydosh 1993).

Depending on the concentration ($x$) of the particles carrying the magnetic moment, different regions can be distinguished:

(i) In diluted magnetic systems, the specific heat contribution ($C_{sg}$) and the characteristic temperature

can be scaled with the impurities concentration, leading to a universal $C_{sg}/x$ vs. $T_x$ dependence. On the $T < T_{sg}$ range, $C_{sg}(T)$ arises linearly with temperature, with a $T^2$ dependence at $T \to 0$ (i.e., $C_{sg} = aT + bT^2$). For $T \gg T_{sg}$ the expected $C_{sg} \propto T^{-2}$ dependence is verified (Sereni *et al.* 1979 and references therein). Some of these features are illustrated by the $Th_{0.972}Gd_{0.028}$ alloy in the inset of Fig. 4.

(ii) For higher concentrations short-range correlations occur, leading the formation of magnetic clusters. There, the scaling properties are lost and the anomaly can be described by, $C_{cl} = R(\Delta_{cl}/T)^2 e^{\Delta_{cl}/T}/(e^{\Delta_{cl}/T} - 1)^2$, where $\Delta_{cl}$ represents the energy gain in the cluster formation, which depends on the magnetic moment, the volume of the cluster, and the energy of anisotropy

(iii) when clusters interact among them a short range order (within the clusters) coexists with the glassy character of the mutual cluster interaction.

### 4.3 *Schottky Anomalies*

Another frequent anomaly observed in specific heat measurements is the so-called Schottky anomaly, which is related to the thermal excitations in a level system split by $\Delta$, like in nuclear or electronic GS, where the degeneracy ($g_i$) is removed by hyperfine (nuclear) or crystalline (electric) fields. Because the thermal population of the levels is governed by Maxwell–Boltzman statistics, the specific heat is described by $C_{Sch} = R(g_i/g_o)(\Delta/T)^2 e^{\Delta/T}/[1 + g_i/g_o e^{\Delta/T}]^2$. For $T \ll \Delta$ one gets $C_{Sch} = R(g_i/g_o)\ (\Delta/T)^2 e^{\Delta/T}$ and at high temperatures the typical $T^{-2}$ tail appears (Gopal 1966). Because the involved entropy is fixed by the relative degeneracy of the ground and excited levels, $\Delta S = R \ln(g_i/g_o)$, the value of $C_{Sch}^{max}$ and its temperature depend on $g_i/g_o$ and $\Delta$, respectively. In the case where $g_i = g_o$, one can write $C_{Sch}(T) = R(\Delta/2T)^2 \mathrm{sech}(\Delta/2T)^2$. Note that a similar formula was used for $C_{cl}(T)$, where the Bose statistics was applied and thus $C_{cl}(T) = R(\Delta/2T)^2 \mathrm{cosech}(\Delta/2T)^2$.

### 4.4 *Ordering and Anomalies*

Magnetic transitions may occur superimposed on these anomalies. In such a case, the fraction of degrees of freedom involved are those not yet condensed into the GS, i.e., $\Delta S(T_{ord})/\Delta S_\infty$. This situation frequently occurs in Kondo systems, where $\Delta C_m(T_{ord})$ is reduced with respect to the expected 1.5R value (e.g., see Bredl *et al.* 1978), when the CF excited levels are still thermally populated or two magnetic configurations compete in the formation of the ordered GS like in $CeNi_xGa_{4-x}$. In the last two cases a $C_{Sch}(T)$-type function plays the role of a reference function, as shown in Fig. 4.

In order to distinguish between a broadened transition and a transformation, some thermodynamic criteria are useful. In a broadened transition, $\Delta S(T)$ should have a change of slope at $T_{ord}$, reflected in a sudden increase of the negative slope of $\Delta C_m(T)$ by cooling. Alternatively, in a transformation, the $\Delta C_m(T)$ curvature (i.e., $\delta^2 C_m/\delta T^2$) changes monotonously from negative to positive as $T$ decreases.

## 5. *Phases Involving Strongly Correlated Electrons*

### 5.1 *The Quasi-paramagnetic Region*

In this QP region the magnetic correlations dominate the scenario before the eventual formation of an LRO. When such a situation persists down to very low temperatures, divergencies in $C_m/T(T \to 0)$ are observed because of the enhanced density of low lying spin excitations. Such is the case of $CeCu_{0.9}Au_{0.1}$ shown in Fig. 1 (Löhneysen 1995). A generalized scaling function $C_m/t = -F \log(t) + E$ was proposed for these systems, with $t = T/T_0 (T_0 \propto T_K)$ and $F = 7.2\ \mathrm{J mol^{-1} K^2}$ as a universal constant. Besides the logarithmic, algebraic divergencies of the type $C_m/T = \gamma_0 - \gamma_1 T^\eta$ (with $\eta = 1/2$ or 2) were also proposed. Nevertheless, a continuous spectrum of values can be found experimentally in this non-Fermi-liquid (NFL) region (e.g., see Sereni 1998).

Depending on whether the coupling parameter between the local and band electrons spins increases or decreases, the respective low temperature boundary of the QP region is the LRO or the nonmagnetic phase. In the cases where these two phases converge for $T \to 0$, the NFL region becomes narrow and a zero temperature quantum critical point may occur with $C_m/T$ showing some of the predicted $T$-divergencies (see Löhneysen 1995 and Sparn *et al.* 1998). However, in many cases such a region is quite extended (mostly due to disorder effects) and then a variety of $C_m/T(T \to 0)$ divergencies can be observed (Sereni 1998).

An alternative scenario for incipient magnetic interactions is given by the itinerant magnetism or spin-fluctuations. Due to thermal excitations, spins fluctuate in orientation and amplitude with an associated frequency ($\omega_{sf}$). When $\omega_{sf}^{-1} \propto k_B T_{sf}$ is greater than the thermal energy, the spins look nonmagnetic. On the contrary, at high temperatures thermal fluctuations are more rapid than those of the spins and able to "see" the magnetic component. In this case it is predicted that $C_m/T \propto T^2 \ln(T/T_{sf})$, as shown in Fig. 1 by the exemplary system $UAl_2$ (Stewart 1984).

### 5.2 *The Nonmagnetic Phase: Heavy Fermions and Intermediate Valent*

In a periodic Kondo lattice a narrow electronic band with heavy electrons is responsible for the large $\gamma$ value. These heavy fermion (HF) quasi-particles present a coherent state identified by a significant

reduction of the electrical resistivity ($\rho = AT^2$) and a strongly enhanced Pauli-like susceptibility ($\chi$). Because in an FL system $\gamma$, $\chi_0$ and $A^{1/2}$ are proportional to $N(E_f)$, all these parameters have to be proportional between them. In Fig. 1, the $C_p(T)$ dependence of the HF prototype $CeCu_6$ is shown, with $\gamma = 1.6\,\mathrm{J mol^{-1} K^{-2}}$. Like for Kondo impurities, $\gamma \propto 1/T_K$ and then its characteristic temperature is deduced to be about 5 K. Indeed, $\gamma$ depends on temperature like $\gamma(T) = C_K(T)/T$ and, because the Kondo-lattice state is built up from a doublet ground state, the related entropy is also $R$ ln2.

For large hybridization strength between local and conduction states, both spin and charge components of the wave function are mixed, leading to an intermediate valent (IV) state. In that case, the width of the energy levels becomes comparable to the CF splitting, and then the system gains energy (when $T_K \geqslant \Delta$) by going from a two-fold-degenerated GS (with $J = 1/2$) to the full spin-orbit six-fold-degenerated state (e.g., $J = 5/2$ for Ce). With the consequent increase of the effective level width ($T_K$) and the reduction of $\gamma$ (compare $CeCu_6$ with $CeIr_2$ in Fig. 1). In this IV state, the nonmagnetic character comes from the disappearance of the moment due to the 4f-electron delocalization, whereas in the HF state only the spin compensation is involved. Here the FL behavior is fully verified through the Wilson ($\chi_o/\gamma = 0.036\,\mathrm{emu K^2 J^{-1}}$) and Kadowaki–Woods ($A/\gamma^2 = 1 \times 10^{-6}\,\Omega\,\mathrm{cm\,(J\,K\,mol^{-1})^{-2}}$) ratios, in agreement with the values predicted by the theory (e.g., see Sereni 1991 and references therein). Although the Wilson ratio is claimed to be applicable also for HF systems, the lack of good quantitative determination $\mu_{eff}$ of the doublet GS impedes a reliable experimental verification.

The transformation or cross-over from HF to IV states by doping occurs at a cross-over concentration: $x_{cr}$ (Sereni 1995) where most of physical properties (like $V$, $\gamma$, $\theta_W$, $\rho$, $\chi$) show a change of regime through a change in the concentration dependence. Particularly $\gamma(x)$, shows a maximum at $x_{cr}$. Although a decrease of $\gamma(x)$ should be expected when going from an HF to an IV regime as $T_K$ increases, the experimental observation indicates that the effective width of the hybridized $f$ level does not evolve monotonously (see Coqblin *et al*. 1996 and references therein). Therefore, the maximum observed in $\gamma(x)$ should be related to the change (increase) of the GS degeneracy from $g_0 = 2$ to 6 (c.f. $J = 5/2$) as mentioned before for cerium ions (Sereni 1995).

## 6. Concluding Remarks

This condensed overview on the specific heat of magnetic systems shows some examples of the wide range of information that can be extracted from the experimental study of this thermal parameter. Since it covers macroscopic (thermodynamical) as well as microscopic (e.g., excitation spectrum) properties, it represents one of the basic tools for the characterization of new systems (together with magnetic and transport measurements). Alternatively, since it allows a direct evaluation of the evolution of the entropy with temperature, it gives access to many other thermodynamical parameters through different Maxwell relations. Similar analysis of the specific heat contributions can be applied to other physical phenomena, such as elastic (structural) instabilities, particles diffusion, ferroelectricity, or superconducting properties (see Gopal 1966).

# Magnetic Units

The International System of Units, SI (Le Systéme International d'Unités), was adopted by the Conférence Générale des Poids et Mesures in 1960. It is a coherent system founded on seven base units (meter, kilogram, second, ampere, kelvin, mole, and candela) and its use is recommended by the International Union of Pure and Applied Physics (Cohen and Giacomo 1987). Nevertheless, a significant part of the existing literature, particularly concerning magnetism, is still expressed in terms of the electromagnetic (c.g.s.) or the Gaussian systems. Hence, it might be helpful to provide the relationships between the SI and these systems, although it is not intended to advance the use of the latter.

## *1. Relationship Between SI, c.g.s., and Gaussian Systems*

In contrast to the SI system, the c.g.s. system is based on three base units only (centimeter, gram, and second) being appropriate for mechanical problems. The dual nature of the system emerged from the application to electricity and magnetism, where all quantities may be alternatively expressed in either electrostatic units (esu) or electromagnetic units (emu). The electrostatic system defines charge to be a derived quantity based on Coulomb's law for the force between two charges, while the electromagnetic system defines electric current as a derived quantity based on Ampere's law for the force between two electric current elements:

$$\mathbf{F} = k_e \frac{q_1 q_2 \mathbf{r}}{\varepsilon r^3} \quad d^2\mathbf{F} = k_m \mu \frac{i_1 d\mathbf{l}_1 \times (i_2 d\mathbf{l}_2 \times \mathbf{r})}{r^3}$$

In the electrostatic system, $k_e = 1$ is chosen and the permittivity, $\varepsilon$, is defined to be dimensionless and to adopt unity in free space. In the electromagnetic system, $k_m = 1$ is chosen and the permeability, $\mu$, is defined to be dimensionless and to adopt unity in free space.

One of the main advantages of the SI system is the unification of magnetic quantities with practical electric units of ampere and volt. The unit for current in esu is the statampere ($3 \times 10^9$ esu $s^{-1} \doteq 1$ A) while in emu it is the abampere (1 abampere $\doteq$ 10 A). For the "mixed" (or "symmetrized") c.g.s. or Gaussian system, all electrical quantities are measured in esu and all magnetic quantities in emu, hence statampere is used here.

The duality is removed in the MKSA or practical system, developed by Maxwell and Giorgi, by introducing the current as an additional base unit without the attempt to express the ampere dimensionally in length, mass, or time. This system is said to be "rationalized," since the prefactors of Coulomb's and Ampere's laws are set equal to $1/4\pi$, while the choice of these prefactors is unity in the c.g.s. and Gaussian systems. This leads to the appearance of factors of $2\pi$ and $4\pi$ in situations that involve plane geometry and to their absence in situations with spherical or cylindrical symmetry, where these factors might normally be expected in the c.g.s. and Gaussian systems. These systems are therefore called "nonrationalized." Eventually, the SI system was formulated on the basis of the rationalized MKSA system. A comparison of the basic equations (Maxwell's and material equations) of these two systems is given in Table 1, where the quantities in the Gaussian system are indicated with an asterisk and the symbols recommended by IUPAP (Cohen and Giacomo 1987) are used (**E**, electric field; **P**, electric polarization; **H**, magnetic field; **B**, magnetic flux density; **M**, magnetization; $\chi_m$, $\chi_e$, magnetic or electric susceptibility; $\mu$, permeability; $\varepsilon$, permittivity).

As a result of the fourth base unit in the SI and MKSA system, permeability $\mu = \mu_r \mu_0$ and permittivity $\varepsilon = \varepsilon_r \varepsilon_0$ are dimensional physical quantities where $\varepsilon_0$ and $\mu_0$ must fulfill the condition $\varepsilon_0 \mu_0 c^2 = 1$, in order that electrostatics and electromagnetics are coherent. This avoids the asymmetrical introduction of the factor $c$ into the equations for electric and magnetic

***Table 1***
Maxwell's and material equations.

| Gaussian system with three base quantities | SI system with four base quantities |
|---|---|
| $c\nabla \times \mathbf{E}^* = -\partial \mathbf{B}^*/\partial t$ | $\nabla \times \mathbf{E} = -\partial \mathbf{B}/\partial t$ |
| $c\nabla \times \mathbf{H}^* = 4\pi \mathbf{j}^* - \partial \mathbf{D}^*/\partial t$ | $\nabla \times \mathbf{H} = \mathbf{j} + \partial \mathbf{D}/\partial t$ |
| $\nabla \cdot \mathbf{D}^* = 4\pi \rho^*$ | $\nabla \cdot \mathbf{D} = \rho$ |
| $\nabla \cdot \mathbf{B}^* = 0$ | $\nabla \cdot \mathbf{B} = 0$ |
| $\mathbf{D}^* = \varepsilon_r \mathbf{E}^* = \mathbf{E}^* + 4\pi \mathbf{P}^*$ | $\mathbf{D} = \varepsilon \mathbf{E} = \varepsilon_0 \varepsilon_r \mathbf{E} = \varepsilon_0 \mathbf{E} + \mathbf{P}$ |
| $\mathbf{B}^* = \mu_r \mathbf{H}^* = \mathbf{H}^* + 4\pi \mathbf{M}^*$ | $\mathbf{B} = \mu \mathbf{H} = \mu_0 \mu_r \mathbf{H} = \mu_0 (\mathbf{H} + \mathbf{M})$ |
| $\varepsilon_r = 1 + 4\pi \chi_e^*$ | $\varepsilon_r = 1 + \chi_e$ |
| $\mu_r = 1 + 4\pi \chi_m$ | $\mu_r = 1 + \chi_m$ |

quantities. In the SI system the permeability of vacuum is defined to have the value $\mu_0 = 4\pi \times 10^{-7}$ $\mathrm{NA}^{-2} = 4\pi \times 10^{-7}\ \mathrm{Hm}^{-1} = 4\pi \times 10^{-7}\ \mathrm{VsA}^{-1}\mathrm{m}^{-1}$.

The comparison of the corresponding equations in both systems yield the following relationships: $\sqrt{4\pi/\mu_0} = \mathbf{B}^*/\mathbf{B} = \mathbf{M}/\mathbf{M}^*$; $\sqrt{4\pi\mu_0} = \mathbf{H}^*/\mathbf{H}$; $4\pi = \chi/\chi^*$; $\sqrt{4\pi\varepsilon_0} = \mathbf{E}^*/\mathbf{E} = \rho/\rho^* = \mathbf{j}/\mathbf{j}^* = \mathbf{P}/\mathbf{P}^*$; and $\sqrt{4\pi/\varepsilon_0} = \mathbf{D}^*/\mathbf{D}$, which are useful to convert an *equation* in Gaussian units into the corresponding equation in the SI system and vice versa.

For example, to transform an equation in Gaussian units into SI, replace the quantities with an asterisk by those without an asterisk according to the above relationships (e.g., $\mathbf{B}^* \Rightarrow \mathbf{B}\sqrt{4\pi/\mu_0}$; $w = \frac{1}{2}\mathbf{B} \cdot \mathbf{H}$, $w^* = (1/8\pi)\mathbf{B}^* \cdot \mathbf{H}^*$). Quantities that involve only volume, force, energy, and length transform directly.

## 2. Definition of the Magnetic Quantities

The magnetic quantities are defined in SI as follows (International Organization for Standardization 1992). The magnetic field strength, **H**, is a vector quantity, the rotation (curl) of which is equal to the sum of the electric current density and the time derivative of the electric flux density. The magnetic flux density or magnetic induction, **B**, is a vector quantity such that the force exerted on an element of electric current is equal to the vector product of this element and the magnetic flux density: $\mathbf{F} = I\Delta\mathbf{s} \times \mathbf{B}$. The magnetic moment, **m**, is a vector quantity, the vector product of which with the magnetic flux density of a homogeneous field is equal to the torque: $\mathbf{m} \times \mathbf{B} = \mathbf{T}$. The International Electrotechnical Commission (IEC) defines also the magnetic dipole moment, $\mathbf{j} = \mu_0\mathbf{m}$. The magnetization as the magnetic moment per unit volume is defined by the relationship $\mathbf{M} = \mathbf{B}/\mu_0 - \mathbf{H}$. The permeability is defined by $\mathbf{B} = \mu\mathbf{H}$ and the relative permeability by $\mu_\mathrm{r} = \mu/\mu_0$, where the latter is dimensionless. This is also the case for the magnetic susceptibility defined by $\chi = \mu_\mathrm{r} - 1$. The electromagnetic field energy divided by volume is given by $w = \frac{1}{2}\mathbf{E} \cdot \mathbf{D} + \mathbf{B} \cdot \mathbf{H}$.

## 3. Analogies Between Electric and Magnetic Field Quantities

According to the structure of Maxwell's equations, two types of analogies can be derived for the electric and magnetic field quantities:

(i) The distinction according to the structure of the differential operators (curl and div) leads to the correspondences $\mathbf{E} \leftrightarrow \mathbf{H}$ and $\mathbf{D} \leftrightarrow \mathbf{B}$. This becomes also evident from the integral formulation of Maxwell's relationships, where the electric and magnetic potential differences, $U = \oint \mathbf{E} \cdot \mathrm{d}\mathbf{s}$ and $U_\mathrm{m} = \oint \mathbf{H} \cdot \mathrm{d}\mathbf{s}$, occur as well as the electric flux $\Psi = \oint_{(V)} \mathbf{D} \cdot \mathrm{d}\mathbf{A}$ and the magnetic flux $\Phi = \oint_{(V)} \mathbf{B} \cdot \mathrm{d}\mathbf{A}$. The electric and magnetic energy densities $w_\mathrm{e} = \int \mathbf{E} \cdot \mathrm{d}\mathbf{D}$ and $w_\mathrm{m} = \int \mathbf{H} \cdot \mathrm{d}\mathbf{B}$ also imply this correspondence. This indicates the primacy of **H** based on fictive magnetic surface poles (or "magnetic charges") traditionally used in magnetostatics by analogy with electrostatics. However, this is not a valuable or helpful entry to electromagnetism (see below).

(ii) The distinction by homogeneous and inhomogeneous equations leads to the correspondences $\mathbf{E} \leftrightarrow \mathbf{B}$ and $\mathbf{D} \leftrightarrow \mathbf{H}$, which is also consequent with respect to the influence of matter upon the field quantities: $\nabla \cdot \mathbf{D}$ and $\nabla \times \mathbf{H}$ are determined by the *external* charge and current densities, respectively, and the corresponding equations for $\nabla \cdot \mathbf{E}$ and $\nabla \times \mathbf{B}$ in matter additionally contain polarization charge density $\rho_\mathbf{P} = -\nabla \cdot \mathbf{P}$ and polarization and magnetization current densities $\mathbf{j}_\mathbf{P} = \partial\mathbf{P}/\partial t$ and $\mathbf{j}_\mathbf{M} = \nabla \times \mathbf{M}$, respectively. Thus, the magnetic induction or magnetic flux density, **B**, is the field in matter.

## 4. The Primacy of B or H

The codification of the field quantities goes back to Faraday, Maxwell, and their contemporaries. In this tradition the primary magnetic field is **H** as the "magnetizing force" now called field strength. The term "magnetic induction" for **B** points to the status of a variable quantity that is determined by the sum of **H** and **M** and corresponds to analogy (i) above. Thus the "coefficient of induced magnetization," $\chi$, is the ratio of **M** to **H** and the "coefficient of induction," $\mu$, is the ratio of **B** to **H**, named susceptibility and permeability, respectively, by William Thomson (Bennett *et al*. 1976, Goldfarb 1992).

However, as stated in (ii) above the field within magnetized matter is not **H** but **B**, since **B** is produced by both the conduction and the Amperian (atomic) currents, while **H** has its source in external conduction currents only. Hence, analogy (ii) is more general and those emphasizing the primacy of **B** have an excellent viewpoint but are at a historical disadvantage, since the magnetic pole approach has traditionally been used in magnetostatics by analogy with electrostatics.

For the characterization of magnetic materials the traditional approach is usually used because the desired quantity is $\mathbf{M}(\mathbf{H},T)$. The relevant field in a magnetized sample is the *internal field*, **H**, which occurs in these equations and originates not only from the external field, $\mathbf{H}_\mathrm{ext}$, but also from the stray- or self-field of the magnetized body. Thus, $\mathbf{H}_\mathrm{ext}$ has to be corrected by the demagnetizing field $\mathbf{H}_\mathrm{D} \equiv -N\mathbf{M}$, where $N$ (or $D$) is the *demagnetizing factor* and depends on the sample geometry:

$$\mathbf{H} \equiv \mathbf{H}_\mathrm{int} = \mathbf{H}_\mathrm{ext} + \mathbf{H}_\mathrm{D} = \mathbf{H}_\mathrm{ext} - N\mathbf{M}$$

Only spheres and ellipsoids have a uniform **M** in a uniform $\mathbf{H}_\mathrm{ext}$ and can therefore be calculated in a closed form while for cylinders and parallelepipeds only approximate $N$ values can be given. The

demagnetizing factors for the three orthogonal axes of any uniformly magnetized body sum up to unity; hence, $N = 1/3$ for a sphere. For a review on demagnetizing factors see, e.g., Chen *et al.* (1991) and Goldfarb (1992).

## 5. *SI System*

In the SI system, the relationship between **B**, **H**, and **M** is defined as $\mathbf{B} = \mu_0(\mathbf{H} + \mathbf{M})$ and $\chi = d\mathbf{M}/d\mathbf{H}$. The magnetic polarization $\mathbf{J} = \mu_0\mathbf{M}$ is also a recognized quantity even though it is based on $\mathbf{B} = \mu_0\mathbf{H} + \mathbf{J}$ which is not a defining relationship in SI. The units of **B** and **J** are tesla ($T = Vsm^{-2} = Wbm^{-2}$) and those of **H** and **M** are $Am^{-1}$; accordingly, $\chi$ is dimensionless. **M** and $\chi$ are extensive quantities and are based on a unit volume, i.e., the volume magnetization is defined as the magnetic moment ($Am^2$) per unit volume, which yields $Am^{-1}$. The volume, however, is usually more difficult to determine with the same precision as the mass and is furthermore temperature dependent. For technical applications, the volume magnetization is the commonly used quantity. In condensed matter physics, however, the temperature dependencies of these quantities are of importance; the mass magnetization ($M$ or $\sigma$) and the mass susceptibility ($\chi_\rho$) are preferred although the latter two are not recognized as important SI quantities but are consistent with SI. Their conversion into recognized units requires knowledge of the density as a function of temperature, which is usually not available, in particular for novel materials, at least not with the same precision as the measurement of $M(T)$ or $\chi(T)$. Furthermore, the mass magnetization ($Am^2kg^{-1} = JT^{-1}kg^{-1}$) is preferred to the volume magnetization since atomic quantities such as the magnetic moment per atom, mole, or formula unit (f.u.) can be derived directly. The number, $n$, of Bohr magnetons per mole ($\mu_B mol^{-1}$) is simply obtained from the mass magnetization by $Mm_{mol}/N_A\mu_B = Mm_{mol}/5.5849 = n[\mu_B mol^{-1}]$, where $N_A = 6.0221367 \times 10^{23}\,mol^{-1}$, $m_{mol}$ is the molar mass, and $\mu_B = 9.2740154 \times 10^{-24}\,JT^{-1}$. The same holds also for the effective moment, which is determined from the Curie–Weiss law via $\chi(T)$ measurements.

## 6. *Electromagnetic c.g.s. and Gaussian Systems*

In the c.g.s. and Gaussian systems, the defining relationship is $\mathbf{B}^* = \mathbf{H}^* + 4\pi\mathbf{M}^*$. Accordingly, one major property of these systems is that **B*** and **H*** have the same numerical value in empty space, considered as an advantage by some and as a disadvantage by others (e.g., Brown 1984). **B*** is given in gauss (G) and **H*** in oersteds (Oe), which are dimensionally equivalent ($cm^{-1/2}g^{1/2}s^{-1}$). The term $4\pi\mathbf{M}^*$ can be considered as the field in gauss arising from the magnetization of the material, whereas the magnetization, **M***, considered as the magnetic moment per unit volume, differs numerically by the factor of $4\pi$ but is dimensionally the same (emu $cm^{-3} \doteq erg G^{-1} cm^{-3} = cm^{-1/2}g^{1/2}s^{-1} = G$).

***Table 2***
Magnetic quantities and conversion from Gaussian to SI units.

| Quantity | Symbol | Gaussian system | Conversion factor | SI system |
|---|---|---|---|---|
| Magnetic flux | $\Phi$ | Mx, G $cm^2$ | $10^{-8}$ | Wb, Vs |
| Magnetic flux density, magnetic induction | $B$ | G | $10^{-4}$ | T, $Wbm^{-2}$ |
| Magnetic potential difference, magnetomotoric force | $U$, $F$ | Gb (gilbert) | $10/4\pi$ | A |
| Magnetic field strength | $H$ | Oe | $1000/4\pi$ | $Am^{-1}$ |
| Volume magnetization | $4\pi M$ | G | $1000/4\pi$ | $Am^{-1}$ |
| Volume magnetization | $M$ | emu $cm^{-3}$, G | 1000 | $Am^{-1}$ |
| Magnetic polarization | $J$ | emu $cm^{-3}$, G | $4\pi \times 10^{-4}$ | T, $Wbm^{-2}$ |
| Mass magnetization | $M$, $\sigma$ | emu $g^{-1}$, G $cm^3g^{-1}$ | 1 | $Am^2kg^{-1}$, $JT^{-1}kg^{-1}$ |
| Magnetic moment | $m$ | emu, erg $G^{-1}$ | 1/1000 | $Am^2$, $JT^{-1}$ |
| Magnetic dipole moment | $j$ | emu, erg $G^{-1}$ | $4\pi \times 10^{-10}$ | Wbm, Vsm |
| Volume susceptibility | $\chi$, $\kappa$ | Dimensionless, emu $cm^{-3}$ | $4\pi$ | Dimensionless |
| Mass susceptibility | $\chi$, $\kappa$ | emu $g^{-1}$, $cm^3g^{-1}$ | $4\pi/1000$ | $m^3kg^{-1}$ |
| Molar susceptibility | $\chi_{mol}$ | emu $mol^{-1}$, $cm^3mol^{-1}$ | $4\pi \times 10^{-6}$ | $m^3mol^{-1}$ |
| Permeability, $\mu = \mu_0\mu_r$ | $\mu$ | $\mu^* = \mu_r$ | $4\pi \times 10^{-7}$ | $Hm^{-1}$, $VsA^{-1}m^{-1}$ |
| Relative permeability, $\mu/\mu_0$ | $\mu_r$ | Dimensionless | 1 | Dimensionless |
| Energy density, energy product | $w$ | $ergcm^{-3}$ | 1/10 | $Jm^{-3}$ |
| Demagnetization factor | $N$, $D$ | Dimensionless | $1/4\pi$ | Dimensionless |

Note that emu is not a unit, it is merely an indication that electromagnetic units are in use. This is also evident from the units frequently used for the mass magnetization ($\text{emu g}^{-1} \doteq \text{erg G}^{-1}\text{g}^{-1} = \text{G cm}^3\text{g}^{-1}$) and the mass susceptibility ($\text{emu g}^{-1} = \text{cm}^3\text{g}^{-1} = \text{emu g}^{-1}\,\text{Oe}^{-1}$). In terms of base units, the volume susceptibility is dimensionless; however, $\chi^*$ is frequently expressed as $\text{emu cm}^3 \doteq \text{emu Oe}^{-1}\text{cm}^{-3} \doteq \text{erg Oe}^{-1}\text{G}^{-1}\text{cm}^{-3} = 1$. Accordingly, the notation $4\pi\chi^*$ for the c.g.s. volume susceptibility is numerically equal to the SI volume susceptibility. The permeability is defined in the Gaussian system as the ratio **B**/**H**, hence the Gaussian permeability, $\mu^*$, is identical to the relative permeability in the SI system: $\mu^* = \mu_r = \mu/\mu_0 = 1 + \chi = 1 + 4\pi\chi^*$ (see also the material equations in Table 1).

Table 2 gives numerical factors for the conversion between the two unit systems: multiply the number for the Gaussian quantity by the conversion factor to obtain the number for the SI quantity (e.g., $1\,\text{Mx} \times 10^{-8}\,\text{WbMx}^{-1} = 10^{-8}\,\text{Wb}$). Note that Gaussian and electromagnetic c.g.s. units are the same for magnetic quantities but are different for their electric counterparts.

## Magnetic Viscosity

Under the name of magnetic aftereffect (or time-lag in magnetization or magnetic viscosity) everything is included that is connected with the influence of time on magnetization phenomena in ferromagnetic bodies, with the following exceptions (a) the influence of the sample inductance, (b) eddy currents, (c) the irreversible relaxation of chemical or topological microstructure, and (d) relaxation phenomena with characteristic timescales less than $10^{-5}$ s. Magnetic relaxation phenomena on shorter timescales are dominated by excitation and damping of spin waves, fast motion of domain walls, etc. These phenomena have been extensively investigated by high-frequency resonance experiments (Haas and Callen 1963).

In a typical viscosity experiment the sample has some given magnetic prehistory and the time dependence of magnetization, $J$, is measured at constant values of temperature, $T$, and magnetic field, $H$. In many cases the prehistory begins, as shown in Fig. 1, at some large positive field, $H_s$, where the sample is in the thermodynamic equilibrium state of magnetic saturation. Then a negative field, $H$, is applied as fast as possible. The magnetization reacts rapidly (in less than $10^{-5}$ s) and achieves some value, $J(0)$, on the major demagnetization curve (see Fig. 1(a)). However, now the sample is not in thermal equilibrium and the sudden change of magnetization is followed by a slow relaxation (the aftereffect) on a timescale of seconds, months, or even longer. The first investigation of the magnetic aftereffect was done by J. A. Ewing in the 1880s.

Experimental evidence distinguishes at least four categories of magnetic aftereffects called (a) the reversible aftereffect, (b) the irreversible aftereffect, (c) the anomalous aftereffect, and (d) quantum tunneling of magnetization. Depending on the material investigated and the specific magnetic prehistory of the samples, various types of the time dependence have been observed for the slow relaxation of magnetization. For a large class of experiments a logarithmic time law has been found:

$$J(t) = J(0) + S \ln(1 + t/t_0) \qquad (1)$$

where $S$ is the magnetic viscosity and $t_0$ is some reference time depending on the sample and on the measuring procedure. The value of $t_0$ is usually obtained by fitting Eqn. (1) to the experimental data. If $t_0$ is not appropriately chosen, $J(t)$ will deviate from logarithmic behavior, i.e., in plots such as that of Fig. 1(b), for values of $t$ within an order of magnitude of $t_0$, the data points will deviate from a straight line. This is not related to the above-mentioned deviations expected for very small values of $t$ ($< 10^{-5}$ s).

Obviously Eqn. (1) is also incorrect for $t \to \infty$. Thus, the magnitude of $J(t)$ cannot exceed the value of the saturation magnetization, $J_s$, of the material and, for example, at zero field the thermal equilibrium value $J = 0$ has to be achieved for $t \to \infty$. However, the aftereffect is usually small and, in many cases, deviations from Eqn. (1) have not been observed even for times $t$ as long as weeks or months. In the typical example of Fig. 1(b) the relaxation of magnetization over a period of some hours is only a

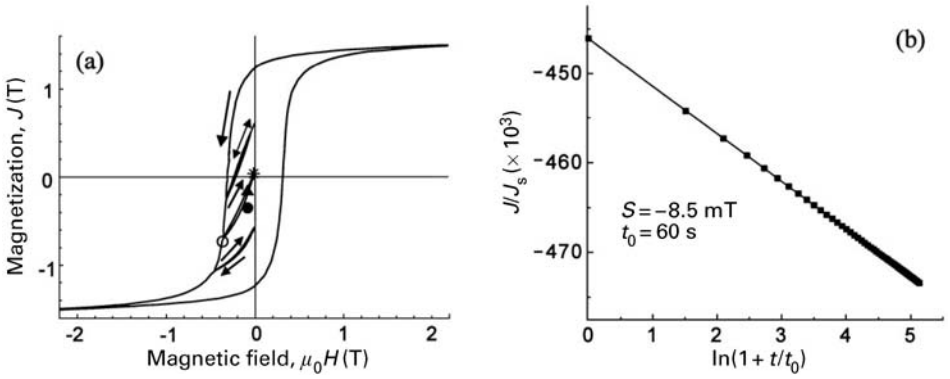

***Figure 1***
(a) Hysteresis loop of the ferromagnetic material $Nd_4Fe_{77}B_{19}$. The marker ○ is at the coordinate ($H$,$J(0)$) where the experiment in (b) starts. Also shown are recoil loops beginning at the major demagnetization curve (left-hand branch of the hysteresis loop). The markers ●, ▲, and * characterize the coordinates where the experiments of Figs. 9 and 10 start. (b) Results of a typical viscosity experiment. The parameters $S$ and $t_0$ are fitted to Eqn. (1); $J_s$ is the magnetization of the previously saturated sample.

few percent. Similar results have been found for all types of ferromagnets ranging from commercial permanent magnets (Givord *et al*. 1987) to the exotic, purely organic soft-magnetic fullerene TDAE-$C_{60}$ (Dunsch *et al*. 1997). Slow relaxation processes similar to the magnetic aftereffect are also known from other fields of physics as the relaxation of remanent magnetization in spin glasses (Huang 1985), the low-frequency dielectric relaxation in ferroelectrics (Jonscher 1983), the elastic aftereffect (found by L. Boltzmann in 1876), or the flux creep in superconductors (Yeshurun *et al*. 1996).

## *1. Reversible Magnetic Aftereffect*

The reversible aftereffect, also called the diffusion or Richter aftereffect, was discovered by G. Richter in 1937 in αFe(C) and interpreted by J. L. Snoek in 1941. This effect is associated with impurity atoms or holes within the ferromagnetic lattice and is observed only in certain substances. In the case of αFe(C) the carbon atoms occupy interstitial sites in the b.c.c. lattice, locally modifying the magnetocrystalline anisotropy in a certain direction (see Fig. 2). When the magnetization is quickly changed owing to a change in the applied magnetic field, the carbon atoms diffuse relatively slowly to a new position. This results in a slow change of the local magnetic anisotropy and, consequently, in a sluggish further change of magnetization. The diffusion aftereffect also occurs if the magnetization is reversibly changed by the magnetic field. If in such a case the field is reversed to its former value, the impurity atoms diffuse back to their former position and the magnetization also relaxes to its former value.

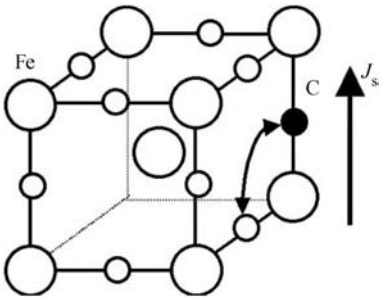

***Figure 2***
Unit cell of the b.c.c. lattice of αFe(C) with one additional carbon atom (●) which diffuses between interstitial sites (●,○) thus changing the effective anisotropy experienced by the local magnetization, $J_s$.

Therefore, this effect is called the reversible aftereffect (Kronmüller 1968). This effect, based on the diffusion of small atoms such as hydrogen, carbon, or nitrogen, has been observed in many crystalline and amorphous alloys as well as intermetallic compounds. An important property of the diffusion aftereffect is that a superposition principle is valid concerning the response of the magnetization, $J(t)$, to previous field jumps, $(\Delta H)_i$, with $i = 1, 2, \ldots$ For viscosity experiments being governed by the reversible aftereffect, a variety of different time dependencies of the relaxing magnetization, $J(t)$, have been reported. This is understandable because, owing to the validity of the superposition principle, the function $J(t)$ can easily be influenced by the magnetic prehistory of the samples.

Depending on the specific selection of the material to be investigated and on the specific magnetic

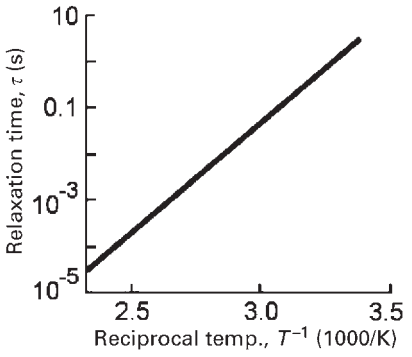

***Figure 3***
Temperature dependence of the relaxation time $\tau$ (according to Eqn. (2)) for an αFe(C) sample (after Chikazumi 1997).

prehistory, a simple exponential time law

$$J(t) = J(0) + J_\tau(1 - e^{-t/\tau}) \tag{2}$$

with a single relaxation time $\tau$ and some constant $J_\tau$, or a sum of such exponential terms or the logarithmic law of Eqn. (1), etc., have been found. As an example, the viscosity experiment on an αFe(C) sample (Chikazumi 1997) can well be described by Eqn. (2), and the temperature dependence of $\tau$ is given by

$$\tau = \tau_0 \exp(E/kT) \tag{3}$$

where $k$ is the Boltzmann constant and $\tau_0$ and $E$ are constants (see Fig. 3). It was shown by H. A. Kramers in 1940 that the Arrhenius formula (Eqn. (3)) results from thermally activated species escaping from a metastable state over an energy barrier $E$. Obviously the diffusion of carbon in αFe(C) is controlled by such an energy barrier.

## 2. *Irreversible Magnetic Aftereffect*

The irreversible aftereffect or fluctuation aftereffect occurs in all ferromagnetic substances and dominates in permanent magnet materials. This effect was discovered by H. Jordan in 1924 who found a field- and a frequency-independent contribution to the losses of a coil with an iron core. The first theoretical analysis of this effect was done by F. Preisach in 1935 who showed that the behavior of the losses is physically equivalent to the logarithmic time law of Eqn. (1) for the magnetization. Preisach also noticed that contrary to the reversible aftereffect, the irreversible aftereffect does not fulfill a superposition principle with respect to a set of succeeding field jumps.

He suggested that the latter effect is based on thermal fluctuations resulting in irreversible changes of magnetization and thus partially destroying the

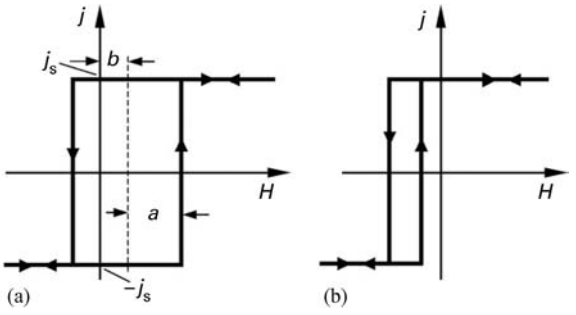

***Figure 4***
Hysteresis loops of two individual bistable units of a Preisach model with the parameters $j_s$, $a$, and $b$: (a) $b>0$, $a>b$; (b) $b<0$, $a<|b|$.

memory of the magnetic prehistory of the sample. Starting with the hypothesis that the irreversible aftereffect and hysteretic magnetization vs. field curves should be based on the same elementary magnetization processes, Preisach introduced a simple model considering ferromagnetic materials as collections of bistable units each of them characterized by its individual rectangular nonsymmetric hysteresis loop (see Fig. 4). If the state of such an individual unit is on its upper branch ($j_s$) or its lower branch ($-j_s$) and the applied field, $H$, is near the critical value $b-a$ or $b+a$ (see Fig. 4), respectively, very small changes of $H$ will result in switching of that unit and, consequently, will contribute to an irreversible change of the total magnetization, $J$, along macroscopic hysteresis curves of the material. In such a critical state of the bistable unit switching will also be caused by small thermal fluctuations, thus contributing to the aftereffect, i.e., to a spontaneous change of $J$ at constant $H$. There has been a resurgence of interest in Preisach-type models (Bertotti 1998) and they have been widely used to describe hysteresis as well as relaxation phenomena.

The role of thermal fluctuations for the irreversible aftereffect was also emphasized by L. Néel in 1951 who introduced the phenomenological relationship

$$S = \mu_0 \chi_{\text{irr}} S_v \tag{4}$$

where $\mu$ is the permeability of vacuum. The irreversible part of the susceptibility, $\chi_{\text{irr}}$, has to be determined from the experimental quantities $\chi$ (susceptibility) and $\chi_{\text{rev}}$ (reversible part of the susceptibility) by $\chi_{\text{irr}} = \chi - \chi_{\text{rev}}$, and the viscosity coefficient, $S_v$, represents some intrinsic fluctuation field. The typical example of Fig. 5 shows that, as expected, $S_v$ does not vary much on a considered hysteresis curve, contrary to the behavior of $\chi_{\text{irr}}$ and $S$. In a theoretical analysis Street *et al.* (1987) found that the quantities in Eqn. (4) depend on the demagnetization factor, $D$, which characterizes the shape of the sample investigated.

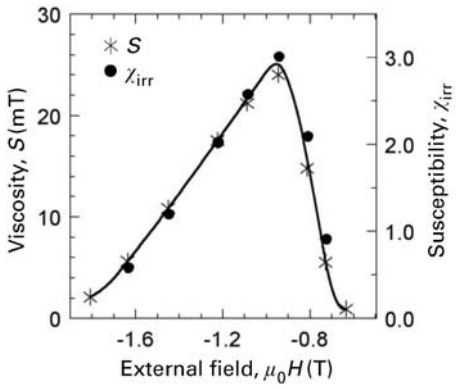

***Figure 5***
Viscosity, $S$, and irreversible susceptibility, $\chi_{irr}$, of a sintered NdFeB permanent magnet at 300 K. The measurements are done on the major demagnetization curve (i.e., starting with a high field $\mu_0 H = 5$ T). The maximum of $S$ and $\chi_{irr}$ is near the coercive field of the material.

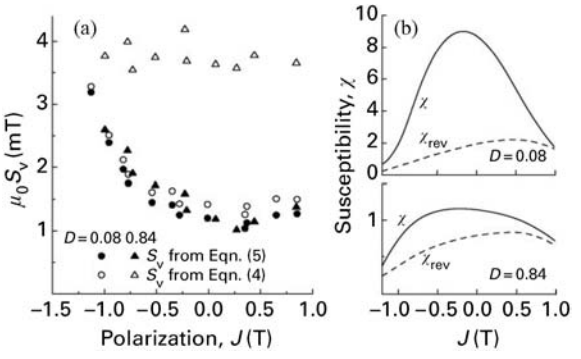

***Figure 6***
(a) Viscosity coefficient, $S_v$, (b) susceptibility $\chi = \partial J/\partial H$ and reversible part of the susceptibility, $\chi_{rev}$, vs. polarization, $J$, for a $Nd_4Fe_{77}B_{19}$ sample (same sample as in Fig. 1), measured on major demagnetization curves for two directions with the demagnetization factors $D = 0.08$ and 0.84. $S_v$ in (a) is calculated according to Eqn. (5) (filled symbols) and Eqn. (4) (open symbols).

Therefore, for $D \neq 0$, Eqn. (4) has to be replaced by

$$S = S_v \frac{\chi_{irr}}{1 - D\chi_{rev}} \tag{5}$$

where now the viscosity coefficient, $S_v$, is independent of $D$ (in its range $0 \leqslant D \leqslant 1$).

This has been experimentally verified for the "spring-magnet" material $Nd_4Fe_{77}B_{19}$ (Müller *et al.* 1994). As can be seen from Fig. 6 the values of $\chi_{rev}$ and $\chi_{irr}$ of this material are very sensitive to $D$, but $S_v$ does not depend much on $D$ if calculated by Eqn. (5). The correlation of the irreversible aftereffect with hysteresis was investigated earlier by J. C. Barbier in 1954 who found a universal relationship between $S_v$ and the coercive field, ${}_JH_c$, for a large class of materials in which both quantities vary over several orders of magnitude (see Fig. 7). From these observations it can be concluded that the magnetic viscosity, just as the coercivity, depends on details of the chemical and topological microstructure of the material considered and modeling of both quantities will be difficult because these microstructural features have to be taken into account.

One of the few model systems for which the problem of slow magnetic relaxation has been exactly solved is an assembly of uniformly oriented small, spherical, noninteracting ferromagnetic particles of equal size, with uniaxial magnetic anisotropy. The particles are characterized, in the continuum theory called micromagnetism, by their spontaneous magnetization, $J_s$, anisotropy constant, $K$, and exchange constant, $A$. The only microstructural parameter of the model is the particle volume, $v$ (or the corresponding

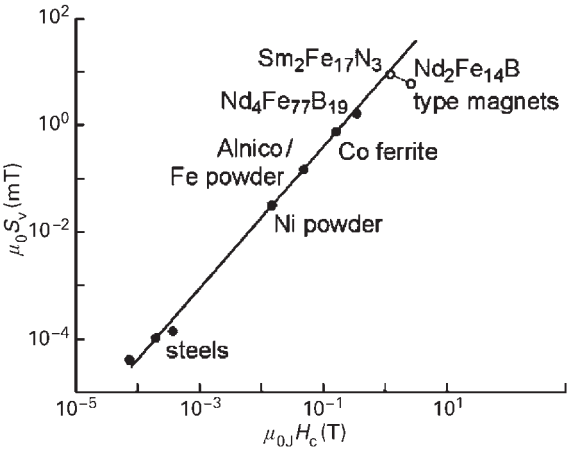

***Figure 7***
Barbier plot showing the correlation between the viscosity coefficient, $S_v$, and the coercive field, ${}_JH_c$, for a large class of magnetic materials. The straight line corresponds to $S_v \sim {}_JH_c^{1.35}$.

diameter, $D$). For $D$ less than a critical size

$$D_c = c\mu_0 (AK)^{1/2} J_s^{-2} \tag{6}$$

where $c$ is about 70, the particles are single domain. For example, for $Nd_2Fe_{14}B$ the value of $D_c$ is about 300 nm. Applying Brownian motion theory it has been shown that for sufficiently low temperature, $T$, and sufficiently large time, $t$, the relaxation of such a

system is well described by Eqns. (2) and (3) where

$$E = Kv \tag{7}$$

$$\tau_0 = c' \frac{J_s}{K} \frac{\hbar}{\mu_B} \left(\frac{kT}{Kv}\right)^{1/2} \tag{8}$$

where $\hbar$ is Planck's constant, $\mu_B$ the Bohr magneton, and $c'$ a number of the order of 1 (Brown 1979, Aharoni 1996). For an $Nd_2Fe_{14}B$ particle of few nanometers in size the room temperature value of $\tau_0$ is about $10^{-11}$ s. It should be noted that in this approach $T$ enters twice, explicitly in the Arrhenius factor of Eqn. (3) and implicitly via the temperature dependence of the material parameters $J_s$, $K$, and $A$.

For real ferromagnetic materials the exponential decay (Eqn. (2)) of magnetization is usually not observed. An often cited example is shown in Fig. 8, where the time dependence of the magnetization obviously obeys Eqn. (1) and the viscosity, $S$, strongly decreases with decreasing temperature. It is well known that Eqn. (2) transforms into Eqn. (1) if a relatively broad distribution, $f(E)$, of activation energies has to be taken into account instead of a single value, $E$ (Street and Wooley 1949, Gaunt 1976). An alternative explanation of the origin of logarithmic relaxation observed in many complex systems has been proposed by Chudnovsky and Tejada (1998). They assume that the slow relaxation is governed by some critical state of the system in which the energy barriers in the Arrhenius relationship of Eqn. (3) depend on the relaxing magnetization, $J$, e.g.,

$$E \sim (J - J_c) \tag{9}$$

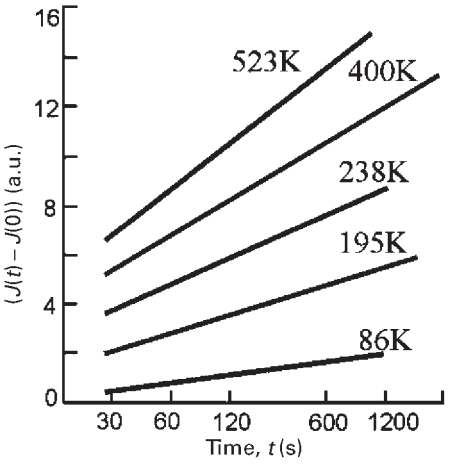

***Figure 8***
Time dependence of the magnetization of an Alnico permanent magnet measured by Street and Wooley (1949) for various temperatures.

If $J$ exceeds the critical value $J_c$ the fast initial change of $J(t)$ stops and, as time goes on, the magnetization grows logarithmically because the system arrives at greater and greater barriers that are more and more difficult to overcome.

To analyze the magnetic viscosity of arbitrary ferromagnetic materials the concept of an activation volume, $v_a$, has been introduced by Street and Woolley (1949):

$$v_a J_s S_v = kT \tag{10}$$

According to Eqns. (3) and (7) the energy barrier $E = kT$ being relevant for the activation of a single-domain particle at temperature $T$ can be written as $vJ_sK/J_s$. A comparison of this expression with Eqn. (10) shows that the anisotropy field, $K/J_s$, is replaced by Néel's fluctuation field, $S_v$, from Eqn. (5) and the particle volume, $v$, by the activation volume, $v_a$. Theoretical and experimental analysis has revealed that $v_a$ is representative for typical elementary magnetization processes such as nucleation of reverse domains or depinning of domain walls. Its value is typically some hundreds of cubic nanometers and the phenomenological relationship $v_a \sim \delta^3 \sim (A/K)^{3/2}$ has been found, where $\delta$ is the domain wall width of the material (Givord *et al.* 1987, Müller *et al.* 1994).

## *3. Anomalous Aftereffect and Thermal Remagnetization*

If a viscosity experiment is dominated by the reversible aftereffect the superposition principle is fulfilled and, consequently, after a sequence of field jumps, $(\Delta H)_i$, with $i = 1, 2, \ldots m$, the rate, $dJ(t)/dt$, may have a sign different from that of the last field jump, $(\Delta H)_m$, or $J(t)$ may even be a nonmonotonic function. The first observation of such a behavior, called the anomalous magnetic aftereffect, was made by A. Mitkevitch in 1936 who measured $J(t)$ in $\alpha$Fe(C) after two field jumps $(\Delta H)_1 < 0$ and $(\Delta H)_2 > 0$ had been applied to the sample.

It had been believed that in viscosity experiments based on the irreversible magnetic aftereffect, the response of magnetization to a sudden change in the applied magnetic field is not very sensitive to the magnetic prehistory of the samples investigated. However, it was shown by Folks *et al.* (1994) by viscosity experiments on recoil curves of a fine-grained, two-phase permanent magnet (similar to the sample of Fig. 1) that some residual information on the magnetic prehistory may be stored even if the superposition principle is not valid. As shown in Fig. 9, the viscosity, $S$, changes its sign if the starting coordinate of the viscosity experiment is moved along the recoil curve. It should be noted that although the two relaxation curves of Fig. 9 are totally different, the magnetic prehistory of the sample is quite similar for

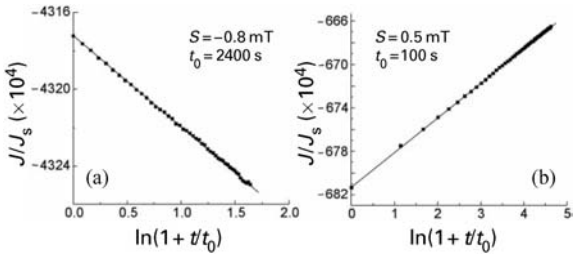

***Figure 9***
Magnetization, $J$, vs. time, $t$, for the sample of Fig. 1 after two field jumps characterized by the markers (a) ○ and ● (in Fig. 1) and (b) ○ and ▲ (in Fig. 1) have been applied. The parameters $S$ and $t_0$ are fitted to Eqn. (1).

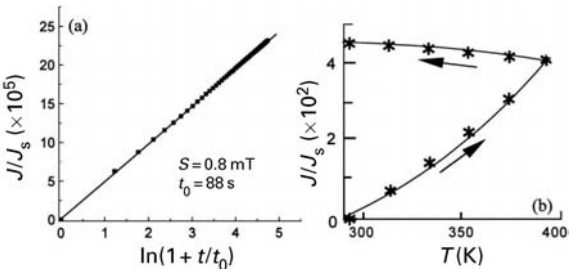

***Figure 10***
Remagnetization phenomena in the sample of Fig. 1 after d.c. field demagnetization characterized by the markers ○ and * (in Fig. 1): (a) spontaneous remagnetization at room temperature (where the sample had been demagnetized); (b) thermal remagnetization.

both cases. The data of both Figs. 9(a) and (b) obey Eqn. (1). However, the magnitude, $|S|$, of the viscosity is considerably smaller compared to the conventional aftereffect experiment of Fig. 1(b). The fit yields very different effective waiting times, $t_0$, although all the measuring procedures were done on the same timescale. Obviously the large value of $t_0$ in Fig. 9(a) represents the more complicated magnetic prehistory compared to that corresponding to Fig. 1. If the coordinate on the recoil curve is appropriately chosen the material of Fig. 1 even shows an anomalous magnetic aftereffect, i.e., the magnetization is a nonmonotonic function of time.

The final coordinate * on the recoil curve which starts at the coordinate ○ in Fig. 1(a) represents the d.c.-demagnetized sample. The time dependence of the magnetization of such a sample is shown in Fig. 10(a). As expected from Fig. 9(b) the sample remagnetizes spontaneously, i.e., without an external field. Seemingly the system moves away from the state of thermal equilibrium where the sample magnetization, $J$, is zero. As shown in Fig. 10(b), a much stronger spontaneous increase of magnetization is observed if the d.c. field-demagnetized sample is heated and subsequently cooled to the starting temperature. This effect is called thermal remagnetization and was discovered by Kavalerova *et al.* (1975) for $SmCo_5$ permanent magnets. In principle, the results of Figs. 9 and 10 are understandable for systems with different relaxation times. If in such a system appropriate initial conditions are realized by an appropriate magnetic history, the magnetization, $J$, may, in certain periods of time, move away from its equilibrium value and the time dependence, $J(t)$, may be nonmonotonic.

However, as has been pointed out by Preisach and has been proved for small particles (Brown 1979, Aharoni 1996), a remarkable relaxation of $J$ will only be observed if the external field, $H$, is close to the coercive field of the sample or to some switching field of a subsystem. If, for example, the Preisach units of Fig. 4 are in the state $j = -j_s$, relaxation will only occur if the applied field, $H$, is close to $(a + b)$, etc. However, it is well known that, for general reasons of symmetry, noninteracting subunits of a system (e.g., particles) have symmetric whysteresis loops. Consequently, in such systems $H > 0$ will always result in $dJ/dt > 0$ and $H < 0$ in $dJ/dt < 0$. Thus the results presented in Figs. 9 and 10 are due to interaction of subunits. The coupling of the subunits can be caused by exchange or by magnetostatic interaction and its effect on slow magnetic relaxation will be particularly pronounced if the Preisach subunits vary much in their "hardness," i.e., in the parameter $a$ in Fig. 4. As a typical example, the so-called spring-magnet material for which the data of Figs. 1, 6, 9, and 10 have been measured consists of a relatively hard and a relatively soft magnetic phase and both phases are assumed to be exchange coupled to each other. (See *Magnets: Remanence-enhanced*)

Hence, if the hard units are predominantly in their upper state $+j_s$, typical soft units will be shifted to the left-hand half of the Preisach plane (see Fig. 4(b)) and even at $H \leqslant 0$ (as in the coordinates ▲ and * in Fig. 1(a)) they may switch from $-j_s$ to $+j_s$ thus contributing to $dJ/dt > 0$ of the sample. The enhancement of this effect by heating (Fig. 10(b)) can be understood by the fact that the anisotropy constant, $K$ (and consequently the parameter $a$ in Fig. 4), decreases more strongly with increasing temperature than the strength of interaction (i.e., parameter $b$ in Fig. 4). Therefore, heating has a similar effect on the subunit in Fig. 4(b) as an increase of the field, $H$, whereas the relatively hard subunits will not be as much influenced by heating.

The relaxation behavior of a Preisach system (Bertotti 1998) is demonstrated in Fig. 11. The material is described by a probability distribution $p(a, b)$ for the parameters $a$ and $b$ of Fig. 4. In an applied field, $H$, all Preisach units with $b < H - a$ have the magnetization $+j_s$, those with $b > H + a$ have the magnetization $-j_s$. The state of the remaining units depends on the prehistory of the system. The time dependence of the assembly is determined by the

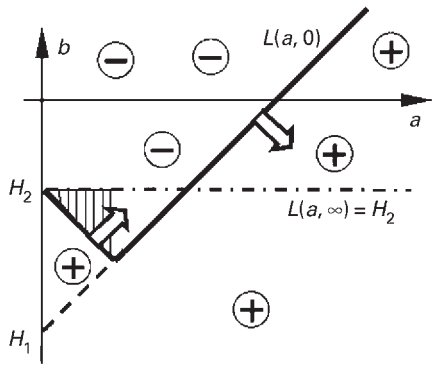

***Figure 11***
In the Preisach plane ($a$, $b$) the state of the collection of units of Fig. 4 is described by the border line $L(a, t)$ separating the units with $+j_s$ (region with + signs) from those with $-j_s$ (regions with – signs). The bold line represents $L(a, t=0)$ immediately after a sequence of field jumps $H=\infty \rightarrow H_1 \rightarrow H_2$ ($H_2 > H_1$, where $H_1$ corresponds to the marker ○ in Fig. 1). $L(a, \infty)$ is the equilibrium line. ⇒ indicates the movement of $L(a, t)$. The units in the hatched region have lower energy barriers than those near the branch of the border line with positive slope.

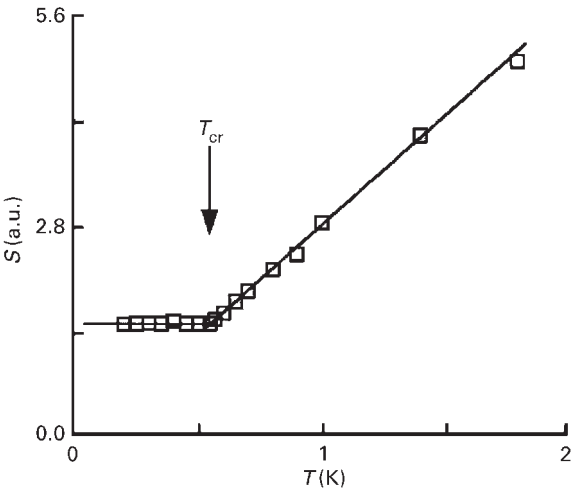

***Figure 12***

border line $L(a, t)$, which separates the units with $+j_s$ from those with $-j_s$. This border line and $p(a, b)$ determine the magnetization of the assembly. The border line $L(a, 0)$ for a sequence of field jumps in the applied field from a large positive value of $H$ to $H_1$ and then to $H_2$, immediately after the jump to $H_2$, is shown in Fig. 11 ($H_2 > H_1$, $H_1$ corresponds to ○ in Fig. 1). The equilibrium state is given by $L(a, \infty) = H_2$ and is reached by a motion of the border line owing to thermally activated reversal processes. The evolution equation for $L(a, t)$ has been derived within generalized thermodynamics, treating the border line as an "internal degree of freedom" and using an Arrhenius-type equation for the magnetization reversal of the single units corresponding to the points ($a$, $b$) near the border line. For the sequence of field jumps described above the two branches of the border line $L(a, 0)$ in Fig. 11 result in contributions of different sign to the magnetization change in time. The units with $a < (H_2 - H_1)/2$ (hatched region) have smaller energy barriers than those with $a > (H_2 - H_1)$, and the typical time constants for the units within the hatched region are smaller. Therefore, in the early stages the units in the hatched region will change more rapidly and the magnetization will first move in a positive direction and later it will decrease.

## 4. *Quantum Tunneling of Magnetization*

As discussed above, most experimental results on viscosity experiments, e.g., those presented in Figs. 3 and 8, suggest that the reversible as well as the irreversible magnetic aftereffects are based on thermally activated processes and, consequently, both effects should disappear at very low temperatures. Contrary to this prediction Lambeck (1971) found for various materials that the magnetic viscosity, $S$, does not go to zero but approaches a finite constant value at low temperatures and it is assumed that the reason for this observation is quantum tunneling through potential barriers, as predicted by H. A. Kramers in 1940 for certain types of metastable states. It has been proved theoretically (Caldeira and Leggett 1981) that for quantum tunneling of macroscopic quantities, such as the magnetization, the tunneling probability may be enhanced by the dissipative coupling of the macroscopic coordinates to the environment. However, it has been shown by Barbara and Gunther (1993) that there are situations (e.g., particular distributions of energy barriers) where a plateau in $S(T)$ can also arise under purely classical thermal activation. In spite of this restriction a finite magnetic viscosity at low temperatures caused by quantum tunneling has been clearly demonstrated for various materials (Chudnovsky and Tejada 1998). For example, the magnetic relaxation in $TbFe_3$ films is found to be perfectly logarithmic and the magnetic viscosity, $S$, defined by Eqn. (1), indicates a crossover from thermal to temperature-independent relaxation at $T_{cr} = 6\,\mathrm{K}$ (see Fig. 12).

# Magnetism in Solids: General Introduction

Magnetism represents a class of fascinating physical phenomena that is intimately connected with the behavior of electrons in materials. Nuclear particles with spin also give rise to magnetic phenomena, but these are characterized by a much weaker (nearly 2000 times) magnetic response. This article is mostly devoted to "electronic" magnetism.

Although properties of the lodestone (magnetite) were already known to the Ancient Greeks by 800 BC, magnetism remains even nowadays a field of permanently growing interest. The interest is on the one hand motivated by outstanding magnetic and related electronic properties of novel materials which find frequent use in everyday modern life.

On the other hand, open questions about the electronic structure of materials and its projection in magnetic, magnetoelastic (see *Magnetoelastic Phenomena*), magnetotransport (see *Magnetoresistance: Magnetic and Nonmagnetic Intermetallic*; *Giant Magnetoresistance: Metamagnetic Transitions in Metallic Antiferromagnets*), and magnetocaloric (see *Magnetocaloric Effect: From Theory to Practice*) phenomena represent a serious challenge both to theorists and experimentalists active in research into condensed matter.

For studies of the relationship between magnetism and electronic structure investigation of materials exposed to extreme conditions, such as high magnetic field or high external pressure, is frequently helpful. In the former, the application of a high magnetic fields allows, for example, the determination of the energy of magnetocrystalline anisotropy and exchange interactions between magnetic moments or magnetic-field-induced changes of electronic structure connected, e.g., with itinerant electron metamagnetism (see *Magnetism: High-field* and *Itinerant Electron Systems: Magnetism (Ferromagnetism)*). Application of external pressure, on the other hand, facilitates experiments studying the effects of varying interatomic distances on exchange interactions and other characteristic features of electronic structure (see *Magnetic Systems: External Pressure-induced Phenomena*).

This article is devoted to a brief general introduction to the physics of magnetism in solids. In Sect. 1, basic categories of magnetic behavior of materials are presented phenomenologically. Sections 2 and 3 point to microscopic mechanisms responsible for the bulk magnetic properties. Basic information on magnetic phase transitions and related phenomena is given in Sect. 4, while Sect. 5 focuses on magnetocrystalline anisotropy, its origin, and consequences. Basic models in magnetism are introduced in Sect. 6.

Where desirable, cross-references are given to articles covering particular subjects. For detailed study of various aspects of magnetism in solids several

literature sources are recommended. Besides the extended chapters on magnetism that can be found in widely known text-books on solid-state physics (Kittel 1976, Ashcroft and Mermin 1988), several books concentrating on magnetism are recommended (Chikazumi 1964, Cracknel 1975, Barbara *et al.* 1988, Gilles 1994) including the theory of magnetism (Mattis 1981, Yosida 1996). As a useful reference source the continuously updated series edited by Buschow (e.g., Buschow and Wohlfarth 1993) may be used. In the books listed above information can also be found on further aspects of magnetism in materials.

The most up-to-date information on the research in the field of magnetism can be obtained from numerous journals (e.g., *Journal of Magnetism and Magnetic Materials*, *Physical Review B*, *Europhysics Journal B* (the follower of the *Zeitschrift für Physik B* and *Journal de Physique*), *Journal of Physics: Condensed Matter* and *Journal of Japanese Physical Society*) and at international conferences devoted to physics of magnetism as, e.g., the triennial International Conference of Magnetism (ICM), which was held in 2000 in Recife (Brazil) with proceedings published in the *Journal of Magnetism and Magnetic Materials*; the annual conference of the American Institute of Physics—the Conference on Magnetism and Magnetic Materials (MMM) which has proceedings regularly published in the *Journal of Applied Physics* (the last MMM was held in 2001 in San Antonio). Since different units can still be found in different literature, the reader is referred to *Magnetic Units* for further information.

## 1. Basic Types of Magnetic Behavior

Initial information on magnetic behavior of a particular material is usually obtained from measurements of the magnetic response of a sample to an applied magnetic field $H$. The bulk magnetization $M$ is studied by magnetometers that measure the force exerted on a sample in an inhomogeneous external magnetic field or electrical current induced in pick-up coils by moving through a magnetized sample (Cahn and Lifshin 1993, Chikazumi 1964).

The rate of the magnetization change with the magnetic field

$$\vec{M} = \chi \vec{H} \tag{1}$$

determines the magnetic susceptibility $\chi$. Detailed knowledge of the magnetic field and temperature dependence of magnetization $M(H, T)$ and magnetic susceptibility $\chi(T)$, which are the basic magnetic characteristics of a material, frequently allows the drawing of conclusions about the type of magnetism, especially in simple systems. The basic categories of magnetic behavior of materials are diamagnetism, paramagnetism, ferromagnetism, antiferromagnetism, ferrimagnetism, and metamagnetism.

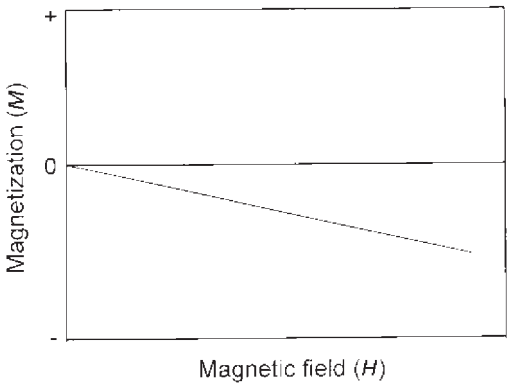

***Figure 1***
Typical magnetic field dependence of magnetization for a diamagnet (full line).

### 1.1 Diamagnetism

Regarding the sign of magnetic susceptibility, a negative material response to an external magnetic field ($\chi < 0$) is classified as diamagnetic. If a diamagnet is exposed to an external magnetic field a negative magnetization (see Fig. 1) is induced due to a moving electron charge in a manner described by Lenz's law of electromagnetism. Consequently a negative susceptibility

$$\chi = -\frac{\mu_0 N Z e^2}{6 m_e} \langle r^2 \rangle \tag{2}$$

is observed, where $n$ is the number of atoms per unit volume, $Z$ is the number of electrons in filled shells per atom, $e$ and $m_e$ are the electronic charge and mass, respectively, $\langle r^2 \rangle$ is the root mean square atomic radius (typically $10^{-21}$ m), and $\mu_0$ is the permeability of the vacuum.

The susceptibility of a diamagnet is very weak and essentially independent of temperature. Typical examples of diamagnets are copper, silver, gold, bismuth, beryllium, and germanium with values of susceptibility ranging from $-5.6 \times 10^{-7}$ (Ge) to $-2.7 \times 10^{-6}$ (Au). Generally speaking, diamagnetism is present in all substances under applied magnetic field due to inevitable electromagnetic induction in a moving electron charge system. Nevertheless, it can be well detected only in materials containing atoms without permanent magnetic moments. Permanent magnetic moments, which are associated with incomplete *d*- and *f*-electron shells (see Sect. 2 and *Localized 4f and 5f Moments: Magnetism*), yield a much stronger positive susceptibility.

A weak temperature-independent diamagnetic susceptibility (Landau diamagnetism) is produced by conduction electrons in metals (Kittel 1976, Ashcroft and Mermin 1988).

Superconductors exhibit strong diamagnetism with the susceptibility reaching $\chi = -1$ (value for an ideal diamagnet). The diamagnetic susceptibility of a superconductor is strongly temperature-dependent and vanishes at temperatures above the superconducting temperature (Cahn and Lifshin 1993, also see *Electrodynamics of Superconductors: Flux Properties*).

### *1.2 Paramagnetism*

Paramagnets are generally known as materials with atoms (ions) carrying weakly interacting permanent magnetic moments. As a consequence of negligible exchange interactions between moments a true paramagnet shows no sign of magnetic ordering down to the lowest temperatures. In sufficiently low magnetic fields and at not too low temperatures $\mu_B \mu_0 H / k_B T \ll 1$ ($k_B$ is the Boltzmann constant and $\mu_B$ is the Bohr magneton). The magnetization of a paramagnet varies linearly with the applied magnetic field yielding a field-independent susceptibility (see Fig. 2).

The magnetic susceptibility of a paramagnet is positive and strongly dependent on temperature. As a rule the susceptibility of a paramagnet follows the Curie law

$$\chi = \frac{C}{T} \tag{3}$$

where $C$, the Curie constant, is proportional to the sum of the squares of the effective moments, $\mu_{\text{eff}}$, in a unit volume. The effective magnetic moment of an atom characterized by total-angular-momentum quantum number $J$ is:

$$\mu_{\text{eff}} = g_J \sqrt{J(J+1)}\mu_B \tag{4}$$

where $g_J$ is the Landé factor (see *Localized 4f and 5f Moments: Magnetism*). The Curie law implies that the inverse susceptibility of a paramagnet is proportional to temperature as can be seen in Fig. 2.

In higher fields and at lower temperatures the magnetization is no longer a linear function of the magnetic field (and consequently the Curie law is no longer valid) but in many cases can be expressed as:

$$M = M_o B_J(x), \tag{5}$$

where

$$M_o \approx g_J J \mu_B, \tag{6}$$

is the maximum attainable magnetization for a material with one type of "magnetic" atoms characterized by $J$. The function $B_J(x)$ is the Brillouin function of the argument

$$x = \frac{g_J J \mu_0 H \mu_B}{k_B T} \tag{7}$$

The graphical representation of $B_J(x)$ for several typical values of $J$ is shown in Fig. 3. For further

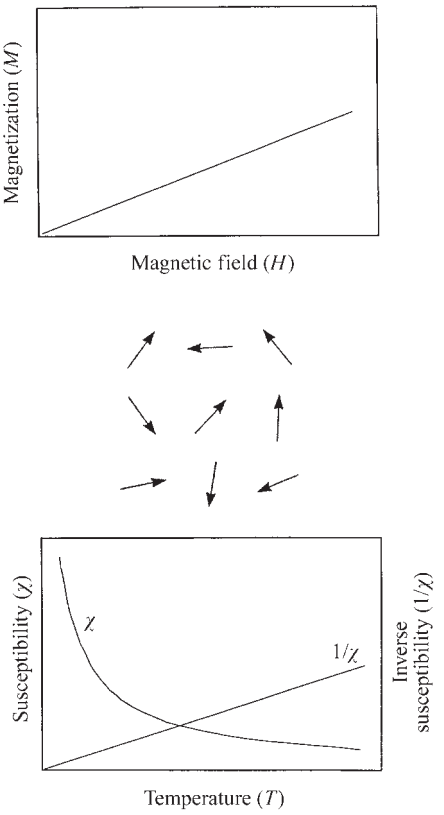

***Figure 2***
Typical magnetic field dependence of magnetization and temperature dependence of inverse susceptibility for a paramagnet with localized magnetic electrons. The randomly oriented magnetic moments in a paramagnet are illustrated schematically.

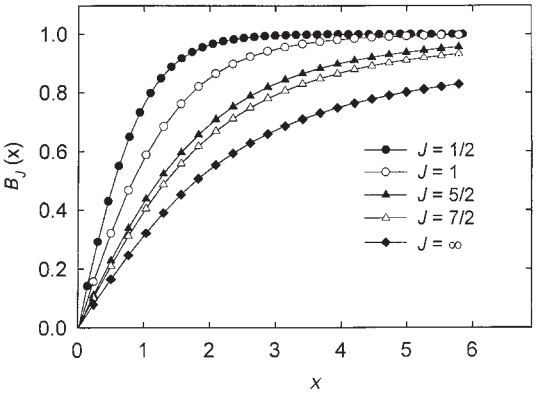

***Figure 3***
The Brillouin function plotted for several typical values of $J$.

details see, e.g., Kittel (1976), Ashcroft and Mermin (1988), or Gilles (1994).

In metals the Pauli paramagnetism that is characterized by a nearly temperature-independent susceptibility is also observed. The Pauli susceptibility is proportional to the density of conduction–electron states at the Fermi level $E_F$. This behavior is a consequence of the magnetic-field-induced splitting of the spin–up and spin–down conduction–electron energy sub-bands (Kittel (1976, Ashcroft and Mermin (1988). The Pauli susceptibility can be strongly enhanced in systems with narrow bands crossed by $E_F$ at a high density of states (see also *Itinerant Electron Systems: Magnetism (Ferromagnetism)* and *Heavy-fermion Systems*).

### *1.3 Ferromagnetism*

In a material with strongly interacting magnetic moments cooperative phenomena can be observed, yielding long-range ordering of magnetic moments (magnetic ordering) at temperatures below a characteristic temperature. The most widely known type of magnetic ordering is ferromagnetism. Ferromagnetic ordering of magnetic moments means that they are aligned parallel to one another (see Fig. 4), which is accomplished by a ferromagnetic exchange interaction (see Sect. 3). The characteristic temperature of a ferromagnet is the Curie temperature ($T_C$), at which the susceptibility diverges. At temperatures below $T_C$ a spontaneous magnetization (i.e., a finite magnetization existing in zero external magnetic field) emerges. Values of the Curie temperature of some typical ferromagnets are given in Table 1.

At temperatures considerably higher than $T_C$, the magnetic moments behave as in a paramagnet and the magnetic susceptibility follows the Curie–Weiss law:

$$\chi = \frac{C}{T - \Theta_p} \tag{8}$$

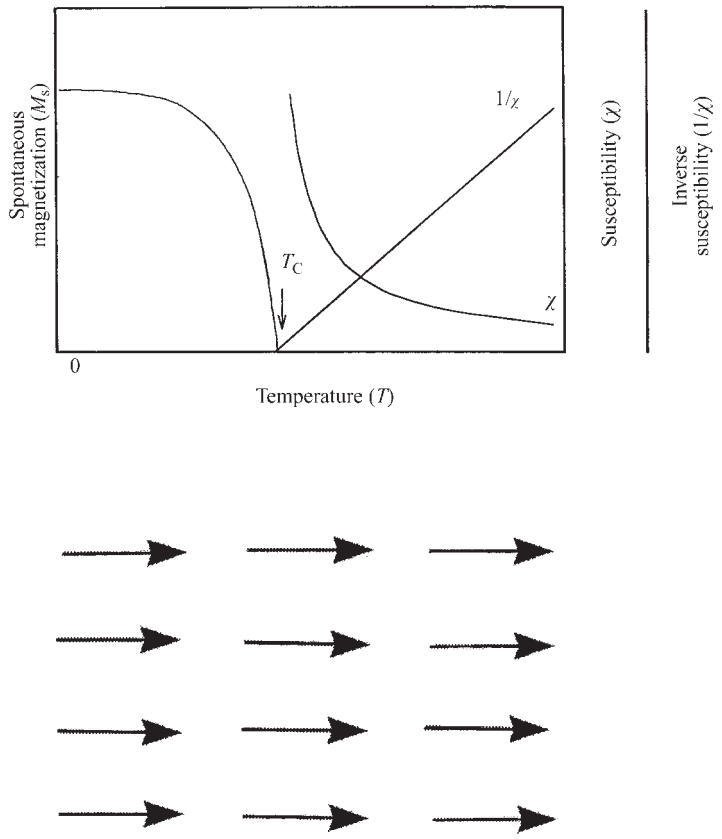

***Figure 4***
Typical behavior of a ferromagnet: temperature dependence of inverse susceptibility at temperatures above the Curie temperature ($T > T_C$) and spontaneous magnetization at $T < T_C$. The ferromagnetically coupled magnetic moments in a ferromagnet $T < T_C$ are illustrated schematically.

***Table 1***
Curie temperatures of several typical ferromagnets.

| Material | Curie temperature $T_C$ (K) |
|---|---|
| Iron (Fe) | 1043 |
| Cobalt (Co) | 1403 |
| Nickel (Ni) | 631 |
| Gadolinium (Gd) | 293 |
| $GdNi_2$ | 79 |
| Alnico | 1123 |
| $SmCo_5$ | 993 |
| $Nd_2Fe_{14}B$ | 585 |

as can be seen in Fig. 4. The parameter $\Theta_p$ is called the paramagnetic Curie temperature and in simple ferromagnets $\Theta_p \approx T_C$. Note in relation to the discussion in Sect. 1.2 that in the paramagnetic regime at temperatures close to $T_C$ and in sufficiently high magnetic fields the magnetic field dependence of magnetization becomes strongly nonlinear and the temperature dependence of the susceptibility cannot be described by the Curie–Weiss law.

At temperatures below $T_C$ ferromagnets show several characteristic features. Principally there is the appearance of a spontaneous magnetization (magnetization observed in zero magnetic field) within one domain (see *Magnets, Soft and Hard: Domains*). The spontaneous magnetization increases with decreasing temperature as shown in Fig. 4. A block of a ferromagnet contains, as a rule, a number of domains whose spontaneous magnetizations compensate mutually so that the total bulk magnetization is zero. When a magnetic field is applied, the magnetization increases with increasing field strength and in a sufficiently high field the magnetization saturates at the value of saturated magnetization, $M_0$, shown schematically in Fig. 5. Ferromagnetic materials exhibit a large variety of magnetization curves which frequently show a hysteresis with respect to the history of application of the magnetic field (see *Magnetic Hysteresis*; *Soft Magnetic Materials: Basics*; *Hard Magnetic Materials, Basic Principles of*). These features of ferromagnets are particularly important in some applications of magnetic materials.

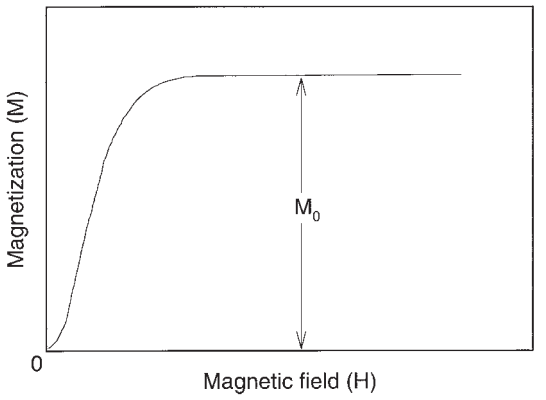

***Figure 5***
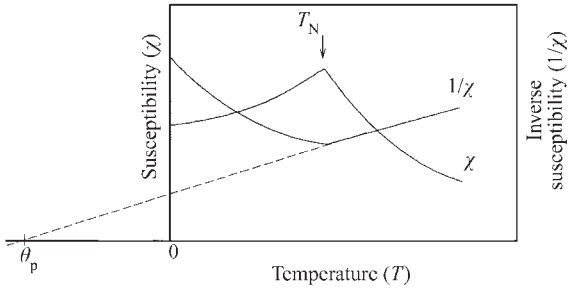
Typical magnetization curve of a ferromagnet (ferrimagnet).



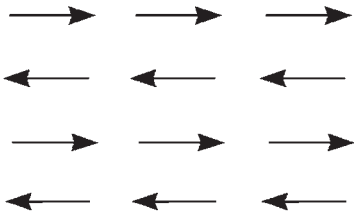


***Figure 6***
Typical temperature dependence of inverse susceptibility for an antiferromagnet. The antiferromagnetically coupled magnetic moments in an antiferromagnet $T < T_N$ are illustrated schematically.

### *1.4 Antiferromagnetism*

In the case of an antiferromagnetic coupling between the neighboring magnetic moments their antiparallel ordering (see Fig. 6) is established at temperatures lower than the Néel temperature $T_N$. At temperatures higher than $T_N$, the magnetic moments behave as in a paramagnet and the magnetic susceptibility follows the Curie–Weiss law (Eqn. (5)). However, for ferromagnets $\Theta_p > 0$, and the paramagnetic Curie temperature for simple antiferromagnets is usually negative ($\Theta_p < 0$). At low temperatures below $T_N$, the susceptibility decreases (inverse susceptibility increases, as shown in Fig. 6). For simple antiferromagnets the maximum on the $\chi(T)$ curve is located at $T_N$. In many real systems $T_N$ does not coincide with the susceptibility maximum but with the maximum in $\partial(T\chi)/\partial T$ (Fisher 1962).

In contrast to ferromagnets, antiferromagnets exhibit zero spontaneous magnetization (see also Sect. 3). This is obvious for a simple antiferromagnet in which pairs of magnetic moments coupled in an antiparallel manner mutually compensate. The behavior of a simple antiferromagnet can be understood within the Néel model by considering the antiferromagnet in terms of two interpenetrating ferromagnetic sublattices A and B with an antiparallel coupling of the sublattice magnetizations $M_A$ and $M_B$ ($|M_A| = |M_B|$) (Chikazumi 1964, Barbara *et al.* 1988).

### 1.5 Ferrimagnetism

Ferrimagnetism is a term that was originally proposed by Néel to describe the magnetic ordering phenomena in ferrites (see *Transition Metal Oxides: Magnetism*), in which Fe ions appear in two different ionic states and hence bear different magnetic moments with mutual antiferromagnetic coupling. The ferrimagnet can be considered in a loose analogy as a two-sublattice antiferromagnet with $|M_A| \neq |M_B|$. In this context ferrimagnets appear sometimes in literature under the name "uncompensated antiferromagnet". As a consequence, a net spontaneous magnetization $M_s$ ($= M_A - M_B$) is observed at temperatures below the ordering temperature $T_C$. Various types of $M_s(T)$ curves are found for ferrimagnets depending on the temperature variation of sublattice magnetizations. Two types of behavior are shown in Fig. 7.

At temperatures well above $T_C$, paramagnetic behavior is observed with the magnetic susceptibility following the Curie–Weiss law, usually with a negative value of $\Theta_p$. At a certain temperature interval above $T_C$, the $1/\chi$ vs. $T$ dependence forms a curve as seen in Fig. 7. This behavior can also be accounted for within the Néel sublattice model.

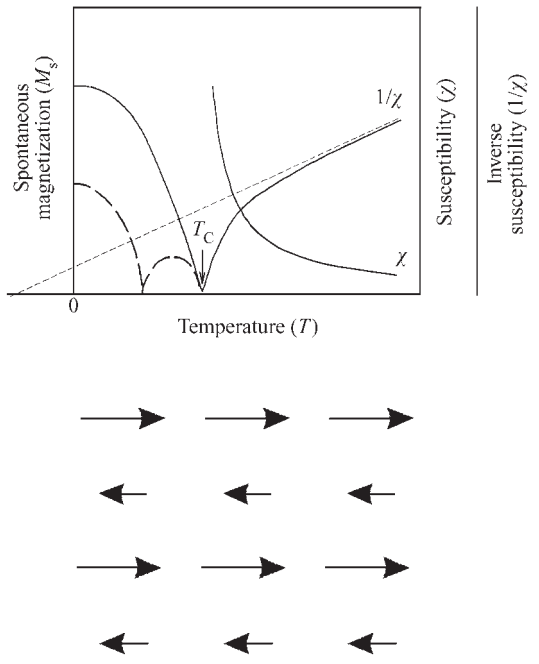

***Figure 7***
Typical behavior of a ferrimagnet: temperature dependence of inverse susceptibility at temperatures above the Curie temperature ($T > T_C$) and spontaneous magnetization $M_s$ at ($T < T_C$). The antiferromagnetically coupled inequivalent magnetic moments in a ferrimagnet at $T < T_C$ are illustrated schematically. When $M_A \gg M_B$ at all temperatures the $M_s(T)$ resembles a ferromagnet (full line). In some materials a special situation appears due to strongly different temperature dependencies of sublattice magnetization. In particular, if $|M_A| < |M_B|$ for $T_{comp} < T < T_C$, $M_A = -M_B$ and $|M_A| > |M_B|$ for $T < T_{comp}$ (dashed line); at $T_{comp}$, $M_A = -M_B$, i.e., the sublattice magnetizations compensate and $T_{comp}$ is called the compensation temperature.

### 1.6 Metamagnetism

When a sufficient magnetic field is applied to some materials which exhibit no or a small spontaneous magnetization an abrupt transition to a high magnetization state may be induced (see Fig. 8) (see also Sect. 5.2). The transition is usually called the metamagnetic transition (MT) and the high magnetization state is called metamagnetic because it is a metastable state (it disappears as soon as the magnetic field is removed). There are several rather different mechanisms which cause a MT (see *Magnetic Phase Transitions: Field-induced (Order to Order)*; *Metamagnetism: Itinerant Electrons*; *Magnetism: High-field*). An important parameter of metamagnetism is the critical field $H_c$ at which the MT occurs ($H_c$ is usually associated with the midpoint of the transition). The low field state ($H < H_c$) of a material exhibiting a MT is usually antiferromagnetic, ferrimagnetic, or in some special cases enhanced paramagnetic.

### 1.7 Remarks

Note that diamagnetism of filled electronic shells is an inevitable property of all solids containing atoms (ions) with some filled electronic shells. In metals there is also a weak paramagnetic Pauli susceptibility term (together with the Landau diamagnetic susceptibility) due to conduction electrons that always contributes to magnetic behavior. These weak susceptibility contributions are in materials with permanent magnetic moments usually hidden by the much stronger positive magnetic (paramagnetic, antiferromagnetic, ferrimagnetic, ferromagnetic, etc.) response. Nevertheless, a proper analysis of magnetic data requires that the weak diamagnetic and the Pauli

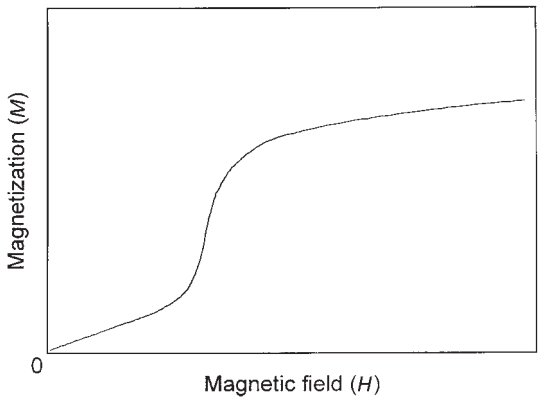

*Figure 8*
Typical magnetic field dependence of magnetization of a material exhibiting metamagnetism.

paramagnetic terms are also taken into account when not completely negligible.

The bulk magnetization is a sum of individual magnetic moments in the material. Therefore it is obvious that the knowledge of magnetic field and/or temperature dependence of the magnetization (susceptibility) allows only rather limited and frequently ambiguous conclusions to be reached concerning details of the arrangement of magnetic moments, their dynamics, relation to electronic structure, etc. Realistic studies of microscopic aspects of magnetism require the application of methods that use local probes to sense phenomena in the material on the microscopic scale.

Traditionally, the most frequently used microscopic methods in magnetism, especially powerful in studies of magnetic structures and magnetic excitations, are based on various aspects of neutron scattering in materials (Bacon 1975, Squires 1978, Barbara *et al*. 1988) (see *Magnetism: Applications of Synchrotron Radiation*). These experiments are made possible by intensive stationary or pulsed beams of thermal or cold neutrons available at large neutron facilities. Representative examples of reactor based facilities (most of which are open to the external user community) are the Institute-Laue-Langevin (ILL), (http://www.ill.fr), JAERI (http://www.jaeri.go.jp), NIST Research Center (http://rrdjazz.nist.gov/), Oak Ridge, Chalk River Laboratories (http://neutron.nrc.ca/), and Hahn-Meitner-Institut (http://www.hmi.de).

Spallation sources provide high-intensity pulsed neutron beams at various facilities: ISIS (http://www.isis.rl.ac.uk/), LANSCE (http://lansce.lanl.gov), IPNS (http://www.pns.anl.gov/), and SINQ at PSI (http://www1.psi.ch).

Excellent complementary microscopic tools are offered by rapidly developing methods based on x-ray scattering in magnetic materials (see *Magnetism: Applications of Synchrotron Radiation*). These methods have developed as a result of the high-intensity x-ray beams produced at the most powerful synchrotron facilities, e.g., ESRF (http://www.esrf.fr), NSLS Brookhaven National Laboratory (http://www.nsls.bnl.gov/), and SPRING-8 Himeji.

Fundamental microscopic experiments revealing direct connections between electronic structure and magnetism can be performed using advanced photoemission methods (see *Photoemission: Spin-polarized and Angle-resolved*).

Mössbauer spectroscopy and other methods studying hyperfine interactions, such as NMR, NQR (nuclear quadrupole resonance), and PAC (perturbed angular correlations) (Cahn and Lifshin 1993) (see Perturbed Angular Correlations (PAC)), allow the study of magnetic systems probed by a hierarchy of nuclear energy levels which is established partly as a result of hyperfine interactions between the nucleus and the electronic system. Methods exploiting muon spin rotation and relaxation ($\mu$SR) offer unique possibilities to observe very small magnetic moments on a level of $10^{-2}\,\mu_B$ as well as various aspects of dynamics of magnetic systems (Schenck and Gygax 1995) (see *Muon Spin Rotation ($\mu$SR): Applications in Magnetism*).

The rapid development of theoretical methods and computer codes and the concomitant increase in capacity and speed of modern computers have made realistic *ab initio* calculations of the electronic structure of magnetic materials widely available. Predictions made by such calculations have motivated new experiments focused on particular problems (Brooks and Johanson 1993, Sandratskii 1998) (see *Density Functional Theory: Magnetism*).

## 2. Magnetic Moments of d and f Transition Elements

An atom (ion) has a net magnetic moment when an inner *d*- or *f*-electron shell is incomplete such that the individual electronic moments within the shell do not cancel completely. In the Periodic Table there are five groups of elements in which this incomplete cancellation occurs: the iron group (3*d*), the palladium group (4*d*), the rare earth (or lanthanide) group (4*f*), the platinum group (5*d*), and the actinide group (5*f*).

Free-atom *d* and *f* electrons possess magnetic moments (Kittel 1976, Ashcroft and Mermin 1988) that are predicted based on the principles of quantum mechanics (see *Transition Metal Oxides: Magnetism* and *Localized 4f and 5f Moments: Magnetism*). When an atom (ion) of a transition element is embedded in a solid, these moments often disappear when the electron orbitals overlap and bond, which leads to delocalization of the *d* or *f* electrons—the electrons become itinerant. Metallic or covalent bonding is

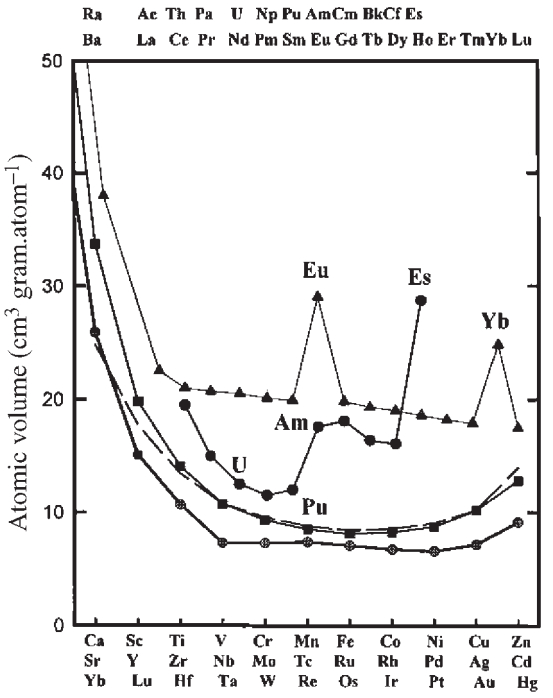

***Figure 9***
Evolution of atomic volume across 3*d* (hexagons), 4*d* (squares), 5*d* (dashed line), 4*f* (triangles), and 5*f* (circles) transition metal series.

inconsistent with magnetic moments that mostly arise from localized electrons. Onset of this bonding is clearly reflected in a decrease in atomic volume. This effect is well seen in Fig. 9 for transition metals (3*d*, 4*d*, and 5*d*). In the first part of the respective series the bonding states are gradually populated and the ion volume decreases. In the second part the population of antibonding states is associated with a gradual increase in volume. The very weak ion volume variation across the 4*f* series is consistent with localized behavior of 4*f* electrons in most of the lanthanide ions. The actinide series (5*f*) provides an excellent natural example of the crossover between the itinerant character of 5*f* states in elements from thorium to neptunium and localized behavior for these beyond plutonium.

An instructive representation of the evolution of magnetism within the transition-element series between the itinerant and localized character of the *d* and *f* electrons has been presented by Smith and Kmetko (1983) in the ''periodic table of transition elements'' (see Fig. 10). Note that the sequence of rows in the table is different from the Periodic Table of elements; in particular the series of *f* elements is placed above the transition metal series. The lower left section of the table comprises elements in which the *d* and 5*f* electrons strongly participate in bonding and are itinerant in character. Most of these materials are superconducting. In the top right segment the majority of lanthanides and heavy actinides are located which exhibit localized *f*-electron magnetism.

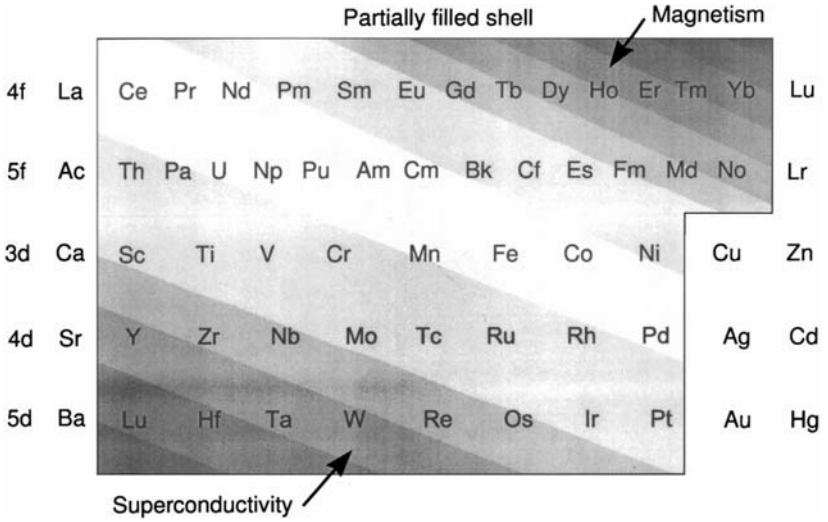

***Figure 10***
A revisited periodic table of the *f* and *d* transition element series. The periodic table is rearranged with the rare-earth, or lanthanide elements on the top row, the actinides in the second row, and the *d*-electron transition metals below them. Most metals have predictable ground states and become magnetic or superconducting as the temperature is lowered below a characteristic temperature of magnetic ordering or superconducting transition. The low-temperature metallic properties of the elements along the diagonal are difficult to explain because, in the solid-state, their *f* or *d* valence electrons are poised between localization and itinerancy (after Smith and Kmetko 1983).

This together with Fig. 9 suggests that the cross-over to localized behavior can be roughly marked by the diagonal white (and nearly white) region. Crossing this region from left to right can be viewed as a Mott transition from a metallic state to an insulating magnetic state for the relevant *d* and *f* electrons. The cross-over region can be moved to the left or right by embedding ions in appropriate compounds (or by applying external pressure) which yields a reduced or increased overlap of the *d*- or *f*-electron wave-functions. The transition-metal *d* electrons then appear to be localized and bear magnetic moments as a rule in insulators (see *Transition Metal Oxides: Magnetism* and *Pnictides and Chalcogenides: Transition Metal Compounds*). On the other hand, itinerant nonmagnetic 4*f* electrons are found in some specific materials like $CeFe_2$ (Ericksson *et al*. 1988).

The magnetism of localized electron states can be treated theoretically and the observed magnetic moments usually compare well with the calculated values. Nevertheless, the moments of localized electrons in solids may be considerably reduced, due mainly to crystal field interaction, which is particularly effective where there are electrons with larger spatial extensions of wave-functions (see *Localized 4f and 5f Moments: Magnetism*). Also, the itinerant electron states that form energy bands may, under certain conditions, yield magnetic moments and magnetic ordering (see *Itinerant Electron Systems: Magnetism (Ferromagnetism)*, and *Metamagnetism: Itinerant Electrons*).

One of the important control parameters is the relevant bandwidth that plays an important role in determining the type of ground state and the possibility of metamagnetic state of an itinerant electron system. In the cross-over region between localized and itinerant behavior narrow-band materials are located, which are characterized by strongly correlated electrons (see *Electron Systems: Strong Correlations*). The specific electronic properties of strongly correlated electron systems (SCES) in the context of the broad spectrum of metallic systems are schematically summarized in Fig. 11. In the cross-over region a number of exotic phenomena is also frequently observed, for example, the heavy-Fermion behavior (see *Heavy-fermion Systems*) and the intermediate-valence behavior (see *Intermediate Valence Systems*).

The variety of observed magnetic phenomena connected with various stages of "magnetic" electron states between localized and itinerant causes problems in formulating a unified theory of magnetism in materials. Reasonable theoretical approaches are available for the extreme cases: the magnetism of localized electrons (see *Transition Metal Oxides: Magnetism*) and magnetism of itinerant electrons. The intimate relationship between magnetism and electronic structure points to the necessity of applying, in magnetism, methods based on electronic structure theories. The density functional theory (Brooks and Johanson 1993) has been proven to be very successful in providing realistic *ab initio* electronic structure calculations in studies of numerous materials (see *Density Functional Theory: Magnetism*).

## 3. Ordering of Magnetic Moments

In Sect.1 ferromagnetism, antiferromagnetism, and ferrimagnetism were introduced phenomenologically. These phenomena are based on long-range ordering of magnetic moments in materials. There are two necessary ingredients of magnetic ordering—magnetic moments and exchange interactions. The latter determine the intersite correlations of magnetic moments.

### 3.1 Exchange Interactions

The prototype of exchange interaction is the interaction that correlates spins in the hydrogen molecule. (The description can be found in most textbooks on quantum mechanics.) These interactions are electrostatic in origin and lead to a splitting of the energies of the antisymmetric and symmetric orbital states and hence the symmetric ($\uparrow\uparrow$) and antisymmetric ($\uparrow\downarrow$) spin states. This is the case for all exchange interactions.

In Fig. 12 the main types of exchange interactions are reviewed in a schematic illustration. If the magnetic atoms are nearest neighbors in a lattice the direct exchange interaction (nearest-neighbor interaction) can be effective in the case of a sufficient overlap of the relevant *d* or *f* orbitals. The best examples of a direct exchange interaction can be found in the ferromagnetic 3*d* metals Fe, Co, and Ni, which order at high temperatures (see Table 1) but exhibit magnetic moments that are considerably reduced compared with the free-ion values.

In alloys and compounds the magnetic moment-carrying ions are frequently separated by other atoms, allowing various types of weaker indirect exchange interactions to become effective. The weak RKKY interaction between two magnetic atoms in metallic materials is mediated by the conduction electrons polarized when appearing in the vicinity of a magnetic ion (Jensen and Mackintosh 1991) (see *Localized 4f and 5f Moments: Magnetism*). Owing to properties of the conduction electrons the RKKY interaction is long-range and oscillates with respect to the distance from the magnetic ion. As a consequence, the ordered arrangements of magnetic moments (magnetic structures) determined predominantly by the RKKY interaction are complex and have long periodicity in some directions. This type of interaction plays a principal role in the magnetic ordering of highly localized electrons bearing magnetic moments, which are typically found in lanthanides and their compounds. The 4*f* moments in these materials are, as a rule, large and compare well with the free-ion moments but the relevant ordering temperatures are rather low (see $GdNi_2$ in Table 1).

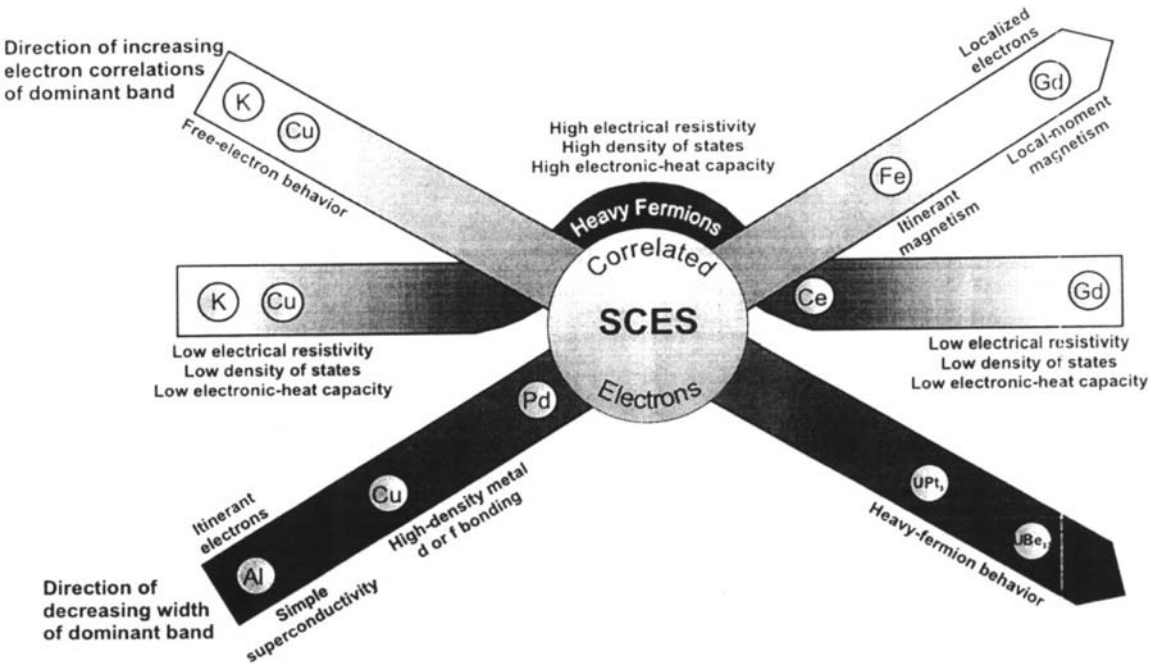

***Figure 11***
Strongly-correlated electron systems (SCES) at a crossover of electronic properties. The figure summarizes some of the unusual electronic properties of SCES, stemming from the dominant role of their narrow *d*- or *f*-band. Along one diagonal, they stand midway between simple metals, whose conduction electrons are essentially uncorrelated and which exhibit free-electron behavior, and heavy-fermion materials, whose conduction electrons exhibit very strong correlations leading to extremely high effective electron masses. Along the other diagonal, SCES stand at the crossover between materials whose itinerant broad-band electrons form superconducting ground states and magnetic materials, whose fully localized electrons (infinitely narrow band) form local magnetic moments and magnetic ground states. Along the horizontal line, SCES materials are distinguished from the elements on either side by their high resistivity and specific heat, high density of electron states at the Fermi energy, and enhanced electronic mass. Smith and Boring (2000) have presented such a figure originally to point out the electronically unique Pu (plutonium), an actinide metal with strongly correlated 5*f* electrons.

The super-exchange interaction is typical for materials in which the magnetic atoms are surrounded by ligands that do not carry permanent magnetic moments. It has been introduced to describe a situation in magnetic oxides and can be applied to similar ionic materials. A typical example is MnO in which $Mn^{2+}$ ions are separated by an $O^{2-}$ ion. The crystal and magnetic structure of MnO is shown in Fig. 13. The essential ingredient of super-exchange interaction in oxides is that the spin moments of the metal ions on opposite sides of an oxygen ion interact with each other through the *p*-orbit of the oxygen ion (Chikazumi 1964, Barbara *et al*. 1988) (see *Transition Metal Oxides: Magnetism*).

A particular analogy of super-exchange is the indirect exchange in intermetallic materials called ''hybridization-mediated exchange interaction'' which is frequently reported in actinide intermetallics (Sechovský and Havela 1998). In this case the interaction between two magnetic ions is mediated by polarization of the valence states of an ion between them (ligand) due to hybridization of relevant magnetic ion and ligand states. Consequently a non-negligible magnetic moment is also observed on the originally nonmagnetic atom (ion).

The idea of a double exchange interaction (Kubo and Ohata 1972) has been introduced to explain ferromagnetism in some perovskite systems containing ions that may possess two different ionic states at crystallographically equivalent sites. The double exchange mechanism became an important issue of the manganese-containing perovskites exhibiting colossal magnetoresistance.

Generally the exchange interaction energy between two ions can be expressed as:

$$H_{ij} = -2J_{ij}\hat{\boldsymbol{S}}_i\hat{\boldsymbol{S}}_j \tag{9}$$

where $J_{ij}$ is the exchange integral ($10^2$–$10^3$ K for direct exchange in $3d$ metals, 10–$10^2$ K for indirect exchange and super-exchange), and $\hat{\boldsymbol{S}}_i$, $\hat{\boldsymbol{S}}_j$ are spin operators of the $i$th and the $j$th ion. For the whole system we have the exchange interaction expressed by:

$$H_{ij} = -\sum_{\substack{i,j \\ i \neq j}} J_{ij} \hat{\boldsymbol{S}}_i \hat{\boldsymbol{S}}_j \tag{10}$$

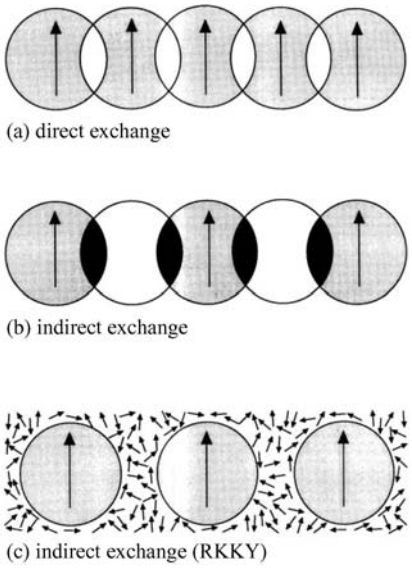

***Figure 12***
Schematic illustration of the main types of exchange interactions (direct, indirect—super-exchange or hybridization-mediated exchange interaction, and RKKY-type indirect exchange interaction mediated by polarized conduction electrons).

A convenient expression for an exchange interaction is obtained in terms of the molecular field $H^{\mathrm{m}}$. The energy of exchange interactions of an ion with the other ions in a solid can be formally replaced by the energy of the ion's magnetic moment in an external magnetic field, $H^{\mathrm{m}}$, which is called the molecular field (also *mean field*). The molecular field is proportional to the spontaneous magnetization (domain magnetization or sublattice magnetization) such that

$$H^{\mathrm{m}} = \lambda M \tag{11}$$

where the molecular field constant $\lambda$ is determined by the strength of the exchange interaction.

For example, the molecular field in iron at room temperature is $6.8 \times 10^8\,\mathrm{A\,m^{-1}}$, which is equivalent to a magnetic induction of 855 T. Introduction of the molecular field allows the theory of magnetization (susceptibility) behavior of ferromagnets, antiferromagnets, and ferrimagnets to be developed easily (Chikazumi 1964, Barbara *et al.* 1988, Gilles 1994) (see *Localized 4f and 5f Moments: Magnetism*). The Curie temperature for a ferromagnet or ferrimagnet, as well as the Néel temperature for an antiferromagnet, is a measure of the sum of the absolute value of molecular-field coefficients (Barbara *et al.* 1988).

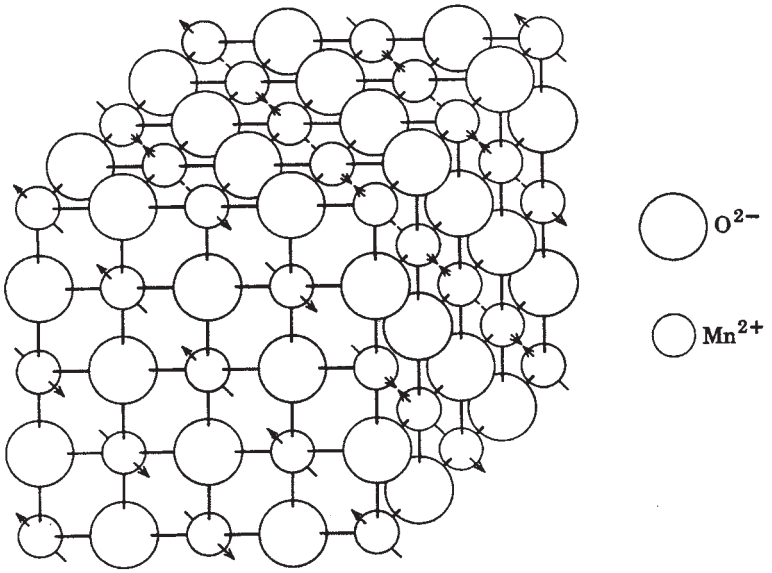

***Figure 13***
Crystal and magnetic structure of MnO.

### *3.2 Types of Magnetic Ordering: Magnetic Structures*

The character of long-range ordering of magnetic moments is reflected in a magnetic structure that has a certain translational symmetry of equivalent magnetic moments (in analogy to the crystal structure). To determine fully the magnetic structure of a particular material, four basic facts need to be established (Rossat-Mignod 1987):

(i) the ordering temperature below which the magnetic moments develop some type of long-range order (ferromagnetic, or another ordering yielding a spontaneous magnetization, below $T_C$ or antiferromagnetic below $T_N$);

(ii) the wavevector $\boldsymbol{q}$ that characterizes the modulation of magnetic moments within the structure. If $\boldsymbol{q}$ is equal to the reciprocal lattice vector of the underlying crystal structure, or if it is a simple fraction thereof, the structure is called commensurate. The other magnetic structures are called incommensurate. The incommensurate collinear structure is usually transformed to a commensurate one at low temperatures. Magnetic structures that should be described by more than one $\boldsymbol{q}$-vector are called "multi-$\boldsymbol{q}$" structures (Bacon 1975, Barbara *et al.* 1988);

(iii) the orientation of magnetic moments with respect to the crystallographic axis and mutual orientation of neighboring magnetic moments. In this respect a large variety of noncollinear magnetic structures (in which magnetic moments on at least some neighboring magnetic sites are neither parallel nor antiparallel) has been observed besides the collinear structures (in which magnetic moments on neighboring magnetic sites are only either parallel or antiparallel);

(iv) the magnitude of the magnetic moment on each "magnetic" site.

The noncollinear structures usually appear as a result of competition between exchange interactions and the magnetocrystalline anisotropy. Besides extensive experimental investigations of noncollinear magnetic structures using neutron scattering, a theoretical approach using the density functional theory provides realistic results for many systems (Sandratskii 1998).

Long-period magnetic structures appear due to the long-range oscillatory character of exchange interactions, e.g., RKKY-type. The magnetic moments may be rotating, precessing (helical structure), or collinear but modulated with a period given by $\boldsymbol{q}$. Incommensurate magnetic structures frequently occur due to exchange interactions being strong in only two dimensions while the exchange interaction along the third direction is much weaker. In this case the incommensurate structure emerging below $T_N$ is replaced by a commensurate ordering at lower temperatures.

Effects of RKKY-type interaction are illustrated by the variety of magnetic structures in rare-earth metals (Barbara *et al.* 1988, Jensen and Mackintosh 1991), ranging from ferromagnetism, e.g., the ground state of dysprosium, to various long-period modulated or spiral structures, e.g., erbium (see *Localized 4f and 5f Moments: Magnetism*).

## *4. Magnetic Phase Transitions*

A material that exhibits a long-range magnetic ordering at low temperatures in zero magnetic field is characterized by at least two phases: the high-temperature paramagnetic phase and the magnetically-ordered ground-state phase. In simple systems, the ground-state phase is established immediately below the magnetic-ordering temperature ($T_C$ or $T_N$). Frequently, the magnetically ordered phase, which appears at temperatures below $T_C$ (or $T_N$), is different from the ground-state phase. Then one or more magnetic phase transitions are observed at temperatures below $T_C$ (or $T_N$).

When applying an external magnetic field new magnetic phases can be induced. These phases are usually called metamagnetic and the related magnetic phase transitions with respect to the external magnetic field as the control parameter are called metamagnetic transitions. These transitions are observed in various real antiferromagnets and ferrimagnets (see *Magnetic Phase Transitions: Field-induced (Order to Order)*).

Metamagnetic phase transitions from a paramagnetic state to a magnetically ordered phase can also be found in nearly magnetic itinerant electron systems (Fig. 6) (see *Metamagnetism: Itinerant Electrons*). Further examples can be found in review papers on magnetism in rare-earth intermetallic compounds (Gignoux and Schmitt 1991, 1995) and uranium intermetallics (Sechovský and Havela 1998).

New magnetic phases and magnetic phase transitions may also be induced by applying external pressure (Sechovský and Havela 1998) or by controlled variation of the material composition (see *Magnetic Systems: External Pressure-induced Phenomena*). In the cross-over region between magnetic ordering and the nonmagnetic state rather unusual phenomena are observed at low temperatures (see *Heavy-fermion Systems*).

A phase transition between two magnetic phases can be a first-or second-order type depending on whether it is connected with a discontinuity of the first derivative (e.g., magnetization) or the second derivative (e.g., magnetic susceptibility) of the magnetic part of the free energy, respectively. Magnetic phase transitions in real materials are usually also reflected in transport properties (Sechovský and Havela 1998) (see *Intermetallics: Hall Effect*, *Elemental Rare Earths: Magnetic Structure and Resistance, Correlation of*; *Magnetoresistance: Magnetic and Nonmagnetic Intermetallic*; *Giant Magnetoresistance:*

*Metamagnetic Transitions in Metallic Antiferromagnets*, and *Rare Earth Intermetallics: Thermopower of Cerium, Samarium, and Europium Compounds*) and in thermodynamic and other material properties (see *Magnetic Systems: Specific Heat*; *Magnetocaloric Effect: From Theory to Practice*; and *Magnetoelastic Phenomena*).

### *4.1 Magnetic Phase Diagrams*

A magnetic phase diagram is a schematic representation of phases adopted by a material over a range of varying parameters. Parameters are usually temperature ($T$) and external magnetic field ($H$), external pressure ($p$), or the concentration of a substituting element ($x$). These are referred to as $H$–$T$, $p$–$T$, or $x$–$T$ magnetic phase diagrams, respectively. Magnetic phase diagrams of simple magnetic systems can contain only two phases: the paramagnetic phase and one magnetically ordered phase. In the case of several competing interactions, especially long-range interactions, the relevant magnetic phase diagram may be rather rich on different phases.

In strongly anisotropic magnetic systems a complete description requires up to three different magnetic phase diagrams, one each for the magnetic fields applied along the three principal crystallographic directions. The compound CeSb (Rossat-Mignod *et al*. 1983, 1990), which crystallizes in one of simplest crystal structure—the cubic NaCl-type, is an excellent example of a very complicated magnetic phase diagram. The enormous number of magnetic

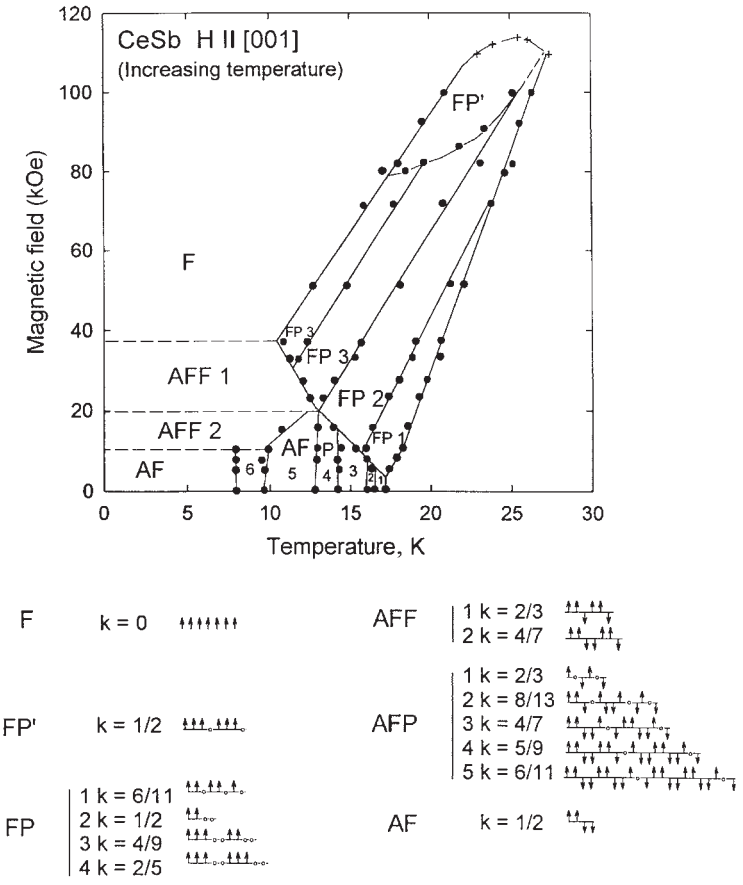

***Figure 14***
Magnetic phase diagram of CeSb. Orderings in the 15 distinct phases corresponds to commensurate structures which have been classified in three categories: AFF, AFP, and FP phases. The structures are built of ferromagnetic (001) planes of magnetic moments oriented perpendicularly to the planes. The actual structures are realized by complex coupling along the moment direction. Some of the planes sometimes appear frustrated and consequently the moments within them become paramagnetic and the particular plane behaves nonmagnetically (after Rossat-Mignot *et al*. 1983, 1990).

phases characterized by a variety of long-period collinear magnetic structures (see Fig. 14) demonstrates the importance of long-range exchange interactions.

Numerous examples of magnetic phase diagrams of specific materials can be found in other articles (see: *Magnetic Phase Transitions: Field-induced (Order to Order)*, Figs. 1–3, *Metamagnetism: Itinerant Electrons*, Figs. 1 and 6) and in review papers on magnetism in rare-earth intermetallic compounds by Gignoux and Schmitt (1991, 1995) and uranium intermetallics (Sechovský and Havela 1998).

## 5. Magnetocrystalline Anisotropy

Magnetocrystalline anisotropy is manifested by locking magnetic moments in certain crystallographic directions. Anisotropy is one of the most important characteristics of materials considered for permanent magnet applications (see *Magnetic Anisotropy* and *Hard Magnetic Materials, Basic Principles of* ). In particular, the anisotropy energy $E_A$ (or the anisotropy field $H_A$) is one of the key parameters determining the coercive field in ferromagnets. The value of $E_A$ depends on the orientation of magnetization with respect to the crystallographic axes and therefore it can be expressed in terms of directional cosines $\alpha_1$, $\alpha_2$, and $\alpha_3$ of the magnetization vector with respect to the main crystallographic directions [100], [010], and [001], respectively (for a detailed explanation see Chikazumi 1964, Gilles 1994). For cubic crystals such as iron and nickel the magnetocrystalline anisotropy energy is given by:

$$E_A = K_1(\alpha_1^2\alpha_2^2 + \alpha_2^2\alpha_3^2 + \alpha_1^2\alpha_3^2) + K_2\alpha_1^2\alpha_2^2\alpha_3^2 + \dots , \qquad (12)$$

where $K_i$ is *the* $i$th anisotropy constant. For Fe, $K_1 = 4.8 \times 10^4\ \mathrm{Jm^{-3}}$ and $K_2 = \pm 5 \times 10^3\ \mathrm{Jm^{-3}}$, and for Ni, $K_1 = -4.5 \times 10^3\ \mathrm{Jm^{-3}}$ and $K_2 = 2.34 \times 10^3\ \mathrm{Jm^{-3}}$; in both cases the values refer to room temperature.

For materials with tetragonal symmetry

$$E_A = K_1\alpha_3^2 + K_2\alpha_3^4 + K_3\alpha_1^4\alpha_2^4. \qquad (13)$$

and for hexagonal crystals $E_A$ is usually expressed using the description of magnetization direction by polar angles:

$$E_A = K_{u1}\sin^2\theta + K_{u2}\sin^4\theta + K_{u2}\sin^6\theta + K_3\sin^6\theta\cos 6\phi, \qquad (14)$$

where $\theta$ is the angle with respect to the hexagonal $c$-axis and $\phi$ represents the orientation within the basal plane. For cobalt at room temperature $K_{u1} = 4.1 \times 10^5\ \mathrm{Jm^{-3}}$ and $K_{u2} = 1 \times 10^5\ \mathrm{Jm^{-3}}$.

The easy magnetization direction is associated with the minimum of $E_A$ whereas the maximum of $E_A$ determines the hard magnetization direction. For hexagonal and cubic crystals, the conditions for various types of anisotropy are summarized in Tables 2 and 3.

In localized electron systems the magnetocrystalline anisotropy arises from the single-ion crystal-field interaction between the aspherical *d*- or *f*-charge cloud and the charge distribution surrounding the *d* or *f* ion (crystal field) (see *Crystal Field Effects in Intermetallic Compounds: Inelastic Neutron Scattering Results*). In this context, the magnetocrystalline anisotropy is a consequence of the directional dependence of the energy of a *d*- or *f*-charge cloud in the crystal field. The crystallographic direction associated with the energy minimum determines the easy magnetization direction along which the *d* or *f* magnetic moment preferentially orients with respect to the crystallographic axes. Shape differences of the *d*- or *f*-electron cloud lead to different easy magnetization directions among analogous materials where the *d* or *f* ions experience the same crystal field (Legvold 1980).

The involvement of delocalized 5*f* states in light actinide intermetallics in anisotropic covalent bonding implies an essentially different interaction, the two-ion (5*f*–5*f*) interaction, which plays a major role in the magnetocrystalline anisotropy of actinide materials. An analogous mechanism may account for the magnetocrystalline anisotropy in metallic 3*d* electron magnets (Gignoux and Schmitt 1991). Generally, the existence of an orbital magnetic moment and a strong spin–orbit interaction is a necessary prerequisite for the magnetocrystalline anisotropy mechanisms. In the case of new observations of strong orbital magnetism and consequently very strong magnetocrystalline

***Table 3***
Summary of magnetocrystalline anisotropy parameters for hexagonal systems.

| Easy magnetization direction | [001] | Basal plane |
|---|---|---|
| $E_A$ | 0 | $K_{u1} + K_{u2}$ |
| Conditions for $K_{u1}$, $K_{u2}$ | $K_{u1} + K_{u2} 0$ | $K_{u1} + K_{u2} < 0$ |

***Table 2***
Summary of magnetocrystalline anisotropy parameters for cubic systems.

| Easy magnetization direction | [100] | [010] | [001] |
|---|---|---|---|
| $E_A$ | 0 | $1/4\,K_1$ | $1/3\ K_1 + 1/27\ K_1$ |
| Conditions for $K_1$, $K_2$ | $K_1 > 0$, $K_1 > -1/9K_2$ | $0 < K_1 > -4/9K_2$ | $0 < K_1 < -1/9K_2$ |

anisotropy in itinerant electron systems the sophisticated electronic structure calculations (Brooks and Johanson 1993) played a principal role.

## 6. Basic Models of Magnetism

For the interpretation of magnetic phenomena relevant microscopic models are frequently used. The basic three models are discussed in this section. Equation (9) defines the Heisenberg Hamiltonian of the isotropic exchange interaction between two $S$-state ions (characterized by spin angular momentum $S$) that is the basis of the Heisenberg model. This model is most applicable to materials where the isotropic exchange interaction dominates the crystal-field interaction and there are possible anisotropic exchange interactions.

At the same time, together with the Ising model, it has been one of the standard models for cooperative phenomena and phase transitions. The Ising model is described by the Hamiltonian

$$H_{ij} = -2J_{ij}\hat{\mu}_i\hat{\mu}_j \tag{15}$$

where $\mu_i$ is a variable with a value of $+1$ or $-1$. This Hamiltonian can be regarded as a limiting case of Eqn. (9) in which $S$ is assumed to be $1/2$ and the exchange coefficient of the transverse component $S_{ix}S_{jx} + S_{iy}S_{jy}$ is negligible. The model is useful for systems where strong uniaxial anisotropy locks the magnetic moments along one crystallographic axis (usually the $z$-axis). On the other hand, the opposite limit of dominating transverse components leads to the XY model expressed by the Hamiltonian

$$H_{ij} = -2J_{ij}(\hat{S}_{ix}\hat{S}_{jx} + \hat{S}_{iy}\hat{S}_{jy}) \tag{16}$$

A possible application of the XY model can be found in materials with strong easy-plane anisotropy.

# Magnetism: Applications of Synchrotron Radiation

Magnetism in solids covers a large variety of properties ranging from bulk characteristics of permanent magnets or recording and storage devices to fundamental microscopic phenomena in quantum systems. The measurement of bulk magnetic properties (such as susceptibility, magnetization, and anisotropy) represents the first and necessary step to determine the magnetic state of a material. However, a proper understanding of the magnetic properties requires a knowledge of the electronic ground state. Magnetic moments originate from unpaired electrons; the electron spins interact through various exchange couplings to form ordered spin structures, while the electron orbital moments contribute to the total magnetization via spin–orbit couplings.

Therefore, magnetism depends on electronic properties at the atomic level and/or at the electron band level. The observation of transport properties provides information on the electronic properties. Nevertheless, the understanding of magnetism necessitates the determination of the electronic states that carry the magnetization, and the knowledge of the magnetic order and magnetic interactions at a microscopic level. Local probes (NMR, Mössbauer spectroscopy, $\mu$SR) can be exploited to obtain some insight as to the nature of the magnetization. Scattering techniques provide microscopic details about the magnetic sites, the arrangement, and the dynamics of the ordered magnetic moments. (For NMR and Mössbauer spectroscopy see Cahn and Lifshin (1993); for $\mu$SR see *Muon Spin Rotation ($\mu$SR): Applications in Magnetism*.)

Scattering experiments convey information on spatial Fourier transforms of correlation functions. Diffraction experiments reveal static correlations, including short- and long-range ordered structures, while inelastic scattering experiments are used to observe time-dependent correlations, i.e., fluctuations, normal modes, and collective or localized excitations. The energy range spanned by the excitations is related to the size of the interactions, which are roughly defined by the ordering temperature in the range 1–300 K (0.1–30 meV energy range). However, the energy scales associated with electronic bands are in the electron volt range. An ideally suited scattering probe should cover all these energies. Traditionally neutron scattering is the probe of choice. However, in the past optical effects in the visible range (Faraday and magneto-Kerr effects) have confirmed the existence of interactions between photon polarization and magnetization: the polarization of light is rotated upon transmission through, or reflection from, a magnetized medium.

Similar phenomena (dichroic signals) are observed in soft and hard x-ray absorption experiments, when the photon energy is adjusted near an x-ray absorption edge of a magnetic atom. Reciprocally, x-ray scattering experiments show large resonant enhancements of the scattered intensities yielding count rates in the range $10^4$–$10^6$ photons $s^{-1}$. These resonant effects in x-ray scattering are superimposed on nonresonant effects, which are much weaker. The developments in the use of x rays rely on tunable photon sources and the scientific interest in the applications of x-ray methods to probe magnetism has increased since the development of modern synchrotron radiation sources.

## *1. Scattering Probes: Synchrotron X Rays vs. Neutrons*

X-ray and neutron scattering techniques are analogous in many ways but their strengths are complementary. Neutrons are considered as the probe of choice for the study of magnetism by means of scattering methods for two reasons (Squires 1978): (a) neutrons possess a spin and the associated neutron magnetic moments couple significantly to the magnetization in materials; and (b) the rather low kinetic energy of neutrons (3–100 meV at reactor sources) allows easy inelastic experiments adapted to magnetic properties. A large fraction of the understanding of microscopic magnetism (magnetic structures, magnetic excitations) comes from neutron scattering results. However, neutron beams have low flux and neutron scattering experiments require large scattering volumes. Furthermore, neutrons as a magnetic probe are sensitive to the total magnetization and do not distinguish readily contributions from different elements, different electronic shells, or spin vs. orbital momentum. Neutrons cannot probe electronic properties.

X rays, when applied to magnetism, suffer from a serious drawback: the nonresonant coupling between the electromagnetic field associated with the photons and the spin and orbital momentum distributions is weak. This interaction was evidenced experimentally in the early 1970s (de Bergevin and Brunel 1972) but was considered as a curiosity until more powerful x-ray sources became available. The reason behind the use of x-ray methods for the study of magnetism arises from the unique properties of x-ray synchrotron radiation: (i) a high brilliance, which gives a large particle flux over an extremely small beam size; (ii) a wide range of photon energy tunability; and (iii) a well-defined polarization state of the emitted radiation. Modern synchrotron sources available worldwide can accommodate different undulators as radiation sources which produce x rays with energy ranging from a few hundred electron volts to 30–40 keV. On the high-energy side, multipole wigglers produce photons up to 300 keV. High brilliances up to $10^{20}$ photons $s^{-1}mm^{-2}mrad^{-2}$ per 0.1% bandwidth have been reached at the European Synchrotron Radiation Facility (ESRF) in Grenoble, France.

The x-ray polarization is readily tunable, with an almost perfect degree of linear polarization. Special insertion devices are designed to produce elliptically or circularly polarized radiation.

The high photon flux available at synchrotrons compensates for the weakness of the nonresonant magnetic x-ray scattering amplitude, and the easily tuned photon energy has boosted resonant studies. Magnetic resonant x-ray scattering combined with the high brilliance of synchrotron x-ray beams makes it possible to investigate small scattering volumes (microcrystals, thin films, surfaces) or weak magnetic moments (down to $0.01\mu_B$). The resonant process is element selective and electronic shell sensitive, allowing detailed studies of the origin of magnetic moments. The time structure of the synchrotron radiation (x-ray bunches at 357kHz at the ESRF) can be exploited to study the dynamics of magnetic processes in real time down to the nanosecond scale (Bonfim *et al*. 1998).

When used together, x-ray and neutron methods offer a broad range of capabilities and the choice of the technique depends on the details of the problem to be solved. Neutrons are essential in determining magnetic structures (magnetic powder diffraction) and in characterizing magnetic excitations (the observation of magnetic excitations will not be discussed). However, synchrotron x rays provide more information about the electronic character of magnetism (separation of orbital momentum and spin, sensitivity to the electronic shell and to the chemical species). Owing to the properties of synchrotron x-ray beams (brilliance, collimation, time structure), x rays are preferred over neutrons for the investigation of minute samples (surfaces, thin films), time-resolved studies, and high $Q$-resolution experiments. However, in the case of scattering experiments, the high collimation of synchrotron beams must be matched by the crystalline quality of the materials. As a consequence, only good-quality crystals can be studied; for powder samples, *ab initio* magnetic structure determinations are performed using neutron diffraction.

In the following, the basic character of the interactions of x rays with magnetism is outlined, including a description of the scattering amplitudes (elastic Bragg scattering or diffraction and Compton scattering) and the spin-dependent x-ray absorption methods (magnetic dichroism). Potential applications are indicated and comparison with neutron methods is made when appropriate.

## 2. Scattering Cross-sections

The x-ray or neutron intensity diffracted by an assembly of atoms is written in terms of an elastic scattering cross-section:

$$\left(\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}\right) = \left|\sum_n \mathrm{e}^{\mathrm{i}QR_n} f_n(k_\mathrm{i}, k_\mathrm{f}, \hbar\omega)\right|^2 \qquad (1)$$

where $\hbar\omega$ is the x-ray energy, $k_\mathrm{i}$ and $k_\mathrm{f}$ are the incident and scattered wave vectors of the photons, $Q$ is the probe momentum transfer ($Q = k_\mathrm{i} - k_\mathrm{f}$), and $f_n$ represents the scattering amplitude from the $n$th atom. Two limiting regimes are distinguished for x rays: the resonant scattering (when the incident photon is close to an absorption edge of a magnetic species in the material) and the nonresonant scattering (when the photon energy is far from any absorption edge). It is convenient to separate the different contributions:

$$f_n(k_\mathrm{i}, k_\mathrm{f}, \hbar\omega) = f_n^{\mathrm{charge}}(Q) + f_n^{\mathrm{nonres}}(k_\mathrm{i}, k_\mathrm{f}) + f_n^{\mathrm{res}}(k_\mathrm{i}, k_\mathrm{f}, \hbar\omega) \qquad (2)$$

where $f_n^{charge}$ denotes the familiar Thomson scattering from charge distribution, $f_n^{nonres}$ is the nonresonant magnetic scattering, and all contributions to the resonant scattering are included in $f_n^{res}$.

The processes discussed here correspond to coherent elastic scattering; there are also inelastic processes, known as Compton scattering, during which photons exchange energy with the scattering system. In such a case, the scattering is incoherent and photons are scattered by individual electrons.

The absorption cross-section, which is measured in spin-dependent absorption experiments, is related to the scattering amplitude in Eqn. (2) through the optical theorem:

$$\sigma_\mathrm{a} = 2\lambda \mathrm{Im}[f_n(k_\mathrm{i}, k_\mathrm{f}, \hbar\omega)] \qquad (3)$$

These different cases for x rays are discussed in the following sections. Neutrons are used in the scattering mode only. Furthermore, only the elastic case is considered here.

## 3. Nonresonant Regime

The nonresonant x-ray regime encompasses coherent Bragg scattering (diffraction) and the Compton inelastic process.

### 3.1 Nonresonant X-ray Magnetic Bragg Scattering

The nonresonant x-ray magnetic scattering amplitude is written as (Blume and Gibbs 1988):

$$f^{\mathrm{nonres}}{}_n(k_\mathrm{i}, k_\mathrm{f}) = -\mathrm{i}r_0\left(\frac{\hbar\omega}{mc^2}\right) \times \left[\frac{1}{2}L_n(Q)A(\varepsilon_\mathrm{i}, \varepsilon_\mathrm{f}) + S_n(Q)B(\varepsilon_\mathrm{i}, \varepsilon_\mathrm{f})\right] \qquad (4)$$

where $L_n(Q)$ and $S_n(Q)$ are the Fourier transforms of the orbital momentum and spin magnetization densities (form factors) at the $n$th site, $r_0$ is the classical radius of the electron ($2.8 \times 10^{-15}$ m), a standard unit

in atomic scattering processes, and $mc^2$ is the rest energy of the electron (511 keV). The vector quantities $A(\varepsilon_i, \varepsilon_f)$ and $B(\varepsilon_i, \varepsilon_f)$ depend on the polarization vectors $\varepsilon_i$ and $\varepsilon_f$ of the incident and scattered wave vectors, respectively; they are not identical and have distinct $Q$ dependencies.

A compact expression has been obtained:

$$f_n^{\text{nonres}}(k_i, k_f) = -ir_0(\bar{\lambda}_e Q)$$

$$\begin{pmatrix} \cos\theta S_2 & -\sin\theta[\cos\theta(S_1 + L_1) \\ & -\sin\theta S_3] \\ \sin\theta[\cos\theta(S_1 + L_1) & \cos\theta[S_2 + 2\sin^2\theta L_2]M \\ +\sin\theta S_3] & \end{pmatrix} \quad (5)$$

where $\theta$ is the Bragg angle and $\bar{\lambda}_c$ is the Compton wavelength ($= 3.81 \times 10^{-3}$ Å). $L(Q)$ and $S(Q)$ are given by their components ($\alpha = 1,2,3$) in the coordinate system $u_1$, $u_2$, $u_3$, where $u_1$ is directed along $k_i + k_f$, $u_2$ is perpendicular to the scattering plane and parallel to $k_i \times k_f$, and $u_3$ is along $Q$. The matrix form for $f_n^{nonres}(k_i, k_f)$ is used to describe the polarization dependence. The basis vectors for the polarization $\varepsilon_i$ and $\varepsilon_f$ correspond to a linear polarization either perpendicular ($\sigma$) or parallel ($\pi$) to the scattering plane. From Eqn. (5) it can be seen that the contributions from $L$ and $S$ to the total magnetization $M = L + S$ can be obtained separately from magnetic x-ray scattering data. Such a separation is not readily possible in neutron diffraction experiments because neutrons are sensitive to the total moment. It should be noted that $f_n^{nonres}(k_i, k_f)$ is not a spherical tensor formed with $(\varepsilon_i, \varepsilon_f)$ in contrast to the usual Thomson scattering:

$$f_n^{\text{charge}}(Q) = -r_0\rho(Q)\varepsilon_i \cdot \varepsilon_f \quad (6)$$

This difference helps in separating the Thomson charge from purely magnetic x-ray scattering. Comparison of Eqns. (5) and (6) provides a rough estimate for the relative amplitude of magnetic scattering and charge scattering. If all form factors and geometrical factors in $A(\varepsilon_i, \varepsilon_f)$ and $B(\varepsilon_i, \varepsilon_f)$ are set to unity, then:

$$\left|\frac{f_n^{\text{nonres}}}{f_n^{\text{charge}}}\right|^2 \approx (\bar{\lambda}_c \cdot Q)^2 m^2 \left(\frac{N_m}{N}\right)^2 \quad (7)$$

where $m$ is the electron average magnetic moment (expressed in $\mu_B$) and $N_m$ is the number of magnetic electrons compared to the total number of electrons, $N$, at site $n$. For conventional diffraction cases, $|Q| = 1$–$6$ Å$^{-1}$, $N_m/N = 0.1$, and the ratio of intensities is around $10^{-6}$. In practice, this ratio is even smaller because of the geometrical factors in Eqn. (5). This explains why the advent of bright third-generation synchrotron sources has boosted the development of x-ray techniques by alleviating the consequences of the inherent weakness of nonresonant x-ray magnetic scattering amplitudes.

The neutron counterpart of Eqn. (4) is written as:

$$f_{\text{neutron}}(Q) = f_{\text{nuc}}(Q) + r_0 \frac{\gamma}{2} p \cdot (Q \times [Q \times M(Q)]) \quad (8)$$

where $p$ is the neutron beam polarization, $\gamma$ is the neutron gyromagnetic factor ($= 1.91$), $M(Q)$ is the Fourier transform of the total magnetization, and $f_{\text{nuc}}(Q)$ is the scattering amplitude from the nuclei in the solid. Note that neutrons couple to the Fourier transform $M(Q) = L(Q) + 2S(Q)$ of the total magnetization. The $L/S$ separation can only be achieved by modeling the $Q$ dependence of the two contributions, $L(Q)$ and $S(Q)$.

In the case of ferro- or ferrimagnetic materials, the magnetic Bragg peaks occur at the same positions in reciprocal space as the more intense crystal structure peaks. Interferences between the magnetic scattering amplitude and the scattering amplitude from the crystal structure allow the observation of the magnetic signal. A practical way to extract the magnetic information is to reverse the magnetization direction by applying an alternating magnetic field (reversing the interference term) and to collect the intensity as a function of field orientation; this gives the so-called flipping ratio, $R$, defined as:

$$R = \frac{I(\uparrow) - I(\downarrow)}{I(\uparrow) + I(\downarrow)}$$

In the x-ray case, because $f_n^{\text{nonres}}(k_i, k_f)$ and $f_n^{charge}(Q)$ are out of phase by $\pi/2$ (Eqns. (4) and (6)), interference only occurs in the case of circular polarization (the $\varepsilon_i$ and $\varepsilon_f$ vectors are complex) or if the crystal structure factor is imaginary (large absorption and/or noncentrosymmetric structure). In the neutron case, a finite neutron polarization is required to have interference effects. In this case, $R$ is obtained by flipping the polarization of the neutron beam:

$$R = \frac{1 + 2pA(Q) + A(Q)^2}{1 - 2pA(Q) + A(Q)^2}$$

where $p$ is the neutron polarization and

$$A(Q) = \frac{M(Q)}{f_{\text{nuc}}(Q)}$$

Owing to the larger neutron magnetic scattering amplitude, weak magnetic moments $M(Q)$ can be extracted (i.e., field-induced magnetization in paramagnets) provided $f_{\text{nuc}}(Q)$ and $p$ are known accurately. Usually, neutrons can detect magnetic moments down to $0.05\mu_B$. However, x rays have an advantage over neutrons when the sample under investigation is very small, because of the high brilliance of synchrotron sources. Ferromagnetic thin films or multilayers and

interfacial magnetism are routinely studied by means of magnetic x-ray scattering.

In the case of antiferromagnetic systems, the magnetic diffraction peaks occur at positions in reciprocal space that are forbidden for crystal structure reflections, and the limiting factor for detection is the scattered intensity. Figure 1 shows examples of data obtained from third-generation synchrotron sources. Figure 1(a) gives an indication of the scattered intensities available at modern synchrotron sources. Also shown in Fig. 1 are the magnetic form factors $L(Q)$ and $S(Q)$ that have been determined independently by exploiting the polarization dependence of the scattering amplitude in Eqn. (5) (Fernandez *et al.* 1998). It is worth noting that at the high-energy limit for Bragg scattering (low Bragg angle $\theta$), the x-ray magnetic scattering is dominated by the spin contribution, whereas the orbital momentum part becomes negligible (Eqn. (5)).

An important aspect of diffraction experiments is the $Q$-resolution. Owing to the highly collimated beams, synchrotron x-ray experiments allow high $Q$-resolution conditions which cannot be reached with neutron scattering experiments. This is particularly useful in detecting minute changes in the lattice parameters occurring at magnetic phase transitions due to magnetostriction effects.

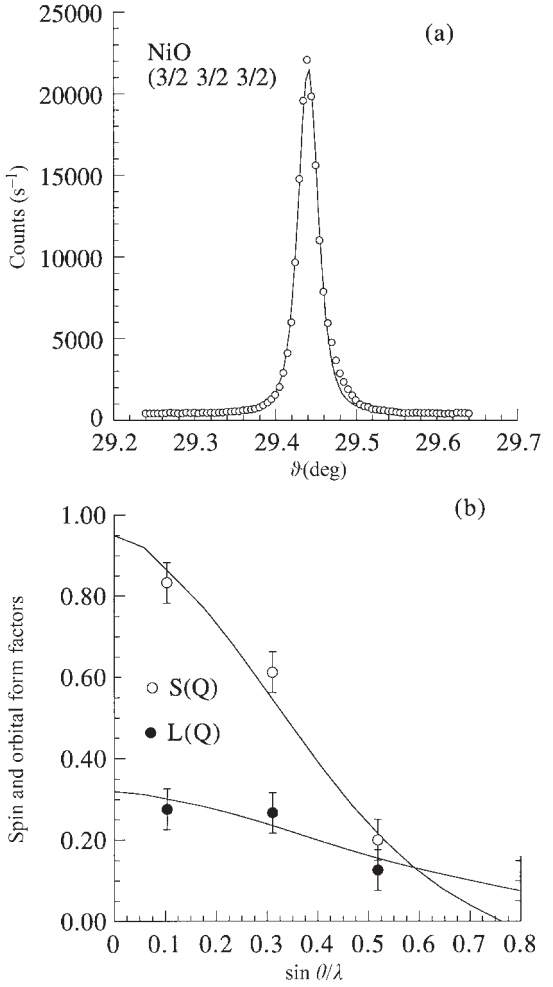

***Figure 1***
Nonresonant magnetic x-ray scattering from NiO. (a) Angular profile of an antiferromagnetic peak. (b) $Q$-dependence of the spin and orbital moment form factor as extracted from the polarization analysis of experimental data.

### *3.2 Magnetic Compton Scattering*

Inelastic Compton scattering is an incoherent process where the scattering cross-section can be written as (Lovesey and Collins 1996):

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega \mathrm{d}\omega} = N\left(\frac{m}{\hbar k_i}\right) \times \left[\left(\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}\right)_{\text{charge}} J(p_z) + \left(\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}\right)_{\text{mag}} J_{\text{spin}}(p_z)\right] \quad (9a)$$

where $J(p_z)$ is the usual Compton profile (a two-dimensional average perpendicular to the scattering vector of the momentum density). The magnetic Compton profile given by $J_{\text{spin}}(p_z) = {}^{1/2}[J_{\uparrow}(p_z) - J_{\downarrow}(p_z)]$ is the difference between the profiles of spin-up electrons and spin-down electrons. The differential cross-sections contain geometrical and polarization factors:

$$\left(\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}\right)_{\text{Charge}} = \frac{1}{2} r^2{}_0 (1 + \cos^2\theta)$$

$$\left(\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}\right)_{\text{spin}} = -r_0^2 p_c \frac{\hbar\omega}{mc^2}(1 - \cos\theta)(\hat{\mathbf{k}}_{\text{i}} \cos\theta + \hat{\mathbf{k}}_{\text{f}}) \cdot z \quad (9b)$$

where $\mathbf{z}$ is the unit vector parallel the magnetic axis, $\hat{\mathbf{k}}_i$ and $\hat{\mathbf{k}}_f$ are unit vectors along $k_{\text{i}}$ and $k_{\text{f}}$; and $p_{\text{c}}$ is the degree of circular polarization of the incident x-ray beam. Similarly to the previous discussions on ferromagnets, the magnetic Compton profile is isolated from the total spectrum by reversing either the magnetization direction, $\mathbf{z}$, or the x-ray helicity, $p_{\text{c}}$. By measuring profiles along several directions, it is possible to reconstruct the three-dimensional spin polarized momentum density and compare it with theoretical electronic band calculations. Only magnetic Compton experiments can supply these experimental confirmations.

## 4. Resonant Regime

The nonresonant x-ray magnetic scattering amplitude in Eqn. (5) vanishes in the forward direction at $Q = 0$, leading to the absence of magnetic effects in x-ray transmission or x-ray reflection measurements. However, the optical index in the visible region varies with the magnetization direction relative to the light polarization, which is the origin of magneto-optics. In the hard x-ray region, the optical index is very close to unity, and similar effects are not observed. Only near an absorption edge does the x-ray index differ from unity due to the anomalous part of the scattering amplitude, and magnetic effects are detected. The scattering experiments and the absorption methods can be treated in parallel near resonance. Indeed, resonant scattering originates from second-order perturbation processes which can be pictured as the absorption of an incident photon, the creation of a short-lived intermediate state, followed by decay back to the ground state. In the case of elastic scattering, a photon is elastically scattered during the decay. These intermediate states correspond to the promotion of an inner shell electron to a bound or nearly bound level in an outer shell with a high density of states, leaving behind a core hole. The same intermediate levels contribute to the white line in normal x-ray spectroscopy. The outer electronic shells are sensitive to the local symmetry of atomic sites and the scattering amplitude reflects the symmetry of the associated wave functions with respect to the relative orientation of the incident x-ray polarization. When the incident photon energy is tuned to a resonance, the scattering amplitude contains terms which reflect the local symmetry, possibly leading to new Bragg peaks which are forbidden away from resonance (Templeton 1994).

The onset of local magnetic moments is a particular case of symmetry breaking which induces resonant terms in the x-ray scattering amplitude, $f_n^{\mathrm{res}}$, contributing to the total scattering amplitude in Eqn. (2) (Blume 1994). The resonance occurs through electric multipole transitions from a core level into empty electronic shells. The sensitivity to the magnetization arises from the difference in transition probabilities due to the spin polarization of the intermediate states, the spin–orbit couplings, and the exchange interactions. The strength of the resonance is given by the multipole electric transition matrix elements and the spin polarization of the intermediate states. The strongest transition is the electric dipole (E1 with $\Delta l = 1$) contribution; the next strongest is given by the electric quadrupole (E2 with $\Delta l = 2$) contribution, but the relative weakness of the E2 contribution must be balanced with the size of the spin polarization of the associated intermediate states. This is illustrated with the example of $4f$ and $5f$ systems. The $f$ electronic states which carry the main magnetic moments are probed directly by E1 transitions at the $M_4$ and $M_5$ edges ($3d \rightarrow f$). They are also examined by E2 transitions at the $L_2$ and $L_3$ edges ($2p \rightarrow f$); but at the same $L_2$ and $L_3$ edges, the $d$ moments, which are polarized by the $f$ electrons, are probed by E1 transitions ($2p \rightarrow d$). This example demonstrates the versatility and the electronic selectivity for the study of the origin of magnetic moments. The resonant process is also chemical selective, because the resonant energy changes with the chemical species and valence state.

The resonant scattering amplitude can be expressed as a series expansion:

$$f_n^{\mathrm{res}}(k_{\mathrm{i}}, k_{\mathrm{f}}, \hbar\omega) = f_{n\mathrm{E1}}^{\mathrm{res}}(k_{\mathrm{i}}, k_{\mathrm{f}}, \hbar\omega) + f_{n\mathrm{E2}}^{\mathrm{res}}(k_{\mathrm{i}}, k_{\mathrm{f}}, \hbar\omega) + \cdots \qquad (10a)$$

where $f_{nEL}^{res}(k_{\mathrm{i}}, k_{\mathrm{f}}, \hbar\omega)$ are contributions from E1 and E2 transitions (Hannon *et al.* 1988).

The E1 contribution to the scattering has the form:

$$f_{nEl}^{res}(k_{\mathrm{i}}, k_{\mathrm{f}}, \hbar\omega) = F^{(0)} \begin{pmatrix} 1 & 0 \\ 0 & \cos 2\theta \end{pmatrix} - \mathrm{i}F^{(1)} \begin{pmatrix} 0 & z_1\cos\theta + z_3\sin\theta \\ -z_1\cos\theta + z_3\sin\theta & -z_2\cos\theta \end{pmatrix} + F^{(2)} \begin{pmatrix} z_2^2 & -z_2(z_1\sin\theta - z_3\cos\theta) \\ z_2(z_1\sin\theta + z_3\cos\theta) & \cos^2\theta(z^2{}_1 tan^2\,\theta + z^2{}_3 \end{pmatrix} \qquad (10b)$$

where $z_i$ are components of the moment direction $\mathbf{z}$ in the coordinate system defined above. $F^{(n)}$ are resonant amplitudes which contain a resonant denominator

$$\frac{1}{E_{\mathrm{a}} - E_{\mathrm{c}} + \hbar\omega - i\dfrac{\Gamma}{2}}$$

dipole radial matrix elements $\langle c|r|a\rangle$, and spin polarization of the intermediate states (only in the case of $F^{(1)}$ and $F^{(2)}$) (Hannon *et al.* 1988). $E_{\mathrm{a}}$, $|a\rangle$ and $E_{\mathrm{c}}$, $|c\rangle$ are the energies and wave functions of the ground and intermediate states, respectively, and $\Gamma$ is the inverse lifetime of the intermediate state.

The first term in Eqn. (10b) is independent of $\mathbf{z}$ and does not contribute to the magnetic scattering; it is the usual anomalous x-ray scattering term which contributes to white lines in the fluorescence signal. The second term is linear in $\mathbf{z}$ and contributes to the amplitude of magnetic Bragg peaks. The third term is quadratic in $\mathbf{z}$ and leads to second-order resonant harmonics. More complex terms appear in the E2 contribution, which contains terms up to fourth-order in $\mathbf{z}$ producing third- and fourth-order resonant harmonics.

In order to exploit the resonant enhancement for a given magnetic species, the photon energy is tuned to an absorption edge where the core electron is promoted into the electronic shell that carries the magnetization via the strong E1 transitions. Examples

***Table 1***
Significant resonances for selected magnetic species.

| Magnetic species | | Resonance process | Resonant energy | |
|---|---|---|---|---|
| | | | Energy (keV) | Wavelength (Å) |
| 3*d* transition metal | Fe | E1 $p \leftrightarrow d$ $L_2$, $L_3$ | 0.71 | 17.5 |
| | | E1, E2 $s \leftrightarrow p$, $d$ K | 7.1 | 1.75 |
| 5*d* transition metal | Pt | E1 $p \leftrightarrow d$ $L_2$, $L_3$ | 11.5–13 | 1.08–0.95 |
| | | E1, E2 $s \leftrightarrow p$, $d$ K | 78.4 | 0.16 |
| 4*f* rare earth | Gd | E1 $d \leftrightarrow f$ $M_4$, $M_5$ | 1.22–1.19 | 10.2–10.4 |
| | | E1, E2 $p \leftrightarrow d$, $f$ $L_2$, $L_3$ | 7.9–7.2 | 1.57–1.72 |
| 5*f* actinide | U | E1 $d \leftrightarrow f$ $M_4$, $M_5$ | 3.7–3.5 | 3.35–3.54 |
| | | E1, E2 $p \leftrightarrow d$, $f$ $L_2$, $L_3$ | 20.9–17.2 | 0.59–0.72 |

are given in Table 1. Theoretical estimates for the resonant enhancements predict that the resonant scattering amplitude would reach $10r_0$ at the M edges of actinides and even $100r_0$ at the M edges of rare earths, but would be more modest at the L edges of rare earths, around $0.1r_0$. A severe limitation arises from the long wavelengths associated with the strongest resonances. At wavelengths larger than 5Å, diffraction experiments are difficult owing to absorption problems and to the lack of accessible Bragg peaks. In practice, actinide materials are studied at the $L_{2,3}$ and $M_{4,5}$ edges, which allows the study of both the *f* and *d* magnetism.

For rare earth materials, resonant scattering experiments are performed at the $L_{2,3}$ edges, where *d* electrons are probed. In the soft x-ray range the $M_{4,5}$ edges that give access to the *f* magnetism, allow measurements of magnetic x-ray reflectivity and spin-dependent absorption. The 3*d* transition metals can be investigated at the L edges, where only reflectivity measurements or studies of artificial multilayers can be performed. The resonant process at the K edge involving *p* electrons is weak and complex.

Figure 2 shows an example of the resonant enhancement as observed in the antiferromagnetic compound UAs. At the $M_4$ edge of uranium, the resonant enhancement of the x-ray magnetic scattering amplitude has been measured to be $9r_0$ yielding scattered intensities in the $10^6$ counts $s^{-1}$ range. Such a large scattering amplitude leads to potential applications, which complement neutron diffraction results, taking advantage of the resonant selectivity and of the large resonant enhancement coupled with the large available x-ray flux. In short, resonant x-ray scattering makes it possible to search for weak signals and to disentangle magnetic properties of different chemical elements or electronic shells. It should be pointed out that the gain in scattered intensity at resonance does not make magnetic powder diffraction experiments readily feasible with x rays, because of absorption and fluorescence effects. Powder neutron diffraction remains the probe of choice for structure determination.

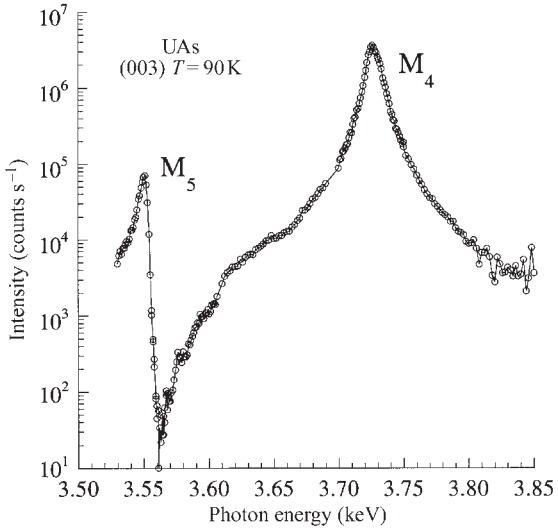

***Figure 2***
Resonant scattering at the $M_4$ and $M_5$ edges of uranium: resonant enhancement of the antiferromagnetic diffracted intensity in UAs as a function of the incident photon energy. The two resonances are clearly seen. The energy line shape of the intensity corresponds to the sum of two interfering amplitudes with resonant denominators.

Weak scattering signals arise either from small magnetic moments or from small scattering volumes. There exist systems which possess extremely small magnetic moments that neutrons cannot "see" unless a large amount of material is available. Resonant x rays are perfectly suited to studies of such systems with constrained dimensions (microcrystals, surfaces, and interfaces). Magnetic thin films and magnetic surfaces are investigated by using soft x-ray reflectivity (Kao *et al.* 1994, Tonnerre *et al.* 1995) or by scattering methods in the harder x-ray region

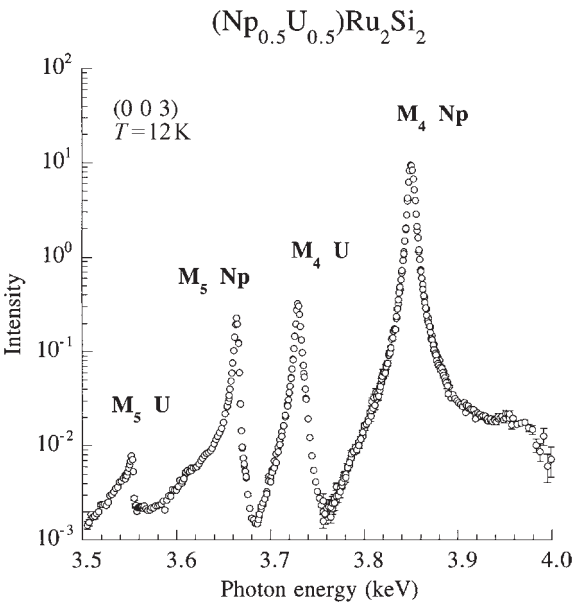

***Figure 3***
Demonstration of chemical selectivity. The intensity of the antiferromagnetic intensity from $Np_{0.5}U_{0.5}Ru_2Si_2$ is measured as a function of photon energy around the $M_{4,5}$ edges of uranium and neptunium. At the neptunium $M_4$ edge the signal arising from the magnetization on the neptunium sites is greater than the uranium contributions by four or five orders of magnitude.

(Watson *et al*. 1996, MacKay *et al*. 1996). The relationship of the magnetic spatial profile and magnetic roughness to the chemical or charge profile can then be determined owing to these enhanced intensities.

The chemical selectivity of resonant x-ray scattering is demonstrated in Fig. 3 which shows the incident photon energy dependence of an antiferromagnetic Bragg peak from a mixed compound, $U_{0.5}Np_{0.5}Ru_2Si_2$, containing two magnetic species, uranium and neptunium. Tuning the photon energy to a given edge (e.g., uranium $M_4$ edge), turns on the signal from the uranium magnetization, while the neptunium response is extinct (or at least several orders of magnitude weaker). Conversely, data taken at the neptunium $M_4$ edge probe the behavior of the neptunium moments only. This selectivity of the scattering species constitutes an advantage of x-ray resonant techniques over nonresonant x-ray methods and neutron techniques.

## 5. *Spin Polarized Photon Absorption*

The x-ray absorption cross-section is given by the imaginary part of the scattering amplitude at $Q=0$ and resonant magnetic effects are also seen in absorption measurements. The observed effects are related to the x-ray polarization. The absorption coefficients vary when the easy direction of the magnetization is changed with respect to the incident x-ray polarization or vice versa: this effect is called magnetic linear dichroism. The absorption of circularly polarized x rays depends also on the helicity of the incident photons relative to the direction of the magnetization: this is magnetic circular dichroism (MCD). In all measurements, the magnetic contrast in the absorption process is obtained by changing the relative orientation of the polarization and the magnetization. The observed dichroic signal is taken as the ratio

$$R = \frac{\mu(L) - \mu(R)}{\mu(L) + \mu(R)}$$

where $L$ and $R$ denote the two photon helicities, and $\mu$ is the fluorescent signal or the absorption coefficient.

Similarly to the resonant scattering amplitude, the MCD signal is simply proportional to the spin polarized density of states of the intermediate states that are excited during the transition (Schütz *et al*. 1987). However, the orbital moment of the intermediate states is also likely to play a significant role in determining transition probabilities, especially in the cases of localized f-electron states. Indeed, a sum rule for the integral of the dichroic signal (the imaginary part of the magnetic scattering amplitude with $\theta=0$ in Eqn. (10b) over a given edge has been derived (Thole *et al*. 1992) which allows a determination of the ground state value of the orbital moment in the electronic available states. This sum rule, which is rigorously valid only in the atomic case, has been extended to single electron band models. Furthermore, other sum rules have also been obtained involving expectation values of the spin operators (Carra *et al*. 1993).

Sum rules are derived for the absorption coefficient, related to $f'' = \mathrm{Im}\{f_n(k_f = k_i,\ \hbar\omega)\}$; equivalent sum rules for the scattering case, where the total scattering amplitude $|f_n|^2$ is measured, would be more difficult to extract. The dichroism methods can bring new information on the ground state electronic properties of magnetic systems. Compared to scattering techniques, absorption methods have two considerable advantages: (a) they can be performed extremely rapidly (only the incident photon energy is varied and nothing else changes); and (b) they do not require single-crystal samples (any type of sample can be studied). However, no information in $Q$-space is obtained and MCD experiments can only probe magnetized samples, such as ferromagnets and ferrimagnets.

Dichroic effects are studied at low-energy absorption edges (L edges for 3*d* transition metals and M edges of rare earths) by using fluorescence or electron

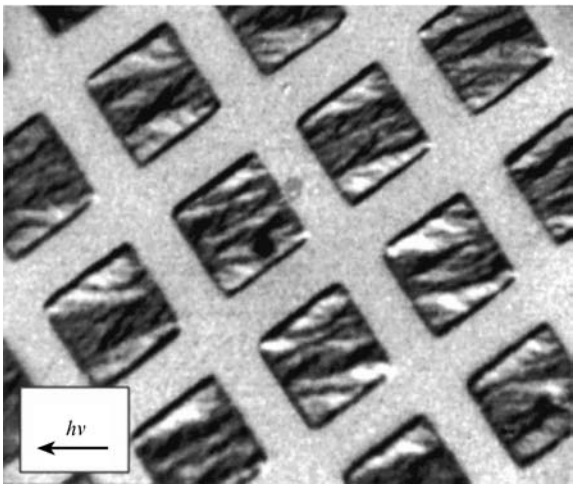

***Figure 4***

yield methods. At these energies, experiments are sensitive to the surface state and to the magnetism at surfaces. Local magnetic environments of magnetic species are revealed by magnetic fluorescence spectra. Because of the chemical selectivity, the various components of magnetic alloys and compounds can be studied independently. Even images of ferromagnetic domains have been obtained, leading to technological applications (Schütz *et al.* 1997, Schneider *et al.* 1997). The combined use of MCD methods and x-ray zone played microscopy can provide high-resolution images of ferromagnetic domains with spatial resolution of 50 nm and real time evolution. Figure 4 shows a magnetic domain pattern in a microstructured CoPt multiplayer. The pattern is obtained by subtracting two images recorded at the cobalt $L_3$ edges with opposite radiation helicity. The resulting contrast arises from the relative orientation of the cobalt magnetization and light incidence. The white (black) areas correspond to regions with magnetization parallel (antiparallel) to the incident light as indicated by the arrow. The magnetization is perpendicular to the incident light in the gray areas.

A very promising application of MCD experiments is the possibility of performing time-resolved studies. The combination of the pulsed time structure of the synchrotron x-ray beam and the fast acquisition rate of MCD allows studies of magnetic dynamics of ferromagnets. The use of energy-dispersive x-ray absorption enables fast dynamics to be studied (down to nanoseconds) over a typical size of 20 μm. An example is given in Fig. 5. The MCD signal has been measured from a complex magnetic system consisting

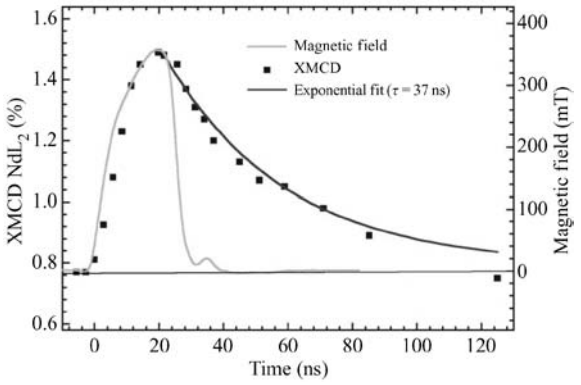

***Figure 5***
Time response of neodymium magnetization under the application of a pulsed magnetic field of 300 mT.

of hard magnetic grains ($Nd_2Fe_{14}B$) embedded in a soft matrix (spring magnet) at the $L_2$ edge of neodymium. Owing to the selectivity of the MCD method, the neodymium hysteresis cycle can be observed together with the relaxation response of neodymium under the application of a pulse field (Fig. 5). The determination of the relaxation time makes it possible to analyze the different mechanisms driving the coercivity. Other applications include the studies of dynamics of recording or switching devices (Bonfim *et al.* 1998). The uniqueness of the chemical selectivity makes time-resolved MCD an ideal diagnostic probe for the magnetic properties of multicomponent magnetic devices such a spin valves and spring magnets.

## 6. *Future Directions*

Synchrotron methods for the study of magnetism have been in use since the early 1980s, and the most remarkable achievements using resonant scattering have been obtained since the early 1990s. New applications have appeared, some of which have arisen owing to the progress in instrumentation and some from a better understanding of the physics. Synchrotron sources and x-ray instruments are likely to improve, yielding new prospects for more applications (studies of microcrystals, coherent effects and magnetic speckles, magnetic inelastic x-ray scattering, time-resolved studies). Theoretical approaches, which have been stimulated by experimental results, will in turn lead to more fundamental applications and studies of the microscopic magnetic properties of solids. Synchrotron x rays will offer new tools for detailed studies of magnetism, which complement neutron scattering techniques.

# Magnetism: High-field

The effect of an applied magnetic field on matter depends on whether the field is large enough to compete with the magnetic interactions that are present within the material. Only then can a modification of the magnetic state can be induced. The related change in magnetization should be large enough to be observed with sufficient accuracy. High magnetic fields are generated worldwide, in many laboratories and in special user facilities. After a brief review of the techniques that are applied to produce high magnetic fields, this article focuses on a representative selection of the large variety of phenomena that may be observed in the magnetization of magnetic materials when they are exposed to high magnetic fields. Also, the information that can be deduced from the observed high-field behavior will be briefly discussed.

In magnetic materials, the exchange interaction between the magnetic moments generally is the most prominent interaction. Depending on the solid, the exchange interaction may be of different type, and, at temperatures where the thermal energy is lower than the strength of the exchange interaction, will give rise to an ordered structure of the magnetic moments. The strength of the exchange interaction may be expressed in terms of an internal ''exchange field'' that acts on the magnetic moments and that may be as high as 1000 T. Also, the magnetocrystalline anisotropy in solids may be appreciable and, in specific materials, may be equivalent to a few hundred teslas.

The examples discussed in this article have been taken from the vast body of high-field research that has been carried out on transition metals, rare-earth metals, alloys, and intermetallic compounds. For other specific subjects and other categories of materials in which the response to high magnetic fields may play a significant role, for instance low-dimensional spin systems, critical phenomena, low-dimensional semiconductor structures, heavy-fermion systems, and superconductors, the reader is referred to the articles devoted to these subjects and materials.

## *1. Production of High Magnetic Fields*

Static magnetic fields can be generated by transmitting electrical current through resistive coils that have to be water-cooled in order to remove the dissipated heat or by transmitting current through superconducting coils. In resistive coils, the largest fields made in this way are in the range 30–35 T, whereas in superconducting coils made of conventional superconductors, the maximum field is around 23 T. Larger static magnetic fields (up to 40–45 T) can be generated in hybrid magnets, in which superconducting coils are placed around a water-cooled resistive-coil system, in this way providing a supporting background field of the order of 10 T.

In resistive-coil systems, the value of the highest possible field is mainly determined by the available electrical power and by the limited cooling capacity. In the case of superconducting coils, the main limiting factor is the field at which the coil material looses its superconducting properties and becomes normal. Coils made of high $T_c$ superconductors may lead to significant progress. However, for this to be possible, a number of important technological problems, for instance the production of wire of adequate mechanical strength, have to be solved.

The range of possible fields is appreciably larger if pulsed fields are considered. In pulsed magnets, the coils are energized only for a short time during which the dissipated heat cannot be removed by the cooling water and is mainly absorbed by the coil, which therefore increases in temperature during the pulse. For pulsed fields, the coils are usually energized by capacitor banks or flywheel generators. In practice, two time regimes are distinguished for the duration of the field pulse:

- long pulses with a duration of the order of 10 ms to 1 s that produce fields in the range 60–80 T; and
- short pulses with a duration in the microsecond region that produce fields in the range 100–500 T.

In general, short-pulse experiments are more difficult than long-pulse experiments and, as a consequence, less accurate. Also, in a metallic material, a pulsed magnetic field induces a current that is proportional to the change of the field with time. Therefore, experiments on this important category of solids should be performed in static fields, in fields that are kept constant for a sufficiently long time, or in long-pulse fields that vary only slowly with time. The magnetization measurements presented in this article have been performed in long-pulse fields. Some examples of facilities where long-pulse fields are generated are given in Table 1.

## 2. 3d Magnetism

In 3d metal-based metallic substances with itinerant electrons, the magnetism arises from electrons that occupy allowed states in incompletely filled electron bands that are filled up to the Fermi energy and that can be subdivided into two subbands with opposite spin directions that are equally occupied in the paramagnetic state. In a ferromagnet, and if a magnetic field is applied also in a paramagnetic metal, the two subbands are unequally occupied, thus giving rise to a magnetic moment (see *Itinerant Electron Systems: Magnetism (Ferromagnetism)*). Besides the exchange, the density of electron states at the Fermi level and its energy dependence determine the magnetic response of a metal to an applied magnetic field. In exchange-enhanced (Pauli) paramagnetic substances with a peculiar band structure near the Fermi energy, an applied magnetic field may induce a first-order phase transition from the paramagnetic to the ferromagnetic state. Transitions of this type, from a state with a relatively small magnetic moment to one with a larger moment, are generally denoted as metamagnetic transitions and occur, as discussed below, in many different types of magnetic materials. $YCo_2$ (Fig. 1) is an example of a nearly ferromagnetic compound that undergoes such a transition at low temperatures at a critical field as high as 69 T, (see *Metamagnetism: Itinerant Electrons*).

***Table 1***
Examples of long-pulse facilities.

| Location | Maximum field in length (T in mm) | Pulse length (ms) |
|---|---|---|
| KU Leuven | 60 in 20; 73 in 10 | 20; 10 |
| NHMFL Los Alamos | 68 in 15; 60 in 32 | 20; 100 |

| NRIM Tsukuba | 65 in 16 | 100 |

## 3. 4f Magnetism

The rare-earth (R) metals with their partially filled 4f shell and R-based compounds exhibit a large diversity of magnetic structures which result from the competition of the exchange interaction, the crystalline electric field (CEF) interaction, and the quadrupolar interaction, the latter in general being much smaller than the former two (see *Localized 4f and 5f*

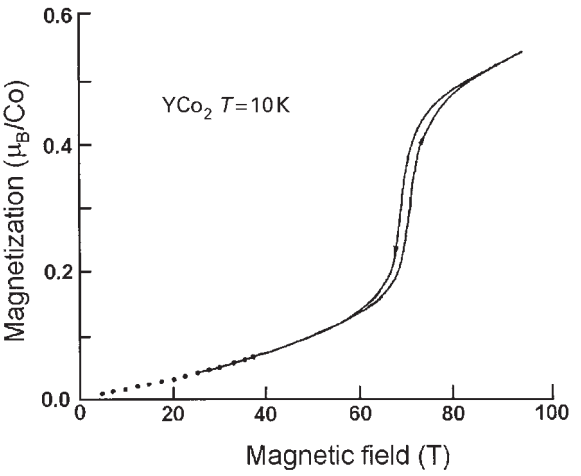

***Figure 1***
Magnetization of $YCo_2$ at 10 K (after Duc and Brommer 1999).

*Moments: Magnetism*). On application of a magnetic field, many R-based compounds exhibit transitions in the magnetization, usually denoted as metamagnetic transitions, examples of which are presented below. For a more detailed survey see Gignoux and Schmitt (1991).

Antiferromagnetic materials with small magnetic anisotropy may, at a certain field value which usually is not very high, exhibit a so-called spin-flop transition in which the collinear antiparallel magnetic moments rotate to a direction perpendicular to the applied field, thereby approximately preserving the collinear structure. This type of metamagnetic transition is often encountered in gadolinium compounds, which generally have small magnetic anisotropy since gadolinium has no orbital moment.

Another type of metamagnetic transition, the spin-flip transition, is found in antiferromagnetic materials with stronger magnetic anisotropy. In this transition, a simple single-step phase transition takes place from the antiferromagnetic state to the forced-ferromagnetic (magnetically saturated) state. A beautiful example is the orthorhombic compound $TbCu_2$ in which the terbium moments form a collinear antiferromagnetic structure with the moments aligned along the *a* direction. If the field is applied along this direction, a spin-flip occurs in 2 T (Fig. 2). If the field is applied along the *b* direction, a similar transition is observed at almost 40 T after the antiparallel terbium moments have been rotated from the *a* to the *b* direction. In many cases, the magnetization process of antiferromagnetic compounds is more complex and two- (Fig. 3) or multistep metamagnetic processes are involved in reaching the forced-ferromagnetic state.

The occurrence of metamagnetic transitions is not limited to magnetically ordered R-based materials. In Fig. 4, the magnetization of the paramagnetic metal praseodymium is seen to exhibit a metamagnetic transition. This transition can be ascribed to the crossing of two crystal field levels, a singlet which is the ground state in zero field and a magnetic excited

level which has the lowest energy above a certain value of the applied field.

### *4. 3d–4f Magnetism*

Intermetallic compounds of R metals and the late-3d transition (T) metals form a very important class of materials that find numerous applications in e.g., permanent magnets, magnetostrictive devices, magneto-optical recording, etc. In the R–T compounds with T = Fe, Co, the strongest interaction is the 3d–3d interaction which primarily determines the Curie temperature. The 4f–4f interaction is very weak and can be neglected. The 4f–3d interaction, although much weaker than the 3d–3d interaction, is of special importance since by this interaction the strongly anisotropic R sublattice magnetization is coupled to the much less anisotropic T sublattice magnetization. The interaction between 4f and 3d moments is based on an indirect interaction between the 4f and 3d spins, which is antiferromagnetic. This, together with Hund's rules, explains why the magnetic order is ferromagnetic in R–T compounds where R is a lighter element in the series and ferrimagnetic if R is a heavier element (see *Alloys of 4f (R) and 3d (T) Elements: Magnetism*).

The way in which the magnetic moment configuration in R–T compounds is affected by a magnetic field, applied along the principal crystallographic directions of a single crystal, can generally be well described in a molecular-field model with two magnetic sublattices, the R and T sublattices. From such an analysis, quantitative information on the magnetic anisotropy (the crystal field interaction) and on the strength of the 4f–3d interaction can be obtained. Evidently, such information is most readily obtained from magnetization measurements on ferrimagnetic compounds, in which the strict antiparallel configuration of the moments will be affected by a sufficiently high magnetic field.

Single crystals of various classes of R–T compounds with R = Co and Fe have become available, for instance the $R_2T_{17}$ and $R_2T_{14}B$ series, and their magnetization behavior has been investigated systematically in high magnetic fields applied along the main crystallographic directions. The magnetic isotherms at 4.2 K of the ferromagnetic compound $Nd_2Fe_{14}B$ are shown in Fig. 5. In this compound, the magnetic moments on the neodymium and the iron atoms are parallel and the Nd–Fe coupling is sufficiently strong to keep the moments rigidly coupled in the parallel orientation during the magnetization process. Therefore, the magnetic transition observed at about 16 T with the field applied in the [100] direction finds its origin exclusively in the magnetic anisotropy. Transitions like this one can be ascribed to higher-order terms in the anisotropy or, equivalently, to higher-order crystal field coefficients

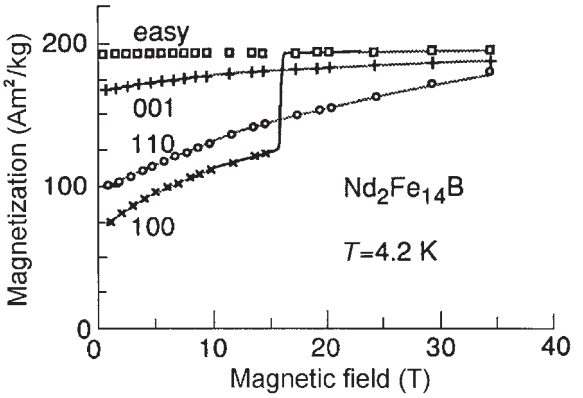

***Figure 5***
Magnetization of $Nd_2Fe_{14}B$ at 4.2 K in magnetic fields applied along several crystallographic directions (Buschow 1988).

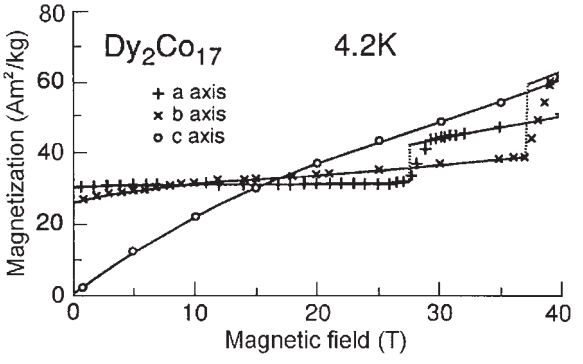

***Figure 6***
Magnetization of $Dy_2Co_{17}$ at 4.2 K in magnetic fields applied along the three main crystallographic directions (Franse and Radwanski 1993).

and allow for a rather precise determination of these parameters. The transition in $Nd_2Fe_{14}B$ is generally referred to as a first-order magnetization process (FOMP). In $Pr_2Fe_{14}B$, two transitions have been found which are of second-order type (SOMP).

High-field magnetic transitions that are based on the competition between the strength of the applied field and the strength of the 4f–3d exchange interaction have been extensively studied on single crystals of ferrimagnetic $R_2Co_{17}$ and $R_2Fe_{17}$ compounds. As an example, the magnetization of the hexagonal compound $Dy_2Co_{17}$ is shown in Fig. 6, measured with the field along the three principal crystallographic directions. As can be seen, the magnetic anisotropy of $Dy_2Co_{17}$ is of easy-plane type, the dysprosium moments lying along the *a* axis in the basal plane, antiparallel with the cobalt moments, as represented by

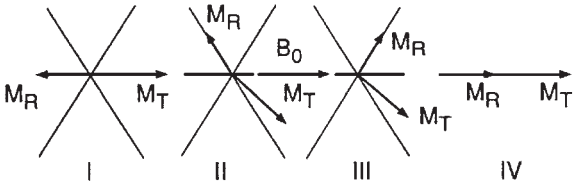

***Figure 7***
Schematic representation of the various moment configurations in hexagonal ferrimagnetic easy-plane $R_2T_{17}$ compounds.

configuration I in Fig. 7. The resulting magnetization is constant up to about 28 T and equal to the difference of the two sublattice magnetizations. At 28 T the collinear magnetic structure of this ferrimagnet is broken and a transition takes place to a moment configuration (II in Fig. 7) in which the dysprosium moments jump to another easy direction and in which magnetostatic energy is gained at the expense of exchange energy. For the field applied along the *b* axis, this transition takes place at a field strength of about 38 T. The solid lines in Fig. 6 correspond to calculations in terms of a molecular-field model by assuming the existence of two magnetic sublattices, one for the dysprosium and one for the cobalt moments. On the basis of the calculations, for the situation with the field applied along the *a* axis, in total three transitions are expected until the parallel, forced-ferromagnetic arrangement of the two sublattice magnetizations is reached. When the field is applied along the *b* axis, two transitions are expected. Such transitions have been reported for a large number of compounds of several series of R–T compounds, such as the $R_2Fe_{17}$, $R_2Co_{17}$, and $R_2Fe_{14}B$ series. Analysis of the magnetization curves has led to knowledge of the crystal field coefficients for these compounds and has provided values for the strength of the 4f–3d interaction (Franse and Radwanski 1993). Also, systematic trends of these parameters have been established.

An experimental method has also been developed to measure directly the strength of the 4f–3d interaction between the R and the T magnetic moments in heavy R–T intermetallic compounds. The method consists of measuring the low-temperature magnetic isotherms in very high magnetic fields of a single crystal or of fine single-crystalline powder particles that can freely rotate in the applied magnetic field. The free-powder magnetization of $DyCo_{12}B_6$ is shown as an example in Fig. 8. In this compound, the breaking of the collinear ferrimagnetic structure starts at about 10 T. The bending of the sublattice moments proceeds smoothly up to about 32 T where the forced ferromagnetic state is reached. The value of the strength of the Dy–Co exchange interaction can be obtained by analyzing the observed magnetization during the bending process in terms of a

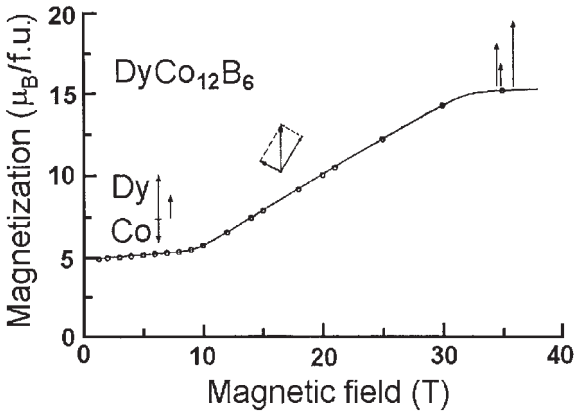

***Figure 8***
Magnetization of free powder of $DyCo_{12}B_6$ at 4.2 K (after de Boer 1996).

mean-field description. The very simple magnetization process of $DyCo_{12}B_6$ is representative of all R–T intermetallic compounds, in which the magnetic anisotropy of the T sublattice moment is negligible with respect to the R sublattice anisotropy. For these cases, if the crystal can freely rotate in the applied field, the R sublattice moment will remain in its easy direction in the crystal during the entire magnetization process and the magnetization process will be simple.

The magnetization process of $DyCo_{12}B_6$ is very exceptional in the sense that it is completed in experimentally accessible fields. In general, even the value of the field where the bending of the sublattice moments starts is experimentally inaccessible. However, because, as the theoretical description tells, this field is proportional to the difference of the two sublattice moments, the value of this field can be reduced by carrying out suitable chemical substitutions that make the values of the two sublattice moments more similar. This is illustrated in Fig. 9 for $Ho_2Fe_{17}$ in which the iron sublattice moment is larger than the moment of the holmium sublattice and the two sublattice moments can be made more similar by aluminum substitution for iron. In this way the bending process can be brought in an accessible field range, allowing for the determination of the Ho–Fe exchange coupling. Systematic trends of the 4f–3d interaction within and among series of R–T intermetallic compounds could be established on the basis of magnetization measurements on free powders of a large variety of properly substituted R–T systems (Liu *et al.* 1994).

## *5. 5f Magnetism*

Intermetallic compounds that comprise actinides, e.g., uranium, are of special interest since the behavior of

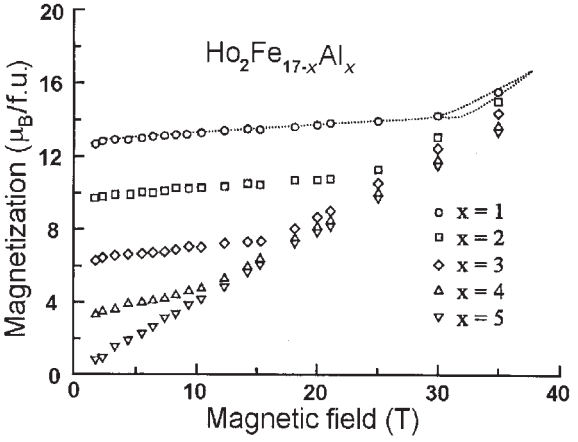

***Figure 9***
Magnetization of free powder of $Ho_2Fe_{17-x}Al_x$ compounds at 4.2 K (after Zvezdin 1995).

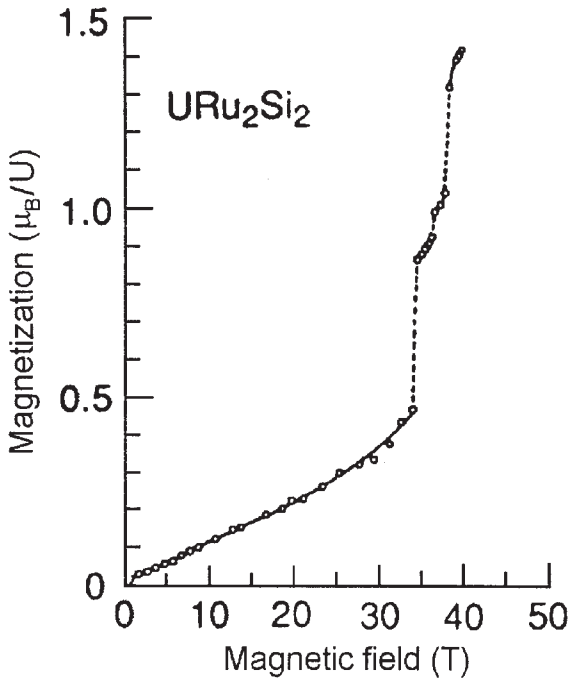

***Figure 10***
Magnetization of $URu_2Si_2$ at 4.2 K in magnetic fields applied parallel and perpendicular to the *c* axis (Sechovsky and Havela 1998).

the 5f electrons is intermediate between itinerant and localized (Sechovsky and Havela 1998). The magnetism of uranium compounds is characterized by complex magnetic structures, unstable magnetic moments, hybridization of the 5f states with d- and p-electron states of the ligand atoms, and extremely large anisotropy that can be associated with this hybridization (see *5f Electron Systems: Magnetic Properties*). The magnetization of the antiferromagnet $URu_2Si_2$ (Fig. 10) nicely illustrates the very large anisotropy and the richness of field-induced transitions that are encountered in uranium compounds. More examples of the high-field behavior of uranium compounds are given in the review of Sechovsky and Havela (1998).

# Magnetization Reversal Dynamics

Many important technological applications involve reversing magnetic moment in a magnetic material within a very short time period. For instance, in computer hard-disk drives, storing a single bit requires reversing the magnetic moments of both the write transducer and the thin film recording medium in a fraction of a nanosecond. Understanding magnetization reversal dynamics is critical in these applications (Bertram and Zhu 1992, Mao 2000, Zhu 2001, Zhu and Zheng 2002).

In general, magnetization reversal in a magnetic material, either of a bulk or thin film, or a particulate form, is always complex. For studying the reversal dynamics, there are many experimental means, including time-resolved Kerr microscopy field *in situ* transmission electron microscopy, field *in situ* scanning electron microscopy with polarization analysis (SEMPA), and field *in situ* magnetic force microscopy (Hubert and Schäfer 2000).

Magnetization reversal dynamics can also be studied via micromagnetic modeling. Combining the gyromagnetic dynamic equation with the classic micromagnetic theory (Strikman and Treves 1963, Brown 1978), the dynamic microscopic magnetization reversal process in a ferromagnetic object can be simulated on a computer or on a cluster of computers (e.g., Zhu 1989). In the modeling, magnetic energy density, $E$, that includes magnetocrystalline anisotropy energy, magnetostatic energy, ferromagnetic exchange energy, and magnetic potential energy (Zeeman energy), is calculated at each location of the object:

$$E = E_{\text{anisotropy}} + E_{\text{magneto}} + E_{\text{exchange}} + E_{\text{Zeeman}} \quad (1)$$

The effective magnetic field exerted on a local magnetic moment is

$$\mathbf{H} = -\frac{\partial E}{\partial \boldsymbol{M}} = -\left(\frac{\partial E}{\partial \boldsymbol{M}_x}\hat{\boldsymbol{e}}_x + \frac{\partial E}{\partial \boldsymbol{M}_y}\hat{\boldsymbol{e}}_y + \frac{\partial E}{\partial \boldsymbol{M}_z}\hat{\boldsymbol{e}}_z\right) \quad (2)$$

### 1. Gyromagnetic Equations with Energy Damping

Consider a magnetic moment with magnetization $\boldsymbol{M}$ in a magnetic field $\boldsymbol{H}$. Due to the fact that magnetic moment in a magnetic material arises from electron spin angular momentum and orbital angular momentum, the magnetic moment precesses around the field direction, described by the following torque equation (Landau and Lifshitz 1935):

$$\frac{\mathrm{d}\boldsymbol{M}}{\mathrm{d}t} = -\gamma \boldsymbol{M} \times \boldsymbol{H} \quad (3)$$

where $\gamma$ is the gyromagnetic constant. In this process, the angle between the magnetic moment and the field remains unchanged. In other words, the energy of the system is conserved. Any energy dissipation (or often referred to as energy damping) in the system results in a reduction of the angle. To include energy dissipation, one phenomenological form is the Gilbert equation:

$$\frac{\mathrm{d}\boldsymbol{M}}{\mathrm{d}t} = -\gamma \boldsymbol{M} \times \boldsymbol{H} + \frac{\alpha}{M}\boldsymbol{M} \times \frac{\mathrm{d}\boldsymbol{M}}{\mathrm{d}t} \quad (4)$$

where $M$ is the magnitude of the magnetic moment and $\alpha$ is referred to as the damping constant (Gilbert 1955). In this form, the damping motion of the moment direction towards field direction is viscous. The above implicit form of the dynamic equation can be transformed into the following explicit one, known as the Landau–Lifshitz equation (Landau and Lifshitz 1935):

$$\frac{\mathrm{d}\boldsymbol{M}}{\mathrm{d}t} = -\gamma_{\mathrm{L}} \boldsymbol{M} \times \boldsymbol{H} - \frac{\lambda}{M}\boldsymbol{M} \times \boldsymbol{M} \times \boldsymbol{H} \quad (5)$$

with

$$\gamma_{\mathrm{L}} = \frac{\gamma}{1+\alpha^2} \quad \text{and} \quad \lambda = \frac{\gamma\alpha}{1+\alpha^2}$$

In both Gilbert and Landau–Lifshitz equations, the magnitude of the magnetic moment is unchanged.

Under the Gilbert equation, if the energy does not depend explicitly on time, the rate of the energy change is given by (Zhu 1989)

$$\frac{\mathrm{d}E}{\mathrm{d}t} = -\mu_0 \frac{\alpha\gamma}{(1+\alpha^2)M^2} |\boldsymbol{M} \times \boldsymbol{H}|^2 \quad (6)$$

### 2. Magnetization Reversal of a Uniformly Magnetized Sphere

Consider a uniformly magnetized single-domain magnetic sphere in a magnetic field. At nonzero damping, the magnetic moment of the sphere rotates towards the field direction while precessing around the field direction. The smaller the damping constant $\alpha$, the greater the number of precession cycles will be before the magnetic moment aligns with the field direction. Figure 1 shows the calculated trajectories according to Eqn. (4) for two different values of the damping constant $\alpha$. The time duration of the reversal, from near antiparallel direction to the parallel direction, with respect to the field is given by

$$\Delta t = \frac{1+\alpha^2}{\alpha\gamma(H - H_{\mathrm{s}})} \ln\left(\frac{\tan(\theta_2/2)}{\tan(\theta_1/2)}\right) \quad (7)$$

where $\theta_2$ and $\theta_1$ are the final and initial angles between the magnetic moment and the field whose amplitude is denoted by $H$, and $H_{\mathrm{s}}$ is the switching field threshold (e.g., the anisotropy field). For a given magnetic field whose amplitude is greater than the

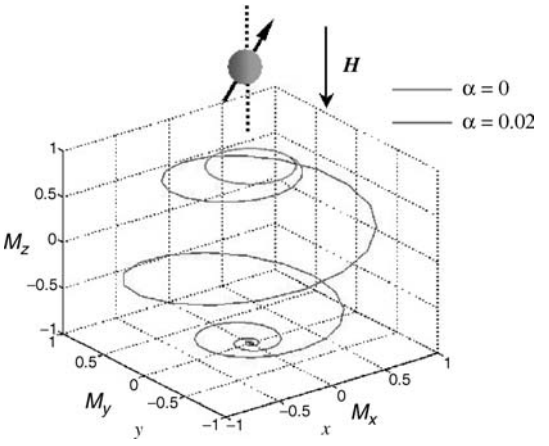

*Figure 1*
Magnetization trajectory of a uniformly magnetized sphere in a magnetic field. With zero damping, magnetization gyrates around the field direction with a constant moment-to-field angle, and the energy of system is unchanged. With the damping constant nonzero, the magnetization reverses into the field direction while gyrating around the field direction.

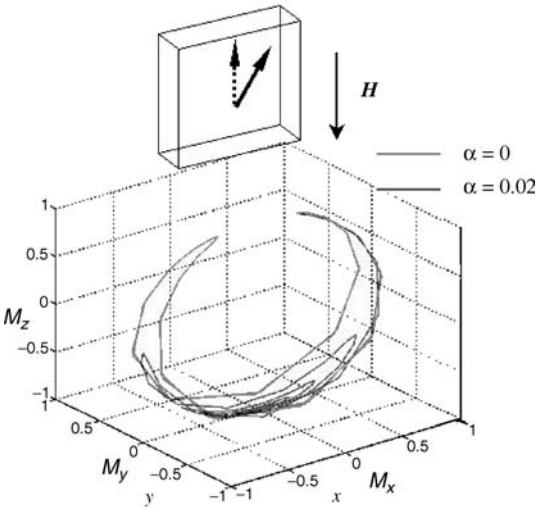

*Figure 2*

switching field threshold, $\alpha = 1$ gives the shortest reversal time (Kikuchi 1956).

### 3. Magnetization Reversal of a Uniformly Magnetized Thin Film

The dynamic magnetization reversal process in an always uniformly magnetized magnetic thin film is quite different than that in an always uniformly magnetized sphere. For a magnetization reversal with an external magnetic field applied in the film plane, the precession of the magnetic moment around the field direction causes the magnetization to rotate out of plane, generating a demagnetization field normal to the film plane. Subsequently, the magnetization precesses around this demagnetization field, yielding the rotation toward the external field direction within the film plane. Figure 2 shows the trajectories of the magnetization unit vector for the case of $\alpha = 0$ (red curve) and the case of $\alpha = 0.02$ (blue curve). The rotation trajectory of the magnetization vector behaves very much like a pendulum: at zero damping, the magnetization swings like an undamped pendulum. At nonzero damping, the magnetization vector eventually rests along the external field direction.

Note that for a uniformly magnetized thin film, it is the precession of the magnetization that drives the magnetization reversal in the film plane, in contrast to the case of uniformly magnetized sphere. The shortest reversal time for a given external field magnitude occurs at a relatively small damping constant depending on the magnitude of the magnetization.

### 4. Magnetization Reversal of Patterned Magnetic Thin Film Elements

The two magnetization reversal processes described in the previous two sections apply only to objects that have physical dimensions smaller than the exchange length, defined as the square root of the ratio of physical dimension significantly greater than the exchange length:

$$l_{ex} = \sqrt{\frac{A}{M_s^2}} \tag{8}$$

where $A$ is the exchange stiffness constant and $M_s$ is the saturation magnetization of the material (Brown 1978). For ferromagnetic objects whose physical dimensions are greater than the exchange length, the dynamic magnetization configurations during a magnetization reversal are usually spatially nonuniform. In the case that the ferromagnetic object is a patterned thin film element, the transient reversal process becomes almost independent of the damping constant, except at very final stage of the reversal. Figure 3 shows a dynamic reversal process for a Permalloy thin film elliptical element with a length of 0.6 μm, a width of 0.3 μm, and a thickness of 25 nm. A damping constant $\alpha = 0$ has been assumed. The

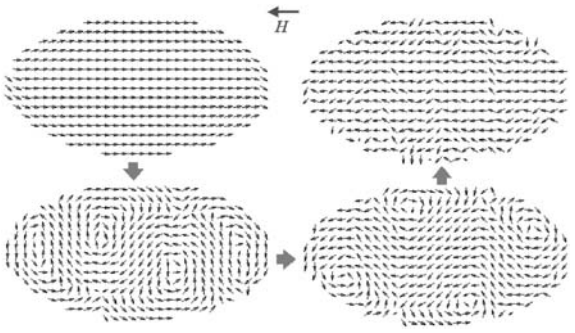

***Figure 3***
Calculated magnetization reversal process of an elliptical permalloy thin film element. The length of the element is 0.6 μm, width 0.3 μm, and thickness 25 nm. The reversal starts with the formation of four vortices along the edges of the element. The four vortices move across the width of the element, leave magnetization reversed. At the end, spin waves are generated in the reversed element.

external applied field is assumed to rise exponentially with a rise time $\tau = 0.1$ ns. The reversal starts as four magnetization vortices nucleate along the edges of the element, followed by the motion of the vortices transverse to the field direction, across the film element. As the vortices move out of the opposite edges of the element, the magnetization of the entire element has virtually been reversed, except magnetization still precesses, forming a set of spin waves in the element. Due to the reversal of the magnetization direction, the Zeeman energy has been reduced. Since there is no energy damping during the reversal process, the Zeeman energy has been transformed into the ferromagnetic exchange energy stored in the resulted spin waves. The changes of various energy densities with time during the reversal are plotted in Fig. 4.

The calculation also show that the transient reversal process is virtually unchanged if a small energy damping is introduced during the reversal process and the reversal time becomes essentially independent of the damping constant (Fig. 5). The only difference is that in the case of nonzero energy damping during the reversal process, no spin wave is generated after the completion of the reversal.

For a reversal of a thin film element within the film plane, in the case of zero energy damping, entropy becomes the driving force of the reversal: the generation of the spin wave at the end of the reversal results in an increase of the system's entropy. Note that spin wave is an excellent energy reservoir. Furthermore, a spin wave could directly couple to lattice vibrations, creating an energy-damping path through magnon–phonon interactions.

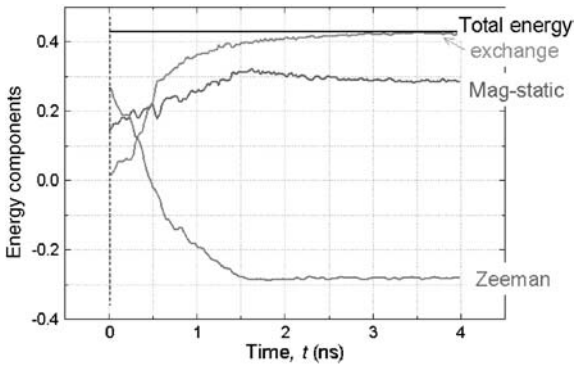

***Figure 4***
The dynamic change of various energy densities during the in-plane magnetization reversal of a patterned nonsingle domain thin film element with zero energy damping ($\alpha = 0$). The reduction of Zeeman energy becomes the ferromagnetic exchange energy and magnetostatic energy stored in the resulted spin waves.

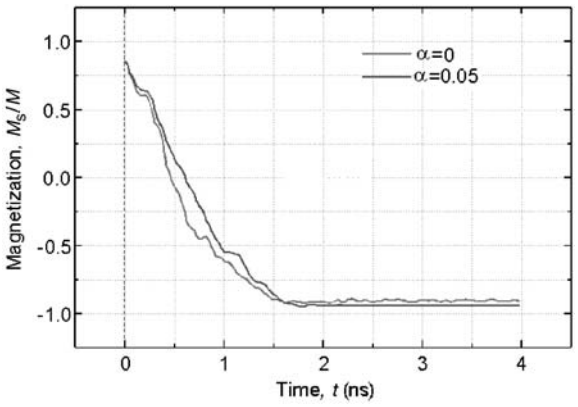

***Figure 5***
Element-averaged magnetization component along field direction during a magnetization reversal for two energy damping constants $\alpha = 0$ (red) and $\alpha = 0.05$ (blue).

## *5. Near-uniform Magnetization Switching*

The magnetization reversal process described in the previous section can be characterized as nucleation and motion of magnetization vortices. The formations of the vortices are driven by the relatively high magnetostatic energy since it is significantly reduced in a magnetization vortex due to the magnetization flux closure. When a film becomes sufficiently thin, magnetization vortices longer form and the magnetization reversal becomes near-uniform rotation. Figure 6 shows the magnetization reversal process of a NiFe film element with a size of $0.5\,\mu m \times 0.3\,\mu m$ and a

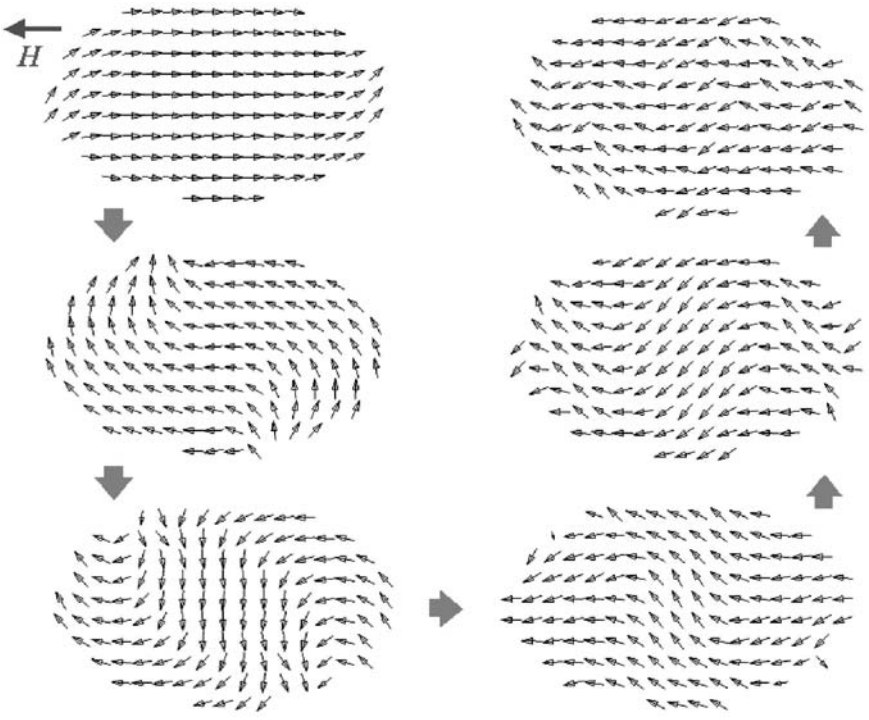

***Figure 6***

thickness only 6 nm. No vortex is present at any stage during the reversal.

### *6. Effect of the Element Ends*

The dynamic magnetization reversal process in a patterned thin film element strongly depends on the element's geometric shape. Reversal of a long rectangular shaped element is particularly interesting. Figure 7 shows a reversal process in a permalloy element with thickness $\delta = 2$ nm. The length and the width of the element are 1.2 μm and 0.2 μm, respectively. The external field is applied along the element length direction. The magnetizations at both ends of the element are oriented parallel to the edges, forming edge domains. The reversal starts from the two ends and expands into the interior of the element via motion of the two domain walls. The magnetization direction within the two domain walls inherits the magnetization directions of the two initial edge domains, which are in the opposite directions in this particular case. As the reversal progresses, the two domain walls move towards each other, forming a 360° domain wall in the middle of the element. The detailed magnetization configuration of the 360° domain wall is shown in Fig. 8. A further significant increase of the field magnitude is needed to move the 360° domain walls out of the side (long) edges. Whereas to reverse the magnetization back with the presence of the 360° domain wall, the critical field magnitude becomes significantly smaller (Fig. 7). The presence of 360° domain wall in the film element is one of the important mechanisms causing nonrepeatable magnetic switching processes.

### *7. Element of Relatively Large Sizes*

Figure 9 shows the calculated magnetization reversal process of a rectangular permalloy thin film element

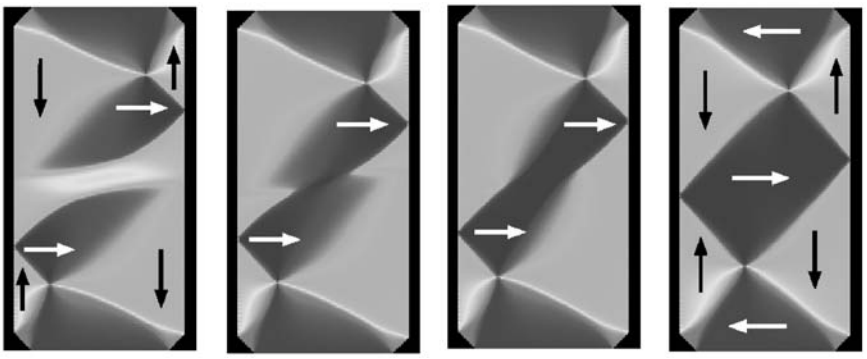

*Figure 11*
The transient magnetization configurations showing the dynamic formation of the closure domain pattern during the magnetization reversal in Fig. 9. The initial (the extreme left) and the final (the extreme right frame) magnetization states correspond to the states shown in frames (3) and (4) in Fig. 9, respectively. The spectrum of natural light is used to represent the magnetization component in the horizontal direction, with blue indicating the magnetization pointing to right and red to the left.

with size $10\,\mu m \times 5\,\mu m$ and thickness 30 nm. The divergence of the magnetization is plotted in gray scale to show the domain walls. Figure 10 shows an example of the exact magnetization pattern corresponding to a wall configuration shown in a gray scale plot. As shown in Fig. 9, from frame (1) to frame (8), the magnetization of the center of the element is completely reversed, from pointing down to pointing up. Prior to the reversal, frame (1) in the figure, there already exist two triangular domains at the top right and bottom left whose magnetizations are already in the reversed (up) direction. As the reversal proceeds, these two reversed domains expand, forcing the formation of the diamond transverse domain in the middle of the element and resulting in the complete flux closure domain configuration shown in frame (4). Continued expansion of the two reverse domains into the entire central area of the element eliminates the transverse diamond domain and the reversal is thus completed.

The formation of the closure domain configuration shown in frame (4) of Fig. 9 is particularly interesting. Figure 11 shows the transient magnetization configurations from the state shown in frame (3) to the state shown in frame (4) of Fig. 9. The connection of the two curved domains forms the central diamond domain in the closure domain configuration.

## 8. Summary

Magnetization reversal dynamics can be very complicated even in ferromagnetic objects of simple geometric shape. The discovery of the giant magnetoresistance, the advancement of spin-dependent tunneling, and the exploration of spin in semiconductors have sparked recent insurgence on the development of many new types of magnetic devices that utilize magnetic multilayer structures patterned into diminutive dimensions. To facilitate the technological advancements, dynamic micromagnetic modeling will continue to be a powerful tool to obtain critically needed understanding of the magnetization reversal characteristics in these devices and structures.

# Magnetocaloric Effect: From Theory to Practice

It is known that as an external magnetic field is applied to a magnet under adiabatic conditions (i.e., under the conditions of constant total entropy of the body, $S = \text{constant}$), the initial temperature $T$ of the body may vary due to the magnetocaloric effect (MCE) by the value $\Delta T$. It can result in an increase or in a reduction of the original temperature of a magnetic material. This is a consequence of the variation, under the field, of the internal energy under the influence of an external field of the material possessing a magnetic structure. In 1881 Warburg first discovered MCE as a heat evolution in iron under a magnetic field. In principle, the term MCE should be considered more widely as a description of the processes of entropy variation of the magnetic subsystem.

MCE investigations were shown to yield the kind of information that can hardly be obtained by other techniques. In recent years the interest in investigations of the MCE and the influence of the magnetic field on the entropy has become renewed due to the possibility to obtain information on magnetic phase transitions and the prospects of using some of these materials in magnetic refrigerators (Tishin 1999). The thermodynamic approach is most elaborate for the understanding of the observed phenomena. Also often used are Landau's theory of second-order phase transitions and the mean-field approximation (MFA).

In general, the heat generation and absorption in magnetic materials during adiabatic processes include not only MCE but also elastocaloric effects (ECE). The ECE is a heat emission or absorption at a constant applied magnetic field (in a simple case at zero field) and changing external pressure. If a pressure change takes place under adiabatic conditions then the ECE (like MCE) manifests itself as heating or cooling of a magnet.

## 1. Elements of Thermodynamic Theory

Considering the total entropy of the system, $S(T, H, p)$, the total differential can be written as:

$$\mathrm{d}S = (\partial S/\partial T)_{\mathrm{H,p}}\mathrm{d}T + (\partial S/\partial H)_{\mathrm{T,p}}\mathrm{d}H + (\partial S/\partial p)_{\mathrm{T,H}}\mathrm{d}p \quad (1)$$

where $p$ is the pressure, $H$ is the magnetic field.

For an adiabatic-isobaric process ($\mathrm{d}p = 0$) one can obtain from Eqn. (1) with Maxwell's relations the following expression for the temperature change due to the change of the magnetic field (the MCE):

$$\mathrm{d}T = -(T/C_{\mathrm{H,p}})(\partial M/\partial T)_{\mathrm{H,p}}\mathrm{d}H \quad (2)$$

where $C_{\mathrm{H,p}}$ denotes the specific heat at constant field and pressure (see *Magnetic Systems: Specific Heat*).

The thermodynamic equations obtained above are sufficiently general, since no assumptions as to the structure of the considered system were made. To obtain more concrete results one should know the form of the functions of the free energy of a specific system, which requires some model assumptions. It is known that in ferromagnets normally a second-order phase transition takes place at the Curie point, $T_{\mathrm{C}}$. Belov (1961) adopted the Landau theory of second-order phase transitions to magnetic transitions. According to this theory, the values of the MCE of a ferromagnet which is brought into a magnetic field, $H$, near the Curie temperature as well as an expression describing the MCE field dependence near the Curie temperature can be calculated.

Above we have considered the MCE in relation to a reversible process of magnetization. Nonreversible magnetothermal effects can arise due to such processes of magnetization as displacement of domain walls and nonreversible rotation of the saturation magnetization, first-order magnetic phase transitions, and Foucalt currents. The nonreversible effects can decrease the sample cooling under adiabatic demagnetization.

The constancy of the total entropy in studies of MCE means (in the case when the total entropy of the magnet can be represented as the sum of three parts: $S_{\mathrm{L}}$, $S_{\mathrm{M}}$, $S_{\mathrm{E}}$—the lattice, magnetic, and electronic entropy, respectively), that as the field is increased from zero up to $H$ it is possible to write:

$$\begin{aligned} &S_{\mathrm{L}}(T) + S_{\mathrm{M}}(0, T) + S_{\mathrm{E}}(T) \\ &\quad = S_{\mathrm{L}}(T + \mathrm{d}T_1) + S_{\mathrm{M}}(H_1,\ T + \mathrm{d}T_1) \\ &\qquad + S_{\mathrm{E}}(T + \mathrm{d}T_1) = \ldots = S_{\mathrm{L}}(T_{i-1} + \mathrm{d}T_i) \\ &\qquad + S_{\mathrm{M}}(H_i,\ T_{i-1} + \mathrm{d}T_i) + S_{\mathrm{E}}(T_{i-1} + \mathrm{d}T_i) = \ldots \\ &\quad = S_{\mathrm{L}}(T + \Delta T) + S_{\mathrm{M}}(H,\ T + \Delta T) + S_{\mathrm{E}}(T + \Delta T) \end{aligned} \quad (3)$$

where $\mathrm{d}T_i$ is the infinitesimal gain in the MCE value as the field increases from $H_{i-1}$ up to $H_i$,

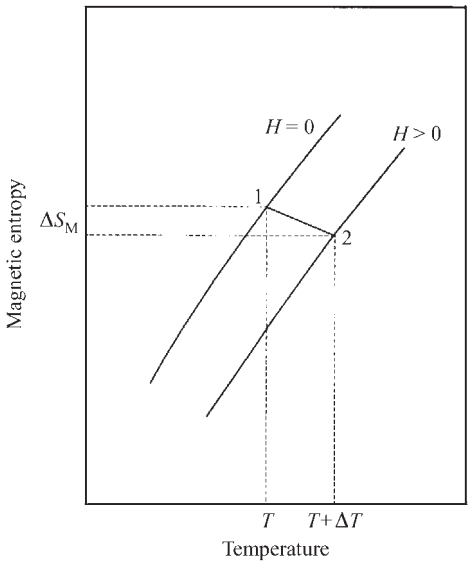

***Figure 1***
The example of the magnetic entropy curves without magnetic field and at magnetic field $H =$ constant.

$T_i = \mathrm{d}T_i + T_{i-1}$. If the value of $S_E(T)$ has a small change then the Eqn. (3) can be rewritten as:

$$-\Delta S_M(H,\ T) = -\left(S_M(H,\ T+\Delta T) - S_M(0,\ T)\right) = S_L(T+\Delta T) - S_L(T) = \Delta S_L(T) \qquad (4)$$

Thus, as the magnetic entropy is changed by the value $\Delta S_M(H, T)$ (in this case the value of $S_M$ is decreased from point 1 to 2 as shown in Fig. 1) the lattice entropy is decreased by the same amount but with the opposite sign. It should be noted that, as one can see from Eqn. (3), as the field changes, the sum of entropies of the magnetic and lattice subsystems remains constant (at each particular moment of time). At the same time, it seems that the specific part of each contribution to the total entropy of the magnet may vary. In simple one-domain isotropic collinear magnetic structures the field effect is known to result in a stricter alignment of the atomic magnetic moments in the magnetic field direction. Thus, a decrease in magnetic entropy as the field increases (the positive MCE) is usually associated with an increasing order of the magnetic subsystem.

The maximum possible variations in the magnetic entropy for one mole of free ions, as predicted by the theory, is $\Delta S_{max} = -R \ln(2J+1)$, where $R$ is the universal gas constant and $J$ is the total angular moment. From the classic point of view, the change of $S_M$ is usually related to the rotation of the magnetic moment vectors under influence of the magnetic field (i.e., the $S_M$ decreases with increasing magnetization in classic magnetic materials). In reality, the magnetic entropy (and consequently the sample temperature) continues to change even in the high field region, just because the probability of atomic magnetic moment deflection from the field direction (due to the thermal fluctuations) remains nonzero even in high magnetic fields.

The magnitude of the isothermal magnetic entropy change, $\Delta S_M$, as well as the total entropy change, $\Delta S$, with the change of magnetic field $\Delta H = H_2 - H_1$ can be calculated from the Maxwell relation on the basis of magnetization data as:

$$\Delta S_M = \int_{H_1}^{H_2} (\partial M(H,T)/\partial T)_H \mathrm{d}H \qquad (5)$$

The magnetic entropy $S_M(H, T)$ can be also calculated as:

$$S_M = \int_0^T (C_M(H,\ T)/T)\mathrm{d}T \qquad (6)$$

where $C_M(H, T)$ is the magnetic heat capacity.

## 2. *Methods of MCE Measurements*

At present, there are two main practical methods for the determination of the $\Delta T$ value. The first method involves direct measurement of the temperature change $\Delta T(H, T) = T_f - T$ (where $T_f$ is the final temperature) of the sample placed in adiabatic conditions under the influence of an external field. The second way is indirect and based on the calculation of the MCE value on the basis of experimental data on the heat capacity and/or magnetization.

The method of direct measurements of the change in material temperature during the application or removal of a magnetic field by an electromagnet (switch-on technique) has been used for MCE experiments since the 1930s. When the field is produced by an electromagnet the rise time has a maximum value of about a few seconds, while it can be several minutes for a superconducting solenoid. During the field rise a dissipation of heat produced in the sample by the MCE can occur. Estimations show that the field rising time must not be greater than 10 seconds for temperatures above 30 K. This implies that MCE measurements made by a switch-on technique are difficult when using a superconducting solenoid.

Consider as an example the pulsed field setup, as described by Dan'kov *et al.* (1997). The principal scheme of this setup is shown in Fig. 2. Changes of the sample temperature were measured by a copper-constantan thermocouple made of small diameter wires ($\sim$0.05 mm). This provides a small mass of thermocouple (typical weight of the sample is about 1 g) and, consequently, a negligible heat load, which significantly reduces the heat that leaks through the electrical wires. The gadolinium sample, measured by

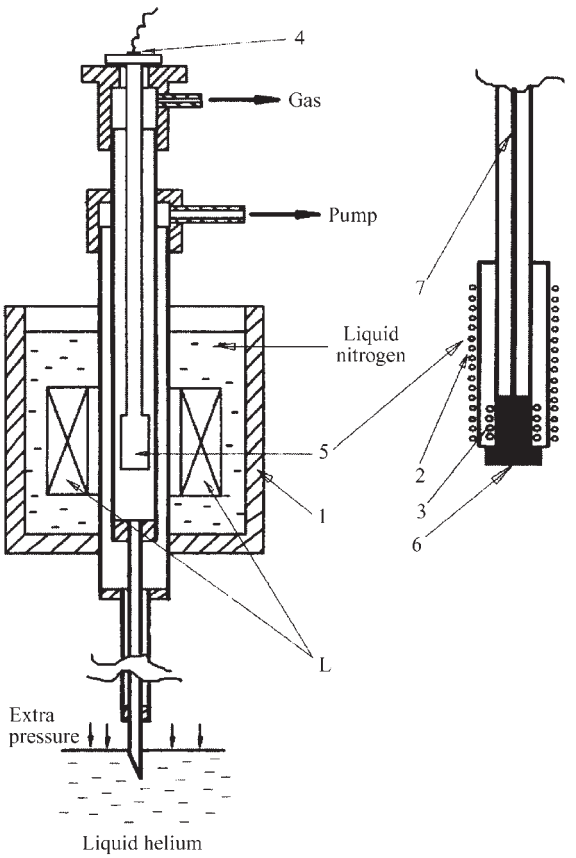

***Figure 2***
Low temperature part of the experimental pulsed-field setup: (1) liquid nitrogen cryostat, (2) sample heater, (3) field measuring coil, (4) vacuum tight feed through connector, (5) sample holder, (6) sample inside the holder, (7) electrical wiring, and L pulsed solenoid (after Dan'kov *et al.* 1997).

Dan'kov *et al.* (1997) was shaped as a parallelepiped with the dimensions $4 \times 4 \times 10$ mm and cut into two equal parts along the long axes. The thermocouple was placed between the parts in the center of the sample. The magnetic field was created by the solenoid L under the discharge of a battery of capacitors C. This technique made it possible to determine the sample temperature change due to the change of the magnetic field, i.e., the MCE at a given field and temperature.

Experimental data on the magnetic field dependence of the magnetization at constant temperatures allows calculation of the magnetic entropy change by means of Eqn. (5) and the MCE by Eqn. (2).

Another method for the evaluation of $\Delta S_M$ is based on the fact that the temperature dependence of the total entropy in the presence of a magnetic field $S(H, T)$ is shifted on the temperature axis relative to the zero-field total entropy $S(0, T)$ to higher temperatures by the value of MCE for a magnetic material under adiabatic conditions. This method is based on the heat capacity measurements and has been proposed by Brown (1976). It allows determination of all parameters required for magnetic refrigeration design.

## 3. *MCE in Different Magnetic Materials*

The heavy rare-earth metals (REM) gadolinium to lutetium (except ytterbium) and yttrium have hexagonal close-packed (h.c.p.) crystalline structures. In the magnetically ordered state they display complex magnetic structures (except gadolinium) (see *Alloys of 4f (R) and 3d Elements (T): Magnetism*, *Localized 4f and 5f Moments: Magnetism*). The MCE and heat capacity of single crystal and polycrystalline samples of heavy REMs have been studied by many authors. The temperature dependence of the MCE of gadolinium obtained by various experimental methods is presented in Fig. 3. A negative MCE is characteristic

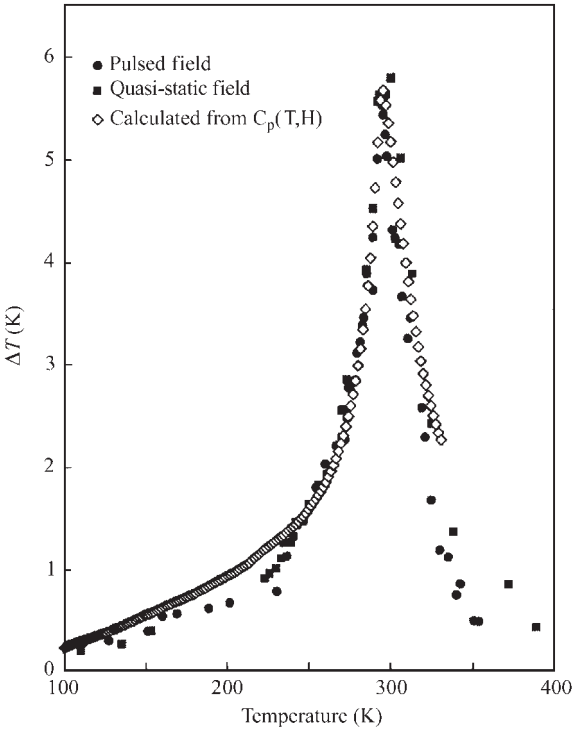

***Figure 3***
The MCE temperature dependencies of high purity polycrystalline Gd measured directly by quasi-static and pulsed techniques (closed symbols) compared with those determined from the heat capacity (open symbols) for $\Delta H = 20$ kOe (after Dan'kov *et al.* 1997).

of antiferromagnets (e.g., terbium and dysprosium in low magnetic fields), in which the external field reduces the magnetic order rather than enhances it, thus increasing the magnetic entropy.

MCE studies of iron, cobalt, and nickel in fields up to 30 kOe have shown that the magnitude of the MCE near $T_C$ is well described by Eqn. (2). Unlike REMs, in 3*d* ferromagnets in the same field the maximum of the MCE is fairly sharp. The MCE in iron and cobalt exceeds that of nickel by several fold.

MCE at the first-order transitions (e.g., from ferri- (FI) or ferromagnetism to antiferromagnetism (AFM)) has also been widely studied. Magnetic fields can induce a transition from an AFM structure present below the transition point, to a ferromagnetic one. This is accompanied by sample cooling. In high magnetic field, at the transition from a helicoidal antiferromagnetic state to the ferromagnetic state a positive MCE is observed.

The MCE and magnetic entropy change induced by a magnetic field in thin films prepared on the basis of 3*d* elements was also measured. MCE is due to the uniform rotation of the spontaneous magnetization. Experimental MCE measurements were made on polycrystalline ferromagnet and single crystalline ferrimagnetic dielectric films.

Investigation of some of oxides showed that the MCE suddenly changes its sign in the low temperature region. An analogous behavior was observed in rare-earth garnets. Such a behavior is related with changes of the ferrimagnetic structure of the rare-earth iron garnets.

The magnetothermal properties of gadolinium gallium garnet (GGG), dysprosium gallium garnet (DGG), and dysprosium aluminum garnet (DAG) were also studied. GGG and DGG have antiferromagnetic ordering below $T_N = 0.8$ K and 0.373 K, respectively. Above $T_N$ they display simple paramagnetic behavior. Rare-earth orthoaluminates (REOA), $RAlO_3$, have an orthorhombically distorted perovskite structure. The magnetic entropy change $\Delta S_M$ induced by a field in $GdAlO_3$, $ErAlO_3$, and $DyAlO_3$ was calculated by Kuz'min and Tishin (1991) in the framework of MFA. Kimura *et al*. (1997) determined experimental values of $\Delta S_M$ for $RAlO_3$ on the basis of magnetization measurements (see Fig. 4). The experimental results for $DyAlO_3$ and $ErAlO_3$ along the easy axes are in good agreement with the previous calculations. This supports the conclusion that $DyAlO_3$ and $ErAlO_3$ are promising materials for magnetic refrigeration below 20 K as proposed by Kuz'min and Tishin (1991) on the basis of theoretical calculations.

Modern experimental investigations in high magnetic fields of 5MOe and higher are nowadays nothing extraordinary—the MCE value in such fields can be extremely high. Therefore, the possibility of its influence on the obtained experimental results needs to be accounted for. A computer simulation analysis

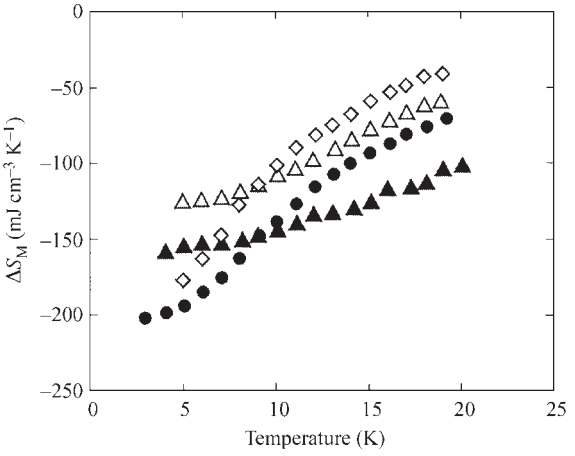

***Figure 4***
Comparison of $\Delta S_M$ temperature dependencies in $DyAlO_3$ (closed triangles) measured along *b*-axis and in $ErAlO_3$ (closed circles) along *c*-axis with that in $Gd_3Ga_5O_{12}$ (open diamonds) and $Dy_3Al_5O_{12}$ (open triangles) measured along [111] direction with a magnetic field change of 50 kOe (after Kimura *et al*. 1997).

of the MCE was developed for calculating peak values of the MCE in rare-earth magnets using a mean-field approximation. The study concentrated on the variation of the key thermodynamic parameters such as magnetic field, temperature, and Curie and Debye temperatures of the magnetic materials in a wide range of values. The results of the numerical simulation agree quite well with the experimental data for the heavy lanthanides only for large magnetic fields.

The calculations reveal the fact that if the temperature is high (near 1000 K), saturation of the MCE and magnetic entropy is absent even in the highest magnetic fields (up to 40 MOe), while near the temperature of the phase transition to the paramagnetic state the value of the magnetic entropy saturates in a field of about 10 MOe. The analysis shows that the $\Delta T_{max}$ value in the vicinity of the transition point in the series of heavy REMs is directly proportional to the product $g_J J T_{ord}$ and can reach, for example, 254 K in the case of terbium. For more details see Tishin (1999).

## *4. Magnetic Refrigeration*

The MCE is utilized in magnetic refrigeration machines. At the beginning of the century Langevin (1905) demonstrated that changes in the paramagnet magnetization generally resulted in a reversible temperature change. The first experiments to put this idea into practice were carried out in 1933–1934. Investigations in the wide temperature region (from

4.2 K to room temperature and even higher) were started by Brown (1976). Technologically, the current interest in the MCE is connected with the real possibility to employ materials with large MCE values in the phase transition in magnetic refrigerators. The current extensive interest aims to demonstrate that magnetic refrigeration is one of most efficient method of cooling at room temperatures and higher. For instance, the Ames Laboratory (Iowa State University, USA) and the Astronautics Corporation of America have been collaborating and developing an advanced industrial prototype of such a magnetic refrigerator (Zimm *et al*. 1998). In principle, these refrigerators could be used in hydrogen liquefiers, large building air conditioning, vehicle passenger coolers, IR detectors, high-speed computers, and SQUIDs.

At present only REM materials are recognized as appropriate for these purposes. According to Barclay (1994), the REM materials can be used in gas cycle refrigerators as passive regenerators. In magnetic refrigerators they can be applied as working materials (bodies) in externally regenerated or nonregenerative cycles. They can also serve as active magnetic regenerative refrigerators (AMRR).

A regenerator serves to expand a refrigerator temperature span, since the temperature span produced by the adiabatic process itself is insufficient to achieve the desired temperature (especially in the case of magnetic materials). With the help of a regenerator the heat is absorbed from, or returned to, the working material at the various stages of a regenerative thermodynamical cycle.

In the low-temperature region the heat capacity of conventional regenerators in cryogenic refrigerators essentially decreases, since the lattice heat capacity of a solid is proportional to $T^3$ and the electronic heat capacity in metals is proportional to $T$. In the refrigerators used for cooling helium gas this leads to a rapid decrease of the refrigerator effectiveness because below about 10 K the volume heat capacity of compressed helium increases. Buschow *et al*. (1975) proposed rare-earth compounds as a possible solution of this problem. The statement was based on the fact that in rare-earth compounds the low magnetic ordering temperatures and the associated heat capacity peaks offer relatively high magnetic contributions to the volume heat capacity. Practical constructions of passive magnetic regenerators using $Er_3Ni$ appeared after investigations of the heat capacity of various R–Ni compounds made by Hashimoto and co-workers (1986). The use of passive magnetic regenerators allowed it to reach 4.2 K and to increase the cooling power.

In magnetic refrigerators a nonregenerative Carnot cycle is used in conjunction with magnetic type regenerative Brayton and Ericsson cycles and with active magnetic regenerator (AMR) cycles (Barclay 1994). A Carnot cycle with a temperature span from $T_{cold}$ to $T_{hot}$ is shown by the rectangle ABCD in the total entropy—temperature ($S$–$T$) diagram in Fig. 5. The heat $Q$, corresponding to the load during one cycle of refrigeration is equal to $T_{cold}\Delta S_M$. Increasing the temperature span beyond a certain optimal value leads to a significant loss of efficiency as point C in Fig. 5 tends to approach point G and the cycle area becomes narrow. The temperature span of the Carnot cycle for a given $T_{cold}$ and $H$ is limited by the distance AG (i.e., by the MCE at $T = T_{cold}$ and the field change from 0 to $H$), when Q becomes zero. At temperatures above 20 K the lattice entropy of solids strongly increases, which leads to a decrease of the Carnot cycle area (see rectangle ABCD in Fig. 5). That is why applications of Carnot-type refrigerators are restricted to temperatures region below 20 K.

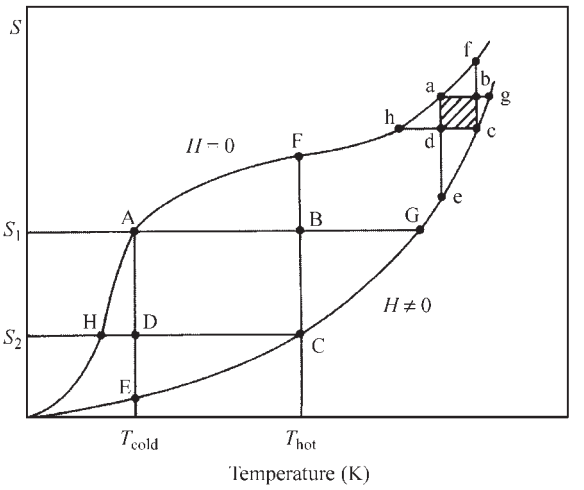

***Figure 5***
*S–T* diagram of thermodynamic cycles used for magnetic refrigeration. Two isofield curves are shown: for $H = 0$ and $H > 0$ (after Kuz'min and Tishin 1991).

Magnetic refrigerators operating at higher temperatures have to employ other thermodynamic cycles, including processes at constant magnetic field. Such cycles, as distinct from the Carnot cycle, allow the use of the area between the curves $H = 0$ and $H \neq 0$ in the $S$–$T$ diagram more fully. The rectangles AFCE and AGCH present the Ericsson and Brayton cycles, respectively. The two cycles differ in the way the field change is accomplished, isothermally in the Ericsson cycle and adiabatically in the Brayton cycle. Realization of isofield processes in both of these cycles requires heat regeneration.

The first room temperature magnetic refrigerator using a regenerative magnetic Ericsson cycle is the device proposed by Brown (1976). The regenerator consists of a vertical column with fluid (0.4 $m^3$, 80% water and 20% alcohol). The magnetic working material immersed in the regenerator consists of 1 mol of

1 mm thick Gd plates, separated by screen wire to allow the regeneration fluid to pass through in the vertical direction. The working material is held stationary in a magnet while the tube containing the fluid oscillates up and down. If initially the regenerator fluid is at room temperature, after about 50 cycles the temperature at the top can reach $+46\,^{\circ}C$ and the temperature at the bottom can reach $-1\,^{\circ}C$. The temperature gradient in this device is maintained in the regenerator column.

In the AMR refrigerator the magnetic working material and regenerator are joint in one unit. In this case the temperature gradient exists inside the working material and such a cycle cannot be described by a conventional gas cycle analogue. Consider the AMRR construction proposed by Zimm *et al.* (1998), which is shown in Fig. 6. A magnetic field up to 50 kOe is provided by a helium cooled superconducting solenoid working in the persistent mode. Two beds, each composed of 1.5 kg of gadolinium spheres, are used as the AMR. The spheres have a diameter of 150–300 μm and are made by a plasma-rotating electrode process. The beds are, by turns, moved in and out of the Dewar bore with a magnetic field. Water is used as a heat transfer fluid. The working cycle of the device started with water cooling by blowing it through the demagnetized bed located inside the magnetic area (bottom position in Fig. 6).

Then the water passes through the cold heat exchanger picking up the thermal load from the cooling object. After this the water is blown through the magnetized bed located in the magnetic field area where it absorbs the heat evolved due to the MCE. Next the water passes through the hot heat exchanger, releasing the heat absorbed from the magnetized bed. The cycle is finished by removing the magnetized bed from the magnet and replacing it by the demagnetized one. Such a device, working at 0.17 Hz with a field of 50 kOe in the room temperature range with a temperature span of 5 K, provides a cooling power of 600 W (which is about 100 times better than in previous constructions) with a maximum efficiency of 60 % that of a Carnot process.

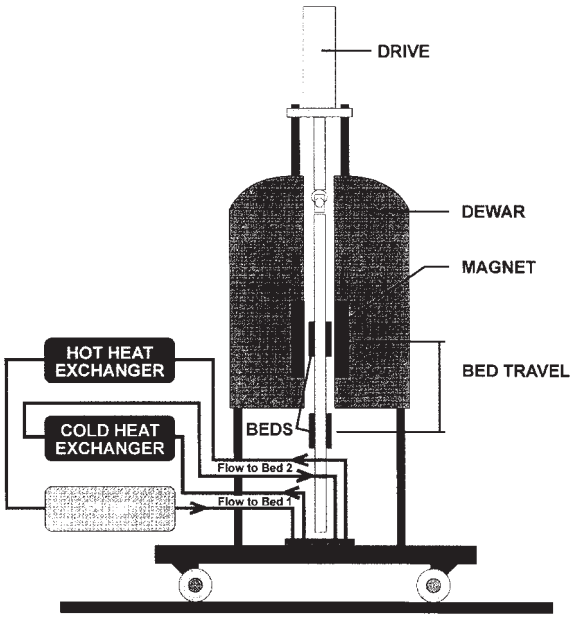

***Figure 6***
Construction of an AMR refrigerator operating at near room temperature (after Zimm *et al.* 1998).

The suggestion to use binary and more complicated rare-earth alloys as working bodies for the room temperature region was made by Tishin in 1990. For the application in an ideal Ericsson magnetic regenerator cycle a magnetic working material should have a magnetic entropy change $\Delta S_M$ that is constant in the cycle temperature span. The use of terbium–gadolinium and dysprosium–gadolinium alloys as magnetic refrigerators near room temperature is more effective than the use of pure gadolinium.

Hashimoto *et al.* (1986) proposed for a magnetic Ericsson cycle with a temperature span from 10 K to 80 K the use of complex magnetic materials consisting of $RAl_2$ intermetallic compounds (R = heavy REM). Pecharsky and Gschneidner (1997) proposed the use of the unique behavior of the alloys $Gd_5(Si_xGe_{1-x})_4$ to improve the efficiencies of the magnetic refrigerators.

As mentioned above, refrigerators without regeneration and working with a Carnot cycle can be used below 20 K. Among various oxide compounds $Gd_2Ga_5O_{12}$, $DyAlO_3$, and $ErAlO_3$ are the most suitable working materials for magnetic refrigerators in the temperature range between 2 K and 20 K.

Thus, we have considered the passive and active magnetic refrigerators and materials that can be used for their operation. In conclusion, it is evident that magnetic cooling is a promising technology for the refrigeration industry and may become an important market for the rare-earth industry in the future.

## Magnetoelastic Phenomena

Magnetoelasticity is a mutual influence of the magnetic and the elastic properties of materials. It originates from the fact that all main interactions between the atomic magnetic moments in solids depend on the distance between them (e.g., exchange interaction, dipole–dipole interaction, interaction of magnetic moments with crystal electric field). The dimensions, shape, and elastic properties of a sample are influenced by its magnetic state. This is the direct magnetoelastic effect or the magnetostriction (MS). The magnetic properties (magnetization, magnetic ordering temperature, magnetic anisotropy energy) are influenced by the applied and internal mechanical stresses (inverse magnetoelastic effects).

The dependence of a magnetostrictive strain, $\lambda$, on the direction of its measurement and the orientation of the magnetization vector (**M**) in a crystal is described by phenomenological formulas specific to a certain crystal symmetry (Clark 1980, Belov *et al.* 1983). For a hexagonal crystal, e.g., cobalt, rare earth (R) metals, and many intermetallic compounds:

$$\lambda = \lambda_1^{\alpha,0}(\beta_x^2+\beta_y^2) + \lambda_2^{\alpha,0}\beta_z^2 + \lambda_1^{\alpha,2}(\beta_x^2+\beta_y^2)(\alpha_z^2-1/3) + \lambda_2^{\alpha,2}\beta_z^2(\alpha_z^2-1/3) + \lambda^{\gamma,2}[0.5(\beta_x^2-\beta_y^2)(\alpha_x^2-\alpha_y^2) + 2\alpha_x\beta_x\alpha_y\beta_y] + 2\lambda^{\varepsilon,2}(\alpha_x\beta_x+\alpha_y\beta_y)\alpha_z\beta_z \quad (1)$$

where $\alpha_i$ are the cosines of the magnetization direction, $\beta_i$ are the cosines of the strain measurement direction, and $\lambda_i$ are the MS constants. The constants with index $\alpha$ describe the changes in interatomic distances within the basal plane ($\lambda_1^{\alpha}$) and along the *c*-axis ($\lambda_2^{\alpha}$) and do not reduce the lattice symmetry. As seen from Eqn. (1), the terms with zero-order constants, $\lambda_i^{\alpha,0}$, do not depend on the magnetization direction and describe the isotropic part of this type of MS, while the terms with second-order constants, $\lambda_i^{\alpha,2}$, correspond to the anisotropic part. A reduction of symmetry is described by the constants with index $\gamma$ (an orthorhombic distortion in the basal plane) and $\varepsilon$ (a deviation from the orthogonality between the basal plane and the *c*-axis). The MS which reduces the symmetry is essentially anisotropic. The MS modes for hexagonal and cubic crystals are shown in Fig. 1.

For a cubic crystal (e.g., iron and nickel and their alloys, ferrites, $RFe_2$):

$$\lambda = \lambda^{\alpha,0} + \lambda^{\gamma,2}(\alpha_x^2\beta_x^2 + \alpha_y^2\alpha_y^2\beta_y^2 + \alpha_z^2\beta_z^2 - 1/3) + 2\lambda^{\varepsilon,2}(\alpha_x\alpha_y\beta_x\beta_y + \alpha_y\alpha_z\beta_y\beta_z + \alpha_x\alpha_z\beta_x\beta_z) \quad (2)$$

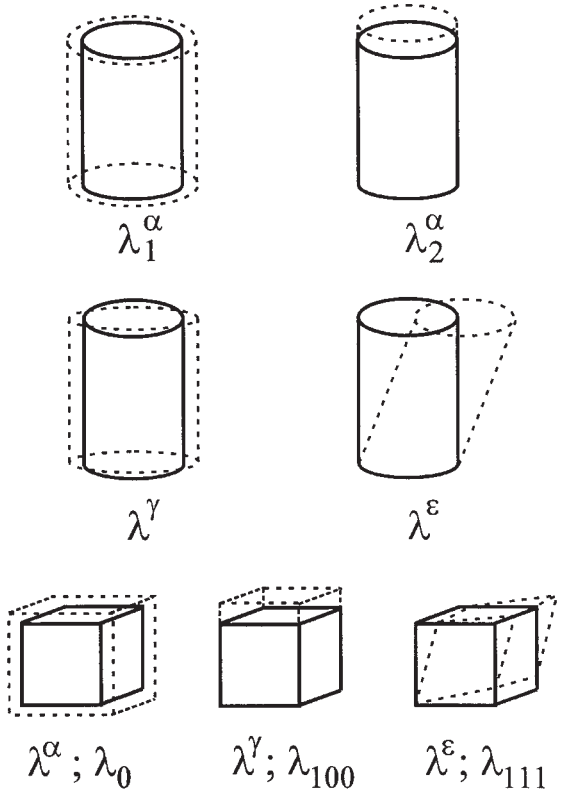

***Figure 1***
Magnetostriction modes for hexagonal and cubic symmetries.

where $\lambda^{\alpha,0}$ is the isotropic strain which does not depend on the orientation of **M**, $\lambda^{\gamma,2}$ describes the tetragonal distortion, and $\lambda^{\varepsilon,2}$ the rhombohedral distortion of the cubic crystal. Instead of $\lambda^{\alpha,0}$, $\lambda^{\gamma,2}$, and $\lambda^{\varepsilon,2}$, the constants $\lambda_0 = \lambda^{\alpha,0}$, $\lambda_{100} = 2\lambda^{\gamma,2}$, and $\lambda_{111} = 2\lambda^{\varepsilon,2}$ are generally used.

### 1. Magnetovolume Effects

Figure 2 shows the temperature dependence of lattice parameters of $Y_2Fe_{17}$ (hexagonal crystal structure) and $Y_6Fe_{23}$ (cubic crystal structure) (Givord *et al.* 1971, Andreev 1995 and references therein). The curves in Fig. 2 represent the phonon contribution to the thermal expansion obtained by extrapolation of the paramagnetic behavior into the ferromagnetic range. Below the Curie temperature, $T_C$, the experimental curves deviate from the extrapolated ones. The differences between the measured and the extrapolated values of the respective lattice parameters

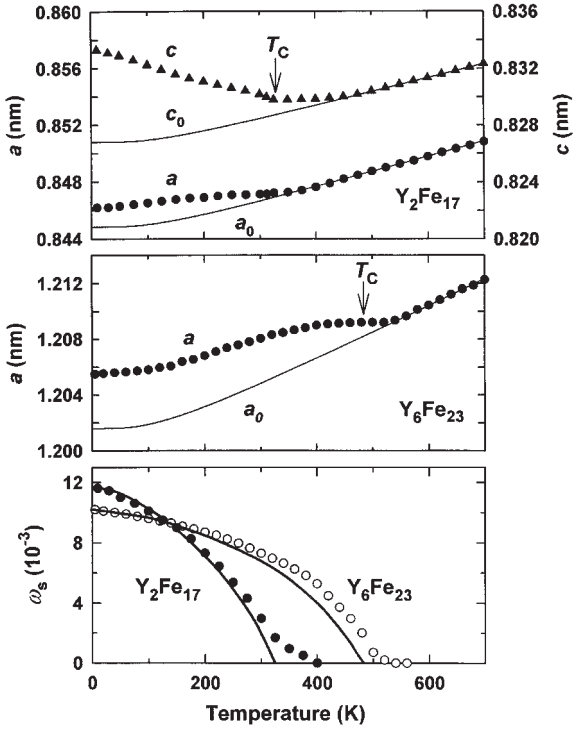

***Figure 2***
Temperature dependence of lattice parameters *a* and *c* of $Y_2Fe_{17}$ and *a* of $Y_6Fe_{23}$. The curves are the phonon contribution to the thermal expansion. The arrows indicate the Curie temperature. Bottom: temperature dependence of spontaneous volume magnetostriction $\omega_s$; the lines represent the $\omega_s(T) = \omega_s(0)M_s^2(T)/M_s^2(0)$ dependence.

correspond to the spontaneous linear MS. Both compounds have a negligible anisotropic MS compared to a large isotropic MS. Therefore, the total values of the basal-plane strain, $\lambda_a$, and uniaxial strain, $\lambda_c$, in $Y_2Fe_{17}$ correspond to the $\lambda_1^{\alpha,0}$ and $\lambda_2^{\alpha,0}$ MS constants, respectively. In cubic $Y_6Fe_{23}$, the spontaneous MS is described only by $\lambda^{\alpha,0}$. Usually, the spontaneous MS is considered in terms of a volume effect $\omega_s = 2\lambda_1^{\alpha,0} + \lambda_2^{\alpha,0}$ (crystals with a unique axis) and $\omega_s = 3\lambda^{\alpha,0}$ (cubic crystal).

The volume MS has two main origins: the volume dependence of the magnetic moment and the volume dependence of the exchange interactions (du Tremolet de Lacheisserie 1993 and references therein). The first is important in itinerant ferromagnets, where the 3*d* electron states responsible for magnetism generally form an energy band (see *Itinerant Electron Systems: Magnetism (Ferromagnetism)*). The magnetization arises as a result of splitting of sub-bands owing to the exchange interaction (spontaneous effect) or to application of the external magnetic field *H* (forced, or field-induced effect). The 3*d*-band polarization causes an increase in the kinetic energy of electrons. This is compensated by a volume expansion. The increase in kinetic energy is proportional to $M^2$ to a first approximation. The corresponding volume change can be expressed as:

$$\omega = \Delta V/V = \kappa C M^2 \tag{3}$$

where $\kappa$ is the compressibility and *C* is the magnetovolume coupling constant.

This formula describes the magnetovolume effect in itinerant ferromagnets both in zero field (spontaneous volume MS, $\omega_s$, in this case $M = M_s$, the spontaneous magnetization) and in magnetic field (forced volume MS). In Fig. 2 the temperature dependence of $\omega_s$ for $Y_2Fe_{17}$ and $Y_6Fe_{23}$ is compared with $M_S^2$. A good agreement with Eqn. (3) is seen for a wide temperature range. However, 15–20% of low-temperature $\omega_s$ value persists at $T_C$ where $M_s$ becomes zero. Finally, $\omega_s$ vanishes at temperatures considerably higher than $T_C$. Such behavior, typical for compounds with a large magnetovolume effect, is attributed to the existence of a short-range magnetic order in a wide temperature interval above $T_C$.

The value of $\omega_s$ in itinerant ferromagnets is usually positive and sometimes very large. As seen in Fig. 2, it exceeds 1% in $Y_2Fe_{17}$ and $Y_6Fe_{23}$. Even larger $\omega_s$ values, up to 3%, are observed in some $R_2Fe_{14}B$ and $La(Fe,Al)_{13}$ compounds (Andreev 1995 and references therein). The $\omega_s$ value can be larger than the phonon contribution below $T_C$. In such a case the total thermal expansion coefficient becomes very small or even negative (see *Invar Materials: Phenomena*). It is observed in many compounds with low ordering temperatures ($<100$K) owing to a relatively low phonon contribution. Even a moderate value of $\omega_s$ ($\sim 10^{-3}$) is sufficient to exceed the phonon contribution and

produce the Invar-like anomaly in a narrow temperature interval. In some rare cases the Invar effect over a wide temperature interval (including room temperature) can be observed. Besides the above-mentioned iron-rich intermetallics, it occurs also in iron-rich f.c.c. alloys. Other typical examples of systems with large magnetovolume effects are weak itinerant ferromagnets ($ZrZn_2$, MnSi) and some antiferromagnetic (AF) alloys and compounds (Cr–Mn, $YMn_2$) (Nakamura 1983).

The second origin of volume MS, the volume dependence of the exchange interactions, dominates in ferromagnets with a weak volume dependence of the magnetic moment. The isotropic MS constant is then proportional to the magnetic Grüneisen coefficient $\Gamma = (\mathrm{d}\ \ln T_C/\mathrm{d}\ \ln V)$:

$$\lambda^{\alpha,0} \sim \Gamma M^2(H,T) \tag{4}$$

where $M$ is a volume-independent magnetic moment. The Grüneisen coefficient is usually negative and of the order of unity for most ferromagnets, but sometimes is large and positive for weak itinerant ferromagnets. The absolute value of $\omega_s$ in these materials is always much smaller than in Invar alloys. Typical values of $\omega_s$ are $-1.1 \times 10^{-3}$ for nickel, $-2.7 \times 10^{-3}$ for iron, and $+2.6 \times 10^{-3}$ for gadolinium (du Tremolet de Lacheisserie 1993).

The forced volume MS ($\omega_f$) has the same physical origins as the spontaneous volume MS. For moderate magnetic fields and temperatures sufficiently lower than $T_C$, the forced volume MS is associated with the paraprocess and $\omega_f$ is a linear function of the applied magnetic field after technical saturation has been achieved. The $\omega_f$ values are small for strong ferromagnets at low temperatures ($\mathrm{d}\lambda^{\alpha,0}/\mathrm{d}H = 4.5 \times 10^{-6}\mathrm{T}^{-1}$ for pure iron at 1.5–300 K (du Tremolet de Lacheisserie 1993)) and $\omega_f$ usually has a maximum around $T_C$. Large $\omega_f$ values at low temperatures are characteristic of weak itinerant ferromagnets.

A very large $\omega_f$ (up to 2%) may be observed at field-induced changes of magnetic structure. This occurs first of all at first-order metamagnetic phase transitions. The field-induced state is ferromagnetic, whereas the initial state can vary. An AF–F transition with large $\omega_f$ is observed, for example, in FeRh (Levitin and Ponomarev 1966) and $La(Fe_{0.88}Al_{0.12})_{13}$ (Palstra *et al.* 1985). The transition from a low-moment to a high-moment state is observed in $Sc_{0.25}Ti_{0.75}Fe_2$ (Kido *et al.* 1988), and from the paramagnetic to the F state in the $YCo_2$- and $LuCo_2$-based alloys (see *Metamagnetism: Itinerant Electrons*). Figure 3 shows the magnetization and MS curves for a polycrystal of $La(Fe_{0.88}Al_{0.12})_{13}$ at 4.2 K. The metamagnetic transition with a wide field hysteresis is accompanied by positive $\omega_f = 1\%$. However, the large $\omega_f$ is not a universal feature of a metamagnetic transition. For example, despite the relatively large longitudinal and transverse magnetostrictions

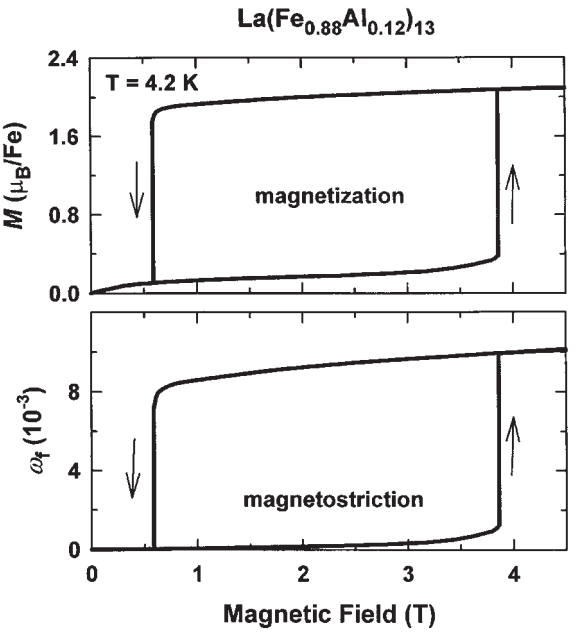

*Figure 3*
Magnetization and forced volume magnetostriction isotherms for $La(Fe_{0.88}Al_{0.12})_{13}$ at 4.2 K.

accompanying the metamagnetic transition in a single crystal of UNiGa (observed when the magnetic field is applied along the *c*-axis of the hexagonal structure), $\omega_f = 2\lambda_a + \lambda_c$ is negligible due to the mutual cancellation of the linear effects (Andreev *et al.* 1995).

When external pressure is applied to a magnetically ordered material, two magnetoelastic effects occur: changes of the magnitude of magnetic moments and of the energies of moment coupling. For details see *Magnetic Systems: External Pressure-induced Phenomena*.

## 2. *Anisotropic MS*

Whereas isotropic (volume) MS depends on the magnitude of magnetic moments and the coupling between them, anisotropic MS describes the changes of dimensions and shape of a sample depending on the orientation of the magnetic moments. Also, the anisotropic MS can be spontaneous or field induced.

The thermal expansion in the magnetically ordered range is affected both by isotropic and by anisotropic MS. The anisotropic MS always causes a reduction of symmetry in the cubic structure. For the hexagonal structure a component of anisotropic MS exists, described by the constants $\lambda_i^{\alpha,2}$ in Eqn. (1), which has no influence on symmetry. Usually, the linear spontaneous strains $\lambda_a$ and $\lambda_c$, which are combinations of $\lambda_i^{\alpha,0}$ and $\lambda_i^{\alpha,2}$, cannot be separated. However, in the

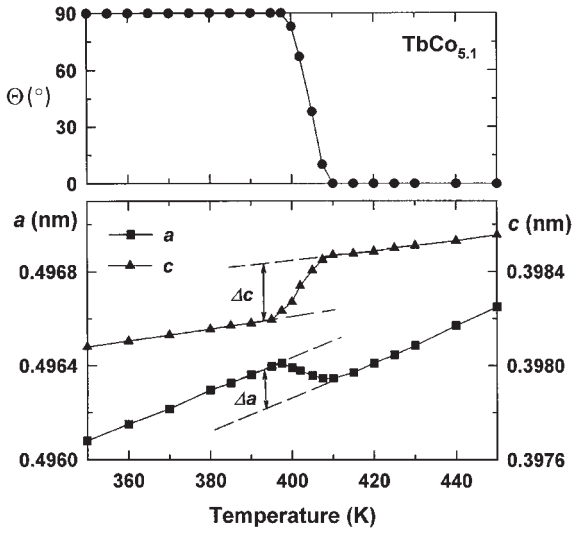

*Figure 4*
Temperature dependence of the angle Θ between the easy magnetization direction and the *c*-axis and of the lattice parameters of $TbCo_{5.1}$ in the vicinity of spin reorientation from the basal plane ($\Theta = 90^\circ$) to the uniaxial anisotropy ($\Theta = 0$).

case of a spontaneous spin reorientation each contribution can be clearly distinguished. Figure 4 shows the temperature dependence of lattice parameters of $TbCo_{5.1}$ in the vicinity of the spin reorientation from the basal plane ($\Theta = 90^\circ$) to the *c*-axis ($\Theta = 0$). The corresponding steps $\Delta a/a$ and $\Delta c/c$ are equal to $\lambda_1^{\alpha,2} \approx -0.3 \times 10^{-3}$ and $\lambda_2^{\alpha,2} \approx 0.6 \times 10^{-3}$, respectively. The volume effect $\Delta\omega_s = 2\lambda_1^{\alpha,2} + \lambda_2^{\alpha,2}$ is thus negligible. For further details see the review of Andreev (1995).

The crystal symmetry is conserved at the magnetic ordering only in the case of uniaxial magnetic anisotropy (the easy magnetization direction is the *c*-axis in the hexagonal, tetragonal, and rhombohedral structures, or a principal axis in the orthorhombic structure, or the *b*-axis in the monoclinic structure). Magnetic order with any type of multiaxial anisotropy (in particular, any possible anisotropy in the cubic structure) yields reduced symmetry, which is manifested as a spontaneous distortion. The easy magnetization direction parallel to the $\langle 100 \rangle$ axis in a cubic crystal yields a tetragonal distortion $c/a - 1 = \lambda^{\alpha,2} = 3/2\lambda_{100}$. In the case of the $\langle 111 \rangle$ easy direction, the resulting rhombohedral distortion is characterized by a change of the angle $\alpha$ from 90° to a value given by $\cos\alpha = 2\lambda^{\varepsilon,2}/3 = \lambda_{111}$. The orthorhombic distortion in the basal plane of hexagonal crystals as well as the rhombohedral distortion in cubic crystals of the rare earth and actinide compounds can reach values of $10^{-3}$–$10^{-2}$ which exceeds by several orders the corresponding values observed in conventional materials based on metals of the iron group. Note that this so-called "giant MS" is still rather small from a structural viewpoint (e.g., $\lambda_{111} = 10^{-3}$ corresponds to only 3.5 minutes of nonorthogonality between the $\langle 100 \rangle$ axes).

If a magnetic field is applied on a ferromagnet, an anisotropic deformation MS occurs. This effect was discovered by Joule in 1842. Since $\lambda$ is an even function of $H$ (Eqns. (1) and (2) contain only even degrees of the direction cosines of **M**), $\lambda = 0$ in the case of pure rotation of 180° domains. In a saturated (single-domain) sample, as well as in a uniaxial multidomain sample containing 180° domains only, the Joule MS is caused by a rotation of **M** from the easy direction towards the field direction. The value of $\lambda$ gradually increases with $H$ and saturates above the anisotropy field $H_a$.

In materials with multiaxial magnetic anisotropy (e.g., in cubic crystals) the Joule MS is caused first of all by a domain wall displacement leading to redistribution of magnetic phases with noncollinear mutual orientation of **M** and to corresponding reorientation of spontaneous distortions. Since the domain walls are usually moving in relatively low $H$, the anisotropic MS in samples with multiaxial anisotropy is much more field sensitive and the MS saturates at the field of technical saturation. Such a field dependence is shown in Fig. 5 for annealed pure nickel.

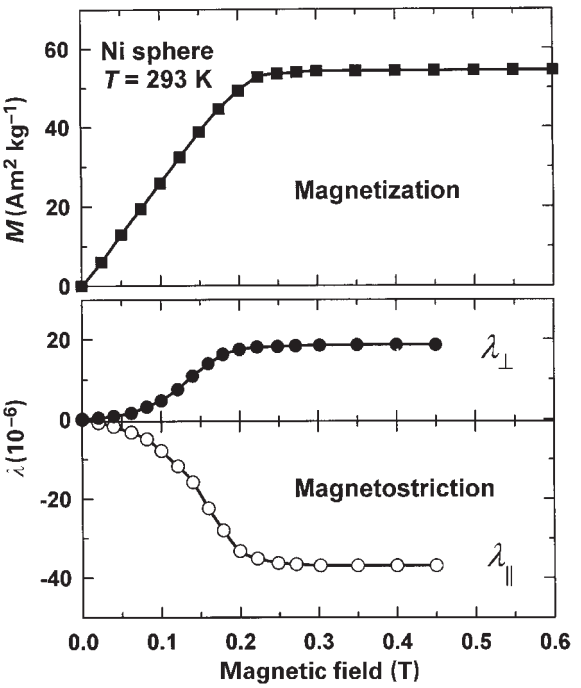

*Figure 5*
Field dependence of magnetization, $M$, and longitudinal ($\lambda_\parallel$) and transverse ($\lambda_\perp$) magnetostriction of a nickel polycrystal at room temperature.

When the demagnetized state of a polycrystalline sample before application of the field is isotropic (a random distribution of non-180° magnetic domains over sample volume), the MS measured in the direction parallel to the field, $\lambda_{\parallel}$, saturates at $\lambda_s$ which is a characteristic of the material. The corresponding deformation in the perpendicular direction $\lambda_{\perp}$ saturates at $-\lambda_s/2$ in this case. Generally, the ratio between $\lambda_{\parallel}$ and $\lambda_{\perp}$ depends on the magnetic state at zero field because the distribution of the volume over domains is not necessarily random. However, the value $\lambda_s = 2/3(\lambda_{\parallel} - \lambda_{\perp})$ remains independent of the demagnetized state. For a cubic polycrystal (Belov *et al.* 1983):

$$\lambda_s = (2/5)\lambda_{100} + (3/5)\lambda_{111} \tag{5}$$

Several microscopic mechanisms are responsible for the anisotropic MS (Belov *et al.* 1983). First is the magnetic interaction between a pair of magnetic atoms, which depends on the orientation of the magnetic dipoles relative to the crystallographic axes. The corresponding dipolar MS is essentially anisotropic, but it is usually very small. Second is the MS caused by the variation of the exchange energy with interatomic distances. This mechanism is responsible mainly for the volume MS but can have anisotropic contributions for some substances with low-symmetry lattices. The most prominent mechanism is the interaction between the anisotropic electron shell of an ion and the crystal field (CF). This single-ion mechanism is responsible for the so-called giant MS ($\lambda > 10^{-3}$) in many rare earth and actinide compounds.

If the magnetic ion has a nonzero orbital momentum, $\mathbf{M}_L$, the orientation of the total magnetic moment, $\mathbf{M}_J$, by the magnetic field causes the rotation of $\mathbf{M}_L$. The "disturbance" of the crystal field by the rotation of the anisotropic electron shell leads to the anisotropic lattice deformation, i.e., MS. For a simple case of a paramagnet, the relation for the magnetoelastic deformation has been derived:

$$\lambda = AH^2 + CH\tanh(g_j\mu_B H/k_B T) \tag{6}$$

where $A$ and $C$ are the functions of the direction cosines of the field and the strain. The first term is proportional to Van Vleck susceptibility while the second term reflects the interaction between the magnetic moment and the crystal field. At low $H$, both terms yield a quadratic dependence of $H$. The second term saturates at high $H$.

The single-ion MS caused by the interaction of the $4f$ shell of R ions with the CF at $T = 0$ can be described by the following (Clark 1980):

$$\lambda(0) = D\alpha J(J - 1/2)\langle r_{4f}^2 \rangle \tag{7}$$

where $D$ is a coefficient determined by a given crystal lattice, which depends on the CF parameters, the elastic modulus, and the concentration of rare earth ions, $\alpha$ is the Stevens factor that depends on the atomic constants of a $4f$ ion, $\langle r_{4f}^2 \rangle$ is the average radius squared of the $4f$ shell, and $J$ is the total angular momentum.

The $\alpha$ factor is determined by the shape of the $4f$ electron charge cloud. For the $3+$ ions of cerium, praseodymium, neodymium, terbium, dysprosium, and holmium $\alpha < 0$ (an oblate $4f$ cloud), while for samarium, erbium, thulium, and ytterbium $\alpha > 0$ (a prolate $4f$ cloud) (see *Localized 4f and 5f Moments: Magnetism*). The sign of single-ion MS changes in a series of heavy rare earth ions between holmium and erbium. Similar changes occur in rare earth intermetallic compounds. The MS constants of $RFe_2$ are presented in Table 1 for the ground state (at 4.2K) (adapted from Clark 1980, Belov *et al.* 1983, Andreev 1995). For a particular symmetry, the MS in

a EMD, easy magnetization direction; $\mu_m$, magnetic moment per formula unit; $\lambda_{100}$ and $\lambda_{111}$ (exp), experimentally determined anisotropic magnetostriction constants; $\lambda_{111}$ (calc), $\lambda_{111}$ values calculated with Eqn. (7) using the experimental value for $ErFe_2$ to determine $D$ factor; $\omega_s$, spontaneous volume magnetostriction. b Saturation magnetostriction, $\lambda_s$, of polycrystal. c Values extrapolated to 0K from the high-temperature range (180–300K).

these compounds (except for $HoFe_2$) is determined mainly by $\lambda_{111}$ ($\lambda_{100} \ll \lambda_{111}$). The $\lambda_{111}$ values calculated with Eqn. (7) are also given in Table 1. $D$ was determined using the experimental value for $ErFe_2$. The signs of experimental and calculated $\lambda_{111}$ coincide. The magnitudes also agree satisfactorily. The CF mechanism of giant MS in compounds with nonzero $L$ moment of the R ion is corroborated by the fact that the compounds with nonmagnetic R = Y, Lu, and with gadolinium ($L = 0$) exhibit MS of two orders of magnitude less. Giant MS is also observed in $UFe_2$ and $NpFe_2$, the actinide analogues of the $RFe_2$ group (Table 1).

According to the theory of magnetoelastic interaction (Callen and Callen 1963), the field and temperature dependence of the magnetoelastic constant of $l$th order is determined by the magnetization:

$$\frac{\lambda_l(T,H)}{\lambda_l(0,0)} = \hat{I}_{l+1/2}\{L^{-1}[m(T,H)]\} \tag{8}$$

where $\hat{I}_{l+1/2}(x) = I_{l+1/2}(x)/I_{1/2}(x)$ is a modified hyperbolic Bessel function and $L^{-1}(m)$ is the inverse Langevin function of the reduced magnetization $m(T, H) = L(x) = \hat{I}_{3/2}(x) = \coth x - 1/x$. Here $x = (\mu_B H_{mol}/k_B T)$ in the molecular field model. In the low-temperature region:

$$\frac{\lambda_l(T,H)}{\lambda_l(0,0)} = m^{l(l+1)/2} \tag{9}$$

The single-ion model allows one to describe the MS also in the metals of the iron group. The orbital moment of 3*d* electrons is nearly quenched due to the CF and is usually very small. Nevertheless, the single-ion contribution to the MS exceeds the dipolar contribution in these compounds.

## 3. *Villari Effect*

The magnetoelastic effect which is the reverse of the Joule MS, i.e., dependence of the magnetization curve on the mechanical stress was extensively studied by Villari in 1865. The magnetization curves shown in Fig. 6 illustrate the effect of tensile stress in nickel in the longitudinal geometry (magnetization is measured along the tensile stress). At high values of stress, the room-temperature magnetization curves are completely determined by the uniaxial magnetic anisotropy induced by tensile stresses. For an isotropic ferromagnet, the magnetoelastic anisotropy energy can be expressed by (Belov 1987):

$$W_{me} = -\frac{3}{2}\lambda_s \sigma\left(\cos^2\phi - \frac{1}{3}\right) \tag{10}$$

where $\sigma$ is a stress, and $\phi$ represents the angle between **M** and $\sigma$. When the stress is positive and the MS is negative (the case of nickel in Fig. 6), $W_{me}$ has

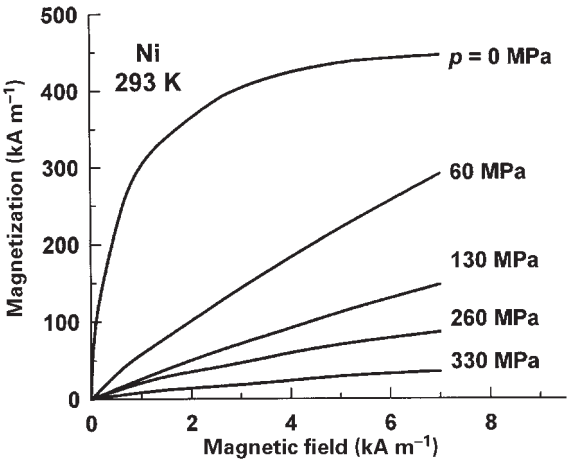

***Figure 6***
Room-temperature magnetization curves of nickel under varying tensile stresses.

a minimum at $\phi = \pi/2$, i.e., the induced easy magnetization axis lies perpendicular to $\sigma$. The direction of $\sigma$ becomes the hard magnetization axis and therefore the saturation field increases with the stress (Fig. 6). When $\lambda_s \sigma > 0$, the easy magnetization axis is along $\sigma$, and the stress makes it easier to reach the saturation of magnetization.

## 4. *Magnetoelastic Contribution to the Magnetic Anisotropy*

Even without any external or internal stresses the magnetoelastic coupling modifies the energy of magnetic anisotropy of a crystal. Besides the magnetocrystalline anisotropy, a magnetoelastic anisotropy of the same symmetry appears, which causes additive contributions to the magnetic anisotropy constants. For a cubic crystal, the magnetoelastic contribution to the first anisotropy constant, $K_1$, can be written as (Belov *et al.* 1983):

$$\Delta K_1 = (9/4)[(c_{11} - c_{12})\lambda_{100}^2 - 2c_{44}\lambda_{111}^2] \tag{11}$$

where $c_{ij}$ are the elastic constants. The magnetoelastic contribution is responsible for the change of the sign of $K_1$ in nickel near 480K. In rare earth and actinide compounds the magnetoelastic contribution $\Delta K_1$ is comparable with $K_1$ and must be taken into account in the description of the magnetization curves and spin-reorientation phase transitions.

## 5. *ΔE Effect*

The elastic properties of a ferromagnet may be perturbed by the magnetoelastic coupling. The magnetic

field dependence of the elastic modulus, $E$ ($\Delta E$ effect), was discovered by Guillemin in 1846. The $\Delta E$ effect is usually described in terms of the ratio $\Delta E/E = (E_0 - E)/E$, where $E$ is the experimentally observed value and $E_0$ is the value for the case when the elastic stress does not cause magnetization rotation and domain walls movement. In a low-anisotropy material it occurs practically at the field of technical saturation but generally $E \to E_0$ for $H \to \infty$ . In ferromagnets, $\Delta E > 0$ and is independent of the sign of $\lambda$ and $\sigma$. A theory of the $\Delta E$ effect for isotropic ferromagnets gives the following relations for the limit of very low (LF) and very high (HF) magnetic fields, respectively (du Tremolet de Lacheisserie 1993):

$$\left(\frac{\Delta E}{E}\right)_{LF} = \frac{9\chi_i \lambda_s E_0^2}{5\mu_0 M_s^2}; \left(\frac{\Delta E}{E}\right)_{HF} = \frac{9\lambda_s^2 E_0}{4MH}\sin^2 2\theta \quad (12)$$

where $\theta$ is the angle between the internal magnetic field and the axis of measurement of $E$. A very large $\Delta E$ effect may be expected at low $H$ in materials exhibiting a large initial susceptibility, $\chi_i$, and a large $\lambda$. Among the giant MS materials, the largest $\Delta E$ effects are exhibited by $TbFe_2$ (up to 0.6) and the low-anisotropy alloy $Tb_{0.3}Dy_{0.7}Fe_2$ (up to 1.6). The same value of $\Delta E/E = 1.6$ is observed also in $UFe_2$. For the high-magnetostrictive Metglass $Fe_{81}B_{13.5}Si_{3.5}C_2$, $\Delta E/E = 15$ (Belov *et al.* 1983 and references therein).

## 6. Direct and Inverse Wiedemann Effects

When a thin ferromagnetic rod is simultaneously magnetized by a longitudinal field, $H_\parallel$, and by a circular field, $H_\perp$, generated by an electrical current flowing along the sample, the resulting helicoidal magnetic field causes twisting of the rod (the direct Wiedemann effect). For an isotropic wire at a sufficiently low current density, $j$, and a sufficiently high magnetizing field ($H_\perp \ll H_\parallel$) the twist per unit length, $\xi$, is given by (du Tremolet de Lacheisserie 1993):

$$\xi = \frac{3\lambda_\perp}{2H_\parallel} j \quad (13)$$

Since, $\xi$, $j$, and $H_\parallel$ can be measured with high accuracy, the Wiedemann effect is a valuable method of determination of $\lambda_s$ in soft ferromagnets.

There are two inverse Wiedemann effects:

(i) The change of the longitudinal magnetization, $\delta M_z$, and the appearance of a circular magnetization, $M_\Phi$, in a long ferromagnetic rod magnetized along its length when subjected to a mechanical torque; a voltage appears between the ends of the rod due to a longitudinal electric field associated with the change of the circular magnetization (the Matteuchi effect).

(ii) The change of the circular magnetization, $\delta M_\Phi$, and the appearance of a longitudinal magnetization, $M_z$, in a long ferromagnetic rod where an electric current passes when the rod is submitted to a mechanical torque.

## 7. Linear Magnetostriction. Piezomagnetism

Most ferromagnets and antiferromagnets exhibit a quadratic field dependence of MS in low magnetic fields. However, in low-symmetry materials the thermodynamic potential can contain nonzero terms linearly dependent on the field and on a component of the elastic stress tensor. For 66 magnetic symmetry classes (including 35 of 59 AF classes) a strain varying linearly with applied magnetic field is possible (Birrs 1964). In fact, a linear MS is rarely observed since it is usually masked by much stronger quadratic effects. The odd linear magnetostrain was observed in AF hematite, $\alpha$-$Fe_2O_3$, as well as in the orthoferrites $YFeO_3$ and $YCrO_3$ in the region of spin-reorientation transitions (du Tremolet de Lacheisserie 1993 and references therein).

An inverse effect to the linear MS (piezomagnetism) is the appearance of a spontaneous magnetization under external stress. Piezomagnetism is observed in $CoF_2$, $MnF_2$, $\alpha$-$Fe_2O_3$, and $FeCO_3$ (du Tremolet de Lacheisserie 1993 and references therein).

## 8. Applications of Magnetoelasticity

Application of isotropic magnetoelastic coupling is limited mainly to the Invar alloys for cases where a low thermal expansion coefficient of the metal is required (e.g., in glass–metal assemblies). Elinvar alloys exhibiting the $\Delta E$ effect are employed whenever the elastic properties must be stable over some temperature interval (e.g., a clock spring).

Joule MS is widely used both in static and dynamic devices. The static MS allows the construction of linear actuators offering sufficiently large displacements (20–200μm) and large forces (500–5000 N) at low voltage. Linear actuators are used in micropositioning tools or for damping structures, as well as for components of more complex actuators.

Spring-type magnetostrictive actuators employing the direct Wiedemann effect have been designed for positioning optical units and mechanical parts up to 5Kg: the pieces may be oriented with an accuracy of $10^{-5}$ degree in a frequency range up to 70Hz.

A magnetic material in an alternating magnetic field undergoes mechanical oscillations due to the MS. A well-known result of such oscillations is the noise of electric power transformers. Therefore, for this and related purposes, the MS should be reduced to as low as possible (zero-MS materials include cobalt-rich amorphous alloys). However, if the MS core has appropriate dimensions, resonance oscillations can appear. Some magnetoelastic materials with sharp resonance (high $Q$-factor) are used in frequency stabilizers and filters.

***Table 2***
Saturation magnetostriction, $\lambda_s$, magnetomechanical coupling factor, $k_{33}$, $Q$-factor, and Curie temperature, $T_C$, for some magnetostriction materials.

| Material | $\lambda_s$ ($\times 10^6$) | $k_{33}$ | Q-factor | $T_C$ (°C) |
|---|---|---|---|---|
| Ni | −37 | 0.25–0.31 | 700 | 360 |
| 96Ni4Co | −31 | 0.6 | | 410 |
| 87Fe13Al | + 40 | 0.32 | 400 | 500 |
| 49Co49Fe2V | + 70 | 0.2–0.4 | 600 | 980 |
| $NiFe_2O_4$ + Cu,Co | −26 | 0.25 | 2000 | 590 |
| $Fe_{81}B_{13.5}Si_{3.5}C_2$ Metglas | + 30 | 0.97 | | 370 |
| $TbFe_2$ | 1750 | 0.35 | 100 | 425 |
| $Tb_{0.27}Dy_{0.73}Fe_2$ | 1000–1500 | 0.6–0.75 | 50–200 | 380 |

An important area of technical application of magnetostrictive materials is in high-power transducers both for acoustic (loudspeakers, sonars, echo-sounders, defectoscopes, etc.) and for mechanical (welding, sealing, cleaning, cutting, etc.) purposes at typical frequencies below 50 kHz. For these devices the most important property of the material is not the MS, $\lambda$, but the magnetostrictivity, $\partial\lambda/\partial H$. A certain amplitude of mechanical oscillation should be reached in as small a magnetic field interval as possible. The relevant parameters are the MS coefficient:

$$h = -\left(\frac{\partial\sigma}{\partial B}\right)_{\varepsilon} = \frac{E\,\partial\lambda}{\mu\partial H} \tag{14}$$

and the coefficient of sensitivity of a magnetostrictor as an acoustic receiver:

$$d = \left(\frac{\partial B}{\partial\sigma}\right)_{H} \tag{15}$$

where $H$ and $B$ are the magnetic field and the magnetic induction, respectively, $\sigma$ is the mechanical stress, $\varepsilon$ is the relative strain, $E$ is the elastic modulus, and $\mu$ is the permeability at constant induction (Belov *et al*. 1983).

The transformation of the magnetic energy, $U_{\text{magn}}$, into the elastic energy, $U_{\text{elast}}$, is characterized by the magnetomechanical coupling factor of the sample, $k = \sqrt{(U_{elast}/U_{magn})}$, showing the fraction of $U_{\text{magn}}$ which can be converted to $U_{\text{elast}}$. The coupling factor is conventionally obtained by measuring the complex impedance of a coil containing the magnetostrictive material. Generally, it depends on the shape of the sample. In the practically important case when the mechanical motion is parallel to the exciting field, $k$ is specified as $k_{33}$, a geometry-independent coupling factor characterizing the material (Clark 1980).

In order to select the maximum $\partial\lambda/\partial H$ in the field dependence of $\lambda$, a static bias magnetic field is usually applied to the MS core. The elastic energy density can be increased using prestress of a magnetostrictive rod. The best reported magnetostrictive transducers allow one to generate a 3kW acoustic power. For a review of devices based on materials with giant MS, see Claeyssen *et al*. (1997).

The magnetoelastic characteristics of some materials are presented in Table 2 (adapted from Clark 1980, Tremolet de Lacheisserie 1993, Golyamina 1992). Nickel is a traditional material widely used in magnetomechanical converters. In order to improve the $\partial\lambda/\partial H$ and $k_{33}$ values, alloying components that reduce the magnetocrystalline anisotropy can be added (the alloy 96Ni4Co with compensated anisotropy possesses a $k_{33}$ factor as high as 0.6). Among the magnetostrictive alloys based on iron and cobalt, the best parameters are shown by the alloy 49Co49Fe2V. Owing to its high $T_C$, the magnetoelastic properties of this alloy are stable over a wide temperature interval. In high-frequency magnetomechanical converters the ferrites are used as core materials owing to their high electrical resistance. The nickel ferrite $NiFe_2O_4$ has relatively high $\lambda_s$ but $k_{33}$ is small. The $k_{33}$ value and $Q$-factor increase with the substitution of copper, zinc, and cobalt for nickel. An outstanding value of $k_{33} = 0.97$ has been obtained on the field-annealed Metglas $Fe_{81}B_{13.5}Si_{3.5}C_2$ in a polarizing magnetic field of $50 Am^{-1}$.

Rare earth intermetallic compounds possess giant MS caused by rare earth ions. The largest room-temperature $\lambda_s$ is found in $TbFe_2$. However, $\partial\lambda/\partial H$ is low owing to a high magnetocrystalline anisotropy and the $\lambda_s$ value is achieved only in fields above 2T. The value of $\partial\lambda/\partial H$ can be substantially improved using quasibinary compositions $(Tb_{1-x}Dy_x)Fe_2$ at $x \sim 0.7$ (Terfenol-D) owing to the compensation of the anisotropy constant $K_1$. This leads to an increase of $k_{33}$ despite a certain decrease of $\lambda_s$ (Table 2).

## Magnetoelasticity in Nanoscale Heterogeneous Materials

When a material becomes magnetic, the magnetoelastic coupling causes a change in volume, the *volume magnetostriction*, and anisotropic changes in linear dimensions, the *Joule magnetostriction*. The magnetic order, and thus the deformation, can be induced either by a temperature variation (*spontaneous magnetostriction*) or by application of a magnetic field (*forced magnetostriction*). The magnetostriction varies from nearly 1% in rare-earth-based intermetallic compounds to almost zero for iron-based amorphous and nanocrystalline alloys (see *Magnetostrictive Materials*).

The local properties of *nanoscale heterogeneous magnetic systems* do vary in the scale of nanometers, for amorphous materials even on an atomic scale (see *Amorphous and Nanocrystalline Materials*). Heterogeneous materials may exhibit surface (interface) magnetic anisotropy and magnetostriction, negligible in bulk material. For many applications, magnetostrictive thin films are of special interest, because cost-effective mass production is possible. In microelectromechanical systems (MEMSs; see *Micromechanical Systems, Principles of*), thin films exhibiting giant magnetostriction (GMS; see *Thin Films Giant Magnetoresistive*), preferably at low fields, are applied as microactuator elements like cantilevers (see Fig. 1) or membranes, since they combine high-energy output, high-frequency, and remote-control operation. Here, good performers are thin films of rare-earth–transition metal (RT) intermetallic compounds. More recently, attention is also focused on the magnetostrictive properties of perovskite manganites and cobaltates, which are known to exhibit large changes in resistivity upon magnetization (colossal magnetoresistance (CMR); see *Transition Metal Oxides: Magnetism*).

In order to reduce the number of explicit references, for many details we only indicate where references can be found in Duc and Brommer (2002).

### *1. Magnetoelastic Effects*

The free energy of a magnetic substance is the sum of the magnetostatic energy and the ''internal'' free energy. The magnetostatic energy originates from the

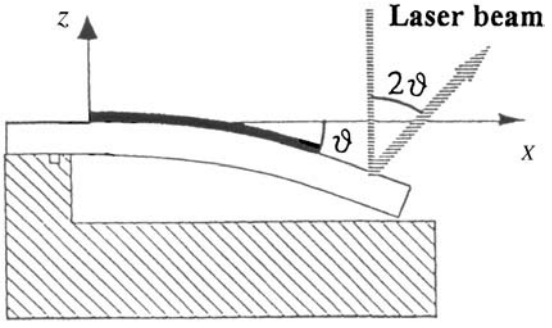

***Figure 1***
A typical magnetostrictive *cantilever* consists of a thin film deposited on a suitable substrate, which is clamped on the sample holder. The deformation caused by application of a magnetic field can be determined by measuring the deflection of a laser beam.

(long-range) dipolar interactions, giving rise to demagnetizing fields and shape anisotropy. The concurrent deformations depend on the geometry of the sample (hence the name *form effect*), but are small ($\leqslant 10^{-6}$), and often negligible. The "internal" free energy is expanded in the symmetrized strains $\varepsilon_{xx}$, $\varepsilon_{yy}$, $\varepsilon_{zz}$, $\varepsilon_{xy}$, $\varepsilon_{yz}$, $\varepsilon_{xz}$, and the direction cosines of the magnetization $\alpha_i$ ($i=1$, 2, 3, corresponding to Cartesian coordinates $x$, $y$, $z$, respectively). The free energy is invariant under symmetry transformations, and thus can best be expressed in linear combinations of the strains (e.g., $e=\varepsilon_{xx}+\varepsilon_{yy}+\varepsilon_{zz}$) and polynomials (such as $\alpha_1^2+\alpha_2^2+\alpha_3^2=1$, $\alpha_1\alpha_2$ or $(\alpha_3^2-\frac{1}{3})$), which span invariant irreducible subspaces. The strain $e$ mentioned above spans a one-dimensional invariant subspace. For an $n$-dimensional irreducible subspace $\gamma$, spanned by strains $\{e_j^\gamma\}$ or polynomials $\{h_j^{\gamma,m}(\boldsymbol{\alpha})\}$ of degree $m$, with $j=1,\ldots,n$, a fundamental group-theoretical theorem states that the only (second-order) invariants are $\sum_j (e_j^\gamma)^2$, $\sum_j (h_j^{\gamma,m})^2$, and the bilinear magnetoelastic coupling terms $\sum_j e_j^\gamma h_j^{\gamma,m}(\boldsymbol{\alpha})$. The magnetostrictive strains follow from the minimization of the free energy part $\frac{1}{2}C^\gamma \sum_j (e_j^\gamma)^2 + B^{\gamma,m} \sum_j e_j^\gamma h_j^{\gamma,m}(\boldsymbol{\alpha})$, yielding $e_j^\gamma = -(B^{\gamma,m}/C^\gamma) h_j^{\gamma,m}(\boldsymbol{\alpha})$, governed by the (first-order) "*coefficient of magnetostriction*" $\lambda^{\gamma,m} = -(B^{\gamma,m}/C^\gamma)$.

As an example, we decompose the free-energy density of an *isotropic* material as $F = F^\alpha + F^\gamma$:

$$F^\alpha = (1/2)C^\alpha e^2/3 + B^{\alpha,0} e/3 \tag{1a}$$

$$\begin{aligned} F^\gamma = (1/2)C^\gamma \Big[ &(3/2)\ (\varepsilon_{zz} - e/3)^2 + (1/2)\ (\varepsilon_{xx} - \varepsilon_{yy})^2 \Big] \\ &+ B^{\gamma,2}[(3/2)\ (\varepsilon_{zz} - e/3)\ (\alpha_3^2 - 1/3) \\ &+ (1/2)\ (\varepsilon_{xx} - \varepsilon_{yy})\ (\alpha_1^2 - \alpha_2^2)] \end{aligned} \tag{1b}$$

Minimizing the free energy results in the *volume magnetostriction* $e = \lambda^{\alpha,0} = -B^{\alpha,0}/C^\alpha$, and the *Joule magnetostriction* components $(\varepsilon_{zz} - e/3) = \lambda^{\gamma,2}(\alpha_3^2 - 1/3)$, and $(\varepsilon_{xx} - \varepsilon_{yy}) = \lambda^{\gamma,2}(\alpha_1^2 - \alpha_2^2)$, with $\lambda^{\gamma,2} = -B^{\gamma,2}/C^\gamma$ (equivalently, for instance, $\varepsilon_{xy} = \lambda^{\gamma,2}\alpha_1\alpha_2$ (cycl.)). Inserting these results in the general expression for the linear expansion, measured in the direction $\boldsymbol{\beta} = (\beta_1, \beta_2, \beta_3)$

$$\Delta\ell/\ell = \varepsilon_{xx}\beta_1^2 + 2\varepsilon_{xy}\beta_1\beta_2 + \text{cycl.} \tag{2}$$

yields

$$\begin{aligned} \Delta\ell/\ell = \lambda^{\alpha,0}/3 + \lambda^{\gamma,2}[&\{(\alpha_3^2 - 1/3)\ (\beta_3^2 - 1/3) + \text{cycl.}\} \\ &+ \{2\alpha_1\alpha_2\ \beta_1\beta_2 + \text{cycl.}\}] \end{aligned} \tag{3}$$

From this expression, one defines the "saturated" relative change of length measured along the field direction (common to the magnetization direction) as $\lambda_s = (\Delta\ell/\ell)_\parallel^{\text{sat}} - \lambda^{\alpha,0}/3 = 2\lambda^{\gamma,2}/3$. The relative change in the plane perpendicular to the field would be $-\frac{1}{2}\lambda_s = (\Delta\ell/\ell)_\perp^{\text{sat}} - \lambda^{\alpha,0}/3$. In practice, it is necessary to measure in two perpendicular directions and determine $3\lambda_s/2 = \lambda^{\gamma,2} = [(\Delta\ell/\ell)_\parallel^{\text{sat}} - (\Delta\ell/\ell)_\perp^{\text{sat}}]$.

For uniaxial symmetry, the six strain components are subdivided into two one-dimensional subsets (indicated by the superscript $\alpha$, and subscripts 1 and 2 for the volume dilatation and the axial deformation, respectively), and two different two-dimensional subsets, indicated by $\gamma$ for in-plane deformations, and by $\varepsilon$ for "skew" deformations. In this case, the magnetostriction can be expressed as

$$\begin{aligned} \Delta\ell/\ell = &\lambda_1^{\alpha,0}/3 + \lambda_2^{\alpha,0}(\beta_3^2 - 1/3) \\ &+ [\lambda_1^{\alpha,2}/3 + (3/2)\lambda_2^{\alpha,2}(\beta_3^2 - 1/3)](\alpha_3^2 - 1/3) \\ &+ \lambda^{\gamma,2}[(1/2)\ (\beta_1^2 - \beta_2^2)\ (\alpha_1^2 - \alpha_2^2) + 2\alpha_1\alpha_2\beta_1\beta_2] \\ &+ 2\lambda^{\varepsilon,2}(\alpha_3\alpha_2\beta_3\beta_2 + \alpha_3\alpha_1\beta_3\beta_1) \end{aligned} \tag{4}$$

Notice here the uniaxial deformation, $\lambda_2^{\alpha,0}$, independent of the direction of the magnetization, and the contribution to the volume magnetostriction, $\lambda_1^{\alpha,2}$, which does depend on the magnetization direction (see fig. 3 in Duc and Brommer 2002, p. 101).

At the surface of an isotropic material the symmetry is reduced from isotropic to uniaxial. The concurrent increase of the necessary number of coefficients (compare Eqns. (4) and (3)) is an example of quite a general rule. This subject is worked out in detail in, for instance, the textbooks written by Du Trémolet de Lacheisserie (1993, 1999).

Most theoretical models for surface anisotropy and magnetostriction are rather phenomenological, based on lower coordination numbers and "missing" pair interactions at the surface. *Ab initio* calculations were reported by Freeman's group (Duc and Brommer 2002, p. 105). Direct experimental evidence of surface magnetoelastic coupling was provided by measuring the strain dependence of the surface magnetization as determined by secondary-electron spin polarization spectroscopy (Duc and Brommer 2002, p. 112).

Since the surface effects contribute "per unit surface area," one defines, for a layer of thickness $t$, effective parameters such that $B^{\text{eff}}$ equals $B^{\text{bulk}} + 2B^{\text{surf}}/t$. Here, the factor 2 is put in, because a layer has two surfaces. In practice, this simple $1/t$ dependence works satisfactorily. For nanocrystallites, both the volume fraction and the "volume-to-surface ratio" of the crystallites (i.e., their radii) must be taken into account.

For higher-order coupling terms, i.e., nonlinear in the strains, analogous symmetry considerations lead to the correct "group-theoretical" invariant magnetoelastic energy contributions. Sander (1999) has shown that for epitaxially grown films, second-order magnetoelastic coupling parameters must be taken into account because of the large "epitaxial" strains due to the mismatch between substrate and film (Duc and Brommer 2002, p. 105)

## 2. *Nanoscale Heterogeneous Structures*

### *2.1 Bulk Material (Ribbons, Thick Films)*

Research on bulk giant magnetostrictive materials has been focused on iron-based rare-earth alloys, because they combine a high rare-earth concentration, thus a high magnetostriction, with a high-ordering temperature. The corresponding crystalline $RCo_2$ compounds are not particularly interesting for applications, because of their lower Curie temperatures: they do exhibit huge magnetostriction, but at low temperatures only.

A high room-temperature magnetostriction was found in Terfenol (polycrystalline $TbFe_2$: Ter for Tb, fe for Fe, nol for Naval Ordnance Laboratory, where it was developed). Terfenol-D (D for Dy: $Tb_xDy_{1-x}Fe_2$, where $x \approx 0.3$) exhibits a reduced magnetic anisotropy, and thus lower (but still rather high) coercivities, together with a large magnetostriction: $\lambda_s \approx 1500 \times 10^{-6}$ ($T_C \approx 650\,K$) (Duc and Brommer 2002, p. 94).

In general, various nanocrystalline structures can be obtained by suitable heat treatments: quenching, (magnetic) annealing. Moreover, the (re)crystallization process can be influenced by additives such as Nb, Mo, Zr, etc. The size of the nanocrystallites determines the surface-to-volume ratio. Combining surface effects and the bulk properties, one can, for instance, achieve low anisotropy (optimal magnetic softness) or minimal magnetostriction (transformers).

### *2.2 Thin Films*

Thin films are often deposited (by sputtering) as an amorphous layer on a substrate. Again, suitable heat treatments can be applied to enhance the properties (e.g., in-plane or perpendicular anisotropy). By controlled recrystallization of Fe-rich amorphous alloys, a material consisting of nanocrystalline grains embedded in an amorphous matrix can be formed (see *Amorphous and Nanocrystalline Materials*). The effective magnetostriction combines the negative contribution of the crystalline phase with the positive contribution of the amorphous phase, whereas in many cases also a surface contribution must be taken into account (see, e.g., the work of Herzer, Szymczak, Ślawska-Waniewska, Żuberek, Gutierez, and others—seeDuc and Brommer 2002, p. 168 *ff*).

In amorphous Fe-based thin films, the variation in the Fe–Fe interatomic distance leads to large variations (different signs) of the Fe–Fe exchange interactions, and thus to frustration and freezing of the Fe-moments in different directions: *asperomagnetism* ($M_s > 0$) or *speromagnetism* ($M_s = 0$). Because of the concurrent variation in the local easy axis for the rare-earth moment, in amorphous (Tb,Fe) both the Tb and the Fe subsystem exhibit asperomagnetism (Fig. 2), with reduced subsystem magnetization, and

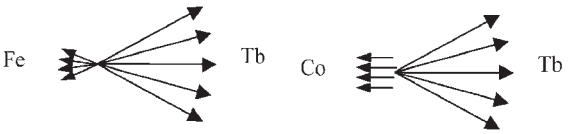

***Figure 2***
Sperimagnetic structure of amorphous Tb–Fe and Tb–Co.

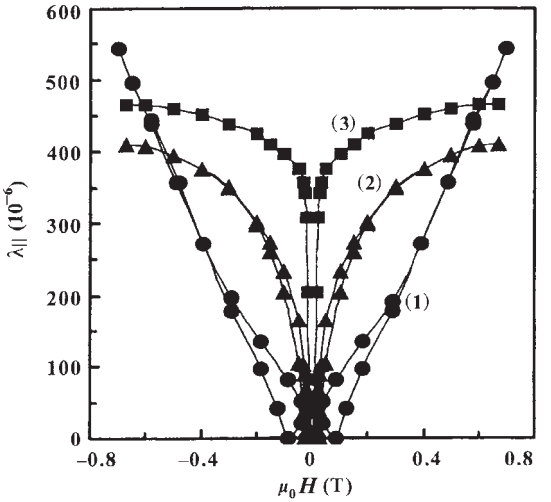

***Figure 3***
Parallel magnetostrictive hysteresis loops for $Tb(Fe_{0.55}Co_{0.45})_{1.5}$ films: (1) as-deposited film, (2) after annealing at 350 °C and (3) at 450 °C (after Duc *et al.* 2000).

hence magnetostriction. The Curie temperature is lower too. In a-(Tb,Co) only the Tb-subsystem exhibits asperomagnetism (Duc and Brommer 2002, p. 116), whereas the Curie temperature is raised. Because of the important role of the "Laboratoire Louis Néel" in their development, Duc (Duc and Brommer 2002, p. 94) proposed to refer to the a-(Tb,Co) alloys, with composition near $TbCo_2$, as "a-TerCoNéel," by an obvious analogy to TerFeNol, to amorphous Tb-$(Fe,Co)_2$ thin film ($\lambda_s \approx 1020 \times 10^{-6}$) as "a-Terfeconéel," and, adding Dy, to "a-Terfeconéel-D." In Hanoi, amorphous $Tb(Fe_{0.55}Co_{0.45})_{1.5}$, to be named "a-Terfecohan," was developed and found to exhibit already a large magnetostriction ($\lambda_{\parallel} \approx 340 \times 10^{-6}$) at $\mu_0 H = 20\,mT$ (Fig. 3).

### *2.3 Sandwich Structures*

Sandwich films of the type RT/R′T/RT consist of layers with typical thicknesses of 100 nm. Because magnetization or anisotropy differ from one layer to

the next, magnetization reversal occurs at a different field for each layer. An *extended domain wall* (EDW) can be formed at an interface, affecting (reducing) appreciably the magnetostriction because of its relatively large volume. The exchange coupling of the layers can be suppressed by fabricating a thin oxide layer at the interface. The observed jumps in the magnetization curve of a TbCo/NdCo/TbCo sandwich (Givord *et al.*—see Duc and Brommer 2002, p. 165), and the corresponding variations of the observed magnetostriction confirm the process depicted in Fig. 4.

EDW formation has also been observed in TbFe/FeCoBSi multilayers (Quandt and Ludwig—see Duc and Brommer 2002, p. 165) with layer thickness above 20–25 nm (see below).

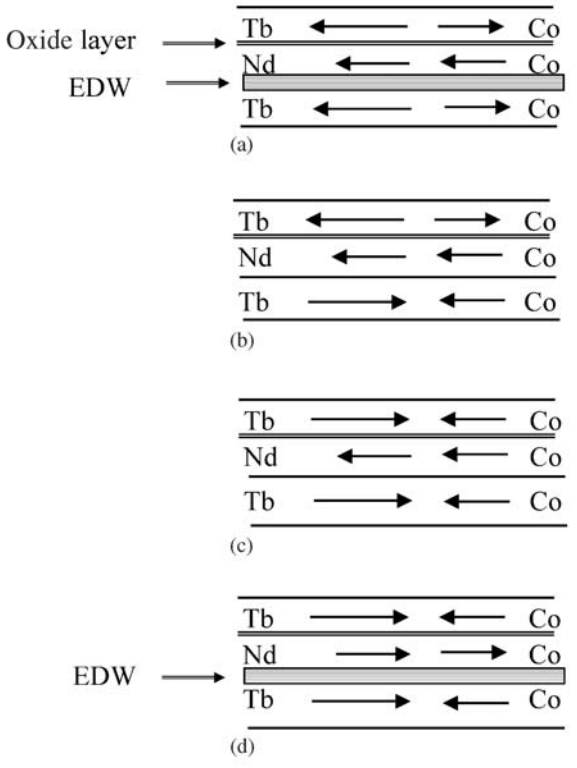

***Figure 4***
Occurrence of extended domain walls in a TbCo/NdCo/TbCo sandwich film during the magnetization process. A well-defined easy magnetization direction was introduced by annealing in a magnetic field. (a) High negative field: an EDW is formed at the coupling interface to match the antiparallel Co moments; (b) low negative field: the EDW is destroyed when the Co moments are parallel; (c) low positive field: the ''uncoupled layer'' is switched first; and (d) high positive field: the EDW is necessary again.

### *2.4 Multilayers*

#### *(a) Spacer layers*

To reduce coercivity significantly in R–Fe alloys, the crystalline-grain size is desirable to be smaller than the Bloch wall width, i.e., below 5 nm. One can limit the grain growth by depositing, for instance, Nb-layers (0.25 nm) as spacers between 5 nm TbDy-Fe + Zr (Fisher and Winzek—see Duc and Brommer 2002, p. 139). Suitable heat treatment now results in a parallel magnetostriction of $520 \times 10^{-6}$, whereas the coercive fields stay distinctively below 100 mT.

Analogous structures may be formed in multilayers when the sharp interfaces are broadened by interdiffusion (Duc and Brommer 2002, p. 151 *ff*).

Notice, that in some cases multilayers (or multithreaded material) can be produced by repeatedly cold rolling or extrusion (Hai *et al.* 2003).

#### *(b) Magnetostrictive spring magnet type multilayers (MSMMs)*

Magnetostrictive, spring magnet type, or rather exchange coupled, multilayers (Fig. 5) combine the large magnetostriction of, for example, a-Tb-(Fe,Co), with the desired soft-magnetic properties and the high magnetization of, for example, (nano)crystalline (Fe,Co). A huge magnetostrictive susceptibility $d\lambda_{\parallel}/dB = 13 \times 10^{-6}\,T^{-1}$ was reported for {a-Terfecohan/(nano)YFeCo} multilayers (Duc and Brommer 2002, p. 152). The layers must be thin enough (1–20 nm) to prevent EDW formation. Then, the multilayer is one magnetic unit in which the $3d-3d$ exchange interactions ensure parallel coupling of the transition metal moments, antiferromagnetically coupled with the Tb-moments (Duc and Brommer 2002, p. 140 *ff*).

For multilayers, the effective magnetostriction as a function of the thickness $t$ of the magnetic layers has been studied extensively (Duc and Brommer 2002, p. 155 *ff*). As mentioned above, in general the effective

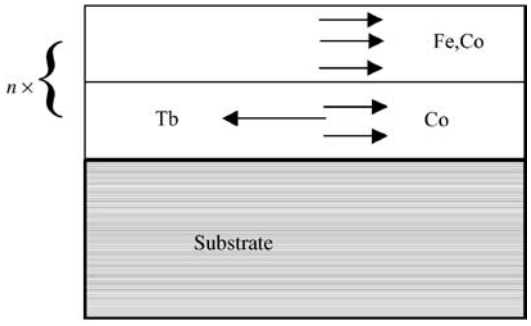

***Figure 5***
Schematic view of an exchange coupled MSMM (Tb,Co)/(Fe,Co). Layer thickness is 1–20 nm. The repetition number $n$ is of the order of 100.

magnetostriction depends linearly on $1/t$, i.e., $\lambda_{\text{eff}} = \lambda_{\text{bulk}} + 2\lambda_{\text{surf}}/t$.

### 2.5 Superlattices

Magnetic rare-earth superlattices R/M (M = Y, Lu) are produced by depositing a distinct number of atomic planes per layer. As an example, a $\{Ho_{31}/Lu_{19}\}_{50}$ superlattice has 50 layers consisting of 31 Ho and 19 Lu planes (alternatively: $[Ho_{31}/Lu_{19}] \times 50$). Remarkable features in these artificial structures are: (i) helical magnetic order (spin density wave) is found to propagate through the (very thin) nonmagnetic layers; (ii) due to epitaxial strains and strains caused by mismatching subsequent layers, the magneto-elastic coupling ($B^\gamma$) in a superlattice layer may be different from that in the bulk; and (iii) large surface effects are observed (Duc and Brommer 2002, p. 159 *ff*). A magnetic-phase diagram was constructed for $\{Ho_6Y_6\}_{100}$ consisting of a ferromagnetic, a fan, and a helical structure. For $\{Ho_nLu_{15}\}_{50}$ superlattices, the relationship $B^\gamma = (B^\gamma_{\text{vol}} + D\varepsilon)f_1(m) + 2t_{\text{Ho}}^{-1}B^\gamma_{\text{surf}}f_2(m)$ appears to describe the observed phenomena satisfactorily as a function of the Ho layer thickness, $t_{\text{Ho}}$, and of the reduced magnetization, $m$. Here $f_1(m)$ is the general function, derived by Callen and Callen (see Duc and Brommer 2002, p. 161) for a single-ion crystal field contribution, expressing the temperature dependence of the magnetostriction through the temperature dependence of $m$. $f_2(m)$ is taken to be proportional to $m^4$ at low temperatures and to $m^2$ at high temperatures. $B^\gamma_{\text{vol}}(= 0.275\ \text{GPa})$ has about the same value as for bulk Ho. $B^\gamma_{\text{surf}}/(c/2)$ $(= -7.0\ \text{GPa}$, where $c$ is the $c$-axis parameter of Ho) represents a contribution of opposite sign, large for a thin Ho layer.

### 2.6 Granular Composites

The recrystallized Fe-rich amorphous alloys, composed of crystalline grains embedded in a residual amorphous matrix, belong to a wide class of heterogeneous structures, ranging from organometallic complexes or metallic clusters deposited on graphite or built-in in polymers on a molecular scale, up to composites consisting of microscale grains embedded either in a metallic binder or in some resin or polymer (see, e.g., Gubin, Kosharov, Herbst, Pinkerton, Duenas, Carman—see Duc and Brommer 2002, p. 168 *ff*). These materials exhibit novel phenomena such as superparamagnetism, giant magnetoresistance, and giant magnetic coercivity (Chien, Hernando, Duc—see Duc and Brommer (2002)). On the one hand, the (nano)crystalline fraction can be manipulated in such a way that zero magnetostriction results (useful for core material), for example, in $Fe_{90}Hf_7B_3$ (Chiriac—see Duc and Brommer (2002)) and $Fe_{85.5}Zr_2Nb_4B_{8.5}$ ribbons (Makino—see Duc and Brommer (2002)), in as-deposited Fe–Al–O and $(Co_{0.94}Fe_{0.06})$–Al–O films, and, after annealing at 300 °C, also for $(Co_{0.92}Fe_{0.08})$–Al–O films (Ohnuma—see Duc and Brommer (2002)). On the other hand, composites containing (microscale) Terfenol-D grains in a nonmetallic binder (epoxy) may optimally have a magnetostrictive response comparable to that of Terfenol-D itself (Duenas and Carman, Armstrong—see Duc and Brommer 2002, p. 173). Such composites are durable and are easily machined into complex shapes.

### 2.7 Perovskite Manganites and Cobaltates

Huge magnetostriction has been found in perovskite manganites $R_{1-x}A_xMnO_3$ (R: trivalent rare earth; A: divalent cation), cobaltates $R_{1-x}A_xCoO_3$, and some related (doped) layered manganese oxides with formula $(R_{1-y}A_y)_{n+1}Mn_nO_{3n+1}$ (in particular the highly anisotropic, almost two-dimensional, $n = 2$ members), exhibiting CMR. Thin films of these ceramics can be produced by (pulsed) laser ablation deposition. Consequently, these materials are regarded as possible alternatives for the more conventional RT epitaxially grown thin films. Combination of CMR and magnetostriction may be useful in applications. In general, the phase diagrams are complex, showing different combinations of insulator (or semiconductor)–metal transitions, antiferromagnetic to paramagnetic or ferromagnetic transitions, charge order (influenced by doping), etc. (Duc and Brommer 2002, p. 174 *ff*). These perovskites are included here, because, in some cases, the structure is described as a nanocrystalline heterogeneous composite of ferromagnetic clusters in an antiferromagnetic (semiconducting) matrix (or the other way round).

## 3. Concluding Remarks

For applications, both zero-magnetostriction (soft-magnetic) materials and materials exhibiting giant magnetostrictive effects (for actuators) are of interest. Reliable magnetostrictive devices (MEMS) have been designed on the basis of Terfenol and Terfenol-D ($TbDyFe_2$). When using amorphous thin films, it is preferable to replace (some) iron by cobalt, because of the asperomagnetic nature of the Fe-subsystem. Magnetoelastic effects in thin films and multilayers are of fundamental interest too, in particular because a better understanding of the magnetoelastic coupling can be obtained by studying surface (interface) effects.

Microactuators and motors have been designed, taking advantage of wireless magnetic excitation, in first instance at room temperature (or higher temperatures). For cryogenic applications, magnetostrictive actuators require low-temperature magnetostrictive materials. In practice, $Tb_{0.6}Dy_{0.4}Zn_1$ (Terzinol) single crystals have been used (Teter—see Duc and Brommer 2002, p. 191), but also perovskites

and rare-earth superlattices must be considered as possible candidates for such applications. Giant magnetostriction has been observed also in high $T_C$ superconductors, e.g., in $Bi_2Sr_2CaCu_2O_8$ single crystals and $YBa_2Cu_3O_7$ ceramics (reviewed by Szymczak 1999).

## Magneto-impedance Effects in Metallic Multilayers

Magnetic sensor technology is a strongly growing industry which has been satisfied in some areas by magnetoresistors, giant magnetoresistors (GMRs; see *Giant Magnetoresistance*), fluxgates and other technologies. Giant magneto-impedance (GMI) is a candidate to equal or even overtake some of these emergent sensor systems in terms of performance and lower cost (Mohri *et al*. 1995). The magneto-impedance phenomenon implying a change of the complex resistivity of a ferromagnetic conductor caused by an external magnetic field has been known for more than 50 years. However, a giant change of the impedance of more than 100%, which certain soft magnetic materials exhibit in the presence of a weak external magnetic field (less than 1–10 Oe), has been found quite recently. It was reported (Panina *et al*. 1994) that in CoFeSiB near-zero magnetostrictive amorphous wires and ribbons having a well-defined circumferential (or transverse) anisotropy, the impedance sensitivity to the direct current (d.c.) longitudinal external field is $\sim$25–100%/Oe at a frequency of 1–10 MHz. It was also understood that although GMI can be considered as a high-frequency analog to GMR, it has quite a different mechanism. If GMR has a quantum origin, occurring due to a spin-dependent scattering of conductive electrons, GMI is a classical phenomenon that occurs due to a re-distribution of the alternating current (a.c.) density in a magnetic conductor subjected to an external magnetic field. Since then, the research on GMI has expanded rapidly, involving new materials such as magnetic/metallic multilayers, new concepts such as asymmetrical GMI, and excitation at higher frequencies (up to 10 GHz).

Recent progress in GMI technology is related to utilising magnetic/metallic multilayers. Using thin film materials is more preferable in a number of applications, because of compatibility with integrated circuit technology, avoiding soldering problems, and allowing miniaturization. Along with this, the principal advantage of magnetic/metallic multilayers is that the nominal values of the impedance change can be several times larger, reaching 400–600%. It has been reported (Morikawa *et al*. 1997) that in CoSiB/Cu/CoSiB multilayers of 7 μm thick, the impedance change is as large as 340% at a frequency of 10 MHz and a d.c. magnetic field of 9 Oe.

A simple three-layer sandwich film F/M/F consisting of two outer ferromagnetic layers (F) and an inner lead (M), having much higher conductivity ensures large impedance changes under the application of a d.c. magnetic field. As layers F, Co-based amorphous films or NiFe films are typically used since they have a small magnetostriction and good soft magnetic properties. Using noble metals (Cu, Ag, Au) for the inner lead M gives the necessary conductivity ratio (between layers M and F) in the range of 10–50. Since the inner conductivity is much higher, the resistance $R$ of the total structure is determined by that for the layer M and the a.c. current mainly flows along it, whereas the magnetic layers contribute to the inductive part of the impedance. The latter can be considerably larger than $R$ at relatively low frequencies because of a high value of the a.c. permeability which, for certain magnetic configurations, is also sensitive to the d.c. magnetic field.

The problem of calculating the impedance $Z$ in a three-layer film F/M/F can be solved exactly accounting for the skin effect, the a.c. permeability tensor

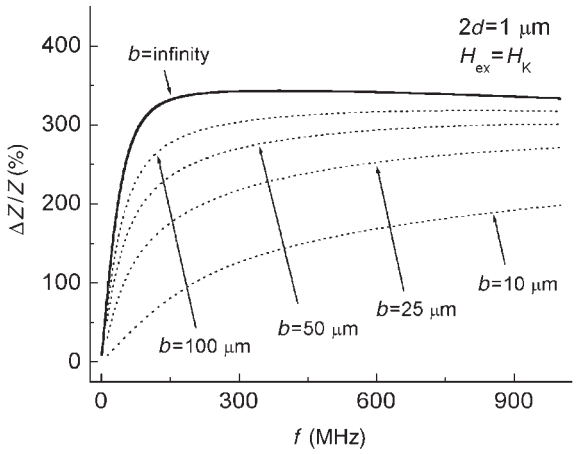

***Figure 1***
GMI ratio vs. frequency in a sandwich with a transverse anisotropy with the width as a parameter. The total film thickness $2d = 1\,\mu m$.

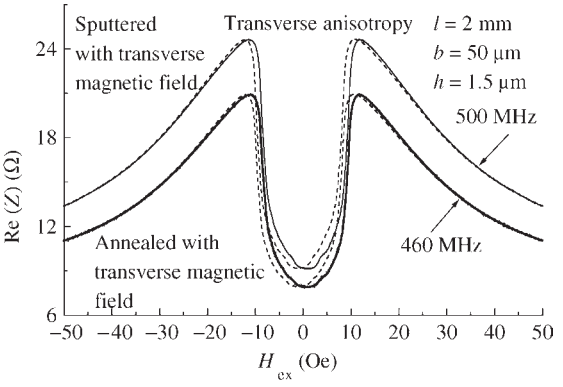

***Figure 2***
Real part of the impedance vs. field in NiFe/Au/NiFe films with a transverse anisotropy, $f = 450$–$500\,MHz$.

(Makhnovskiy *et al.* 2000) and the in-plane dimensions (Panina *et al.* 2001). Figure 1 shows the GMI ratio versus frequency for a transverse configuration: the easy axis of the magnetic anisotropy is transverse with respect to the a.c. current, the d.c. magnetic field $H_{ex}$ is applied in parallel with the current. The GMI ratio, defined as a maximal impedance change ratio is expressed as $\Delta Z/Z = |Z(H_K) - Z(0)|/|Z(0)| \cdot 100\%$, where $H_K$ is the anisotropy field. The function $|Z(H_{ex})|$ has a maximum at $H_{ex} \approx H_K$, associated with that for the rotational permeability. Therefore, the GMI ratio introduced gives the maximum impedance change. The magnetic and electric parameters taken for the calculations correspond to amorphous CoFeSiB and Cu sputtered multilayers. For a wide film (film width $b > 100\,\mu m$, thickness $2d = 1\,\mu m$), the GMI is $\sim 300\%$ in a wide frequency range above 50 MHz, agreeing well with the experimental data. The GMI ratio is higher for thicker films reaching 600–700% for $2d > 5\,\mu m$ and becomes only $\sim 20\%$ for $2d = 0.1\,\mu m$. With decreasing $b$ below some critical value (depending on the transverse permeability and the thickness of the layers M and F), $\Delta Z/Z$ decreases substantially. This degradation in the GMI behavior is related with the flux leakage across the inner lead (a sort of a.c. demagnetizing). This process is similar to that resulting in a drop in the efficiency of inductive recording heads (Paton 1971).

Figure 2 presents the experimental results for impedance versus field behaviour in a sandwich film with $F = Ni_{80}Fe_{20}$ and M = Au. The films are deposited on a glass substrate in the presence of the d.c. transverse field of $\sim 100$ Oe. After the deposition, the films were annealed to release the stress and finally establish the transverse anisotropy. The field characteristics have two symmetrical maximums when the external field equals the anisotropy field ($\sim 10$ Oe). The maximal GMI ratio is in the range of 240% for a frequency of 500 MHz. It is smaller than for the case shown in Fig. 1, since the conductivity ratio using NiFe films is also smaller. Yet, the sensitivity is very high (24%/Oe) and using NiFe is practically more preferable.

For application in magnetic sensors, not only high sensitivity but linearity is also important. On the other hand, the characteristics shown in Fig. 2 are not only nonlinear but shaped in a way that the operation near zero field point presents considerable difficulties. A linear response can be obtained using AGMI characteristics. It was proven that in structures with an asymmetric arrangement of the static magnetization (with respect to $H_{ex}$), the impedance also shows an asymmetric behavior (Panina *et al.* 1999), for example, in multilayers with a cross-anisotropy in the presence of a d.c. bias current $I_b$ (Ueno *et al.* 2000). Here, we present results for NiFe/Au/NiFe multilayers, in which the upper and bottom magnetic films were deposited in cross magnetic fields (by rotating the substrate). Releasing the stress by annealing, a cross-anisotropy film was finally produced. The AGMI characteristics obtained in the presence of the d.c. bias current are given in Fig. 3.

In summary, the GMI effect in multilayers having in principle two soft ferromagnetic films (F) sandwiching a highly conductive lead (M) has significant advantages over that in a single layer. First, the GMI ratio is several times higher ranging within 100–600% for films of 1–10 μm thick. Second, AGMI characteristics needed for linear sensing can be realized using cross-anisotropy films. The application of GMI multilayers in establishing new sensitive and quick response micromagnetic sensors is at an early stage of its development. However, it can be expected that

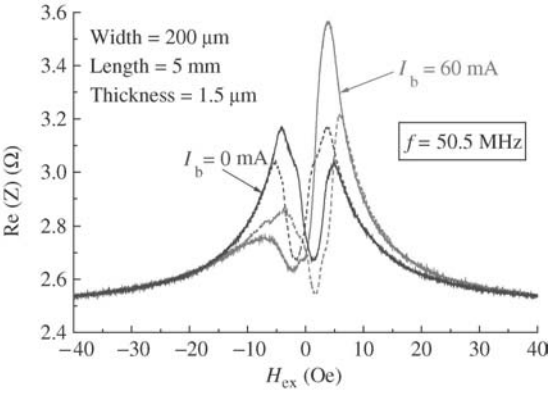

***Figure 3***
Real part of the impedance in NiFe/Au/NiFe multilayers with cross-anisotropy for a d.c. bias current $I_b = 0$ mA and 60 mA.

significant technical achievements in this field will be made in the foreseeable future.

## Magneto-optic Multilayers

The performance of magneto-optic (MO) media decreases when the wavelength is reduced, and therefore alternatives with high MO output at short wavelengths are needed. Multilayers consisting of very thin cobalt or CoNi and platinum or palladium layers have been developed for this kind of application. A part of a typical multilayer structure is depicted in Fig 1. The circles represent atoms, and the two monolayers of cobalt (4 Å) that are drawn are considered thick layers for application purposes. The stacking in a real multilayer is not perfect, and differs from this schematic representation.

Since the early 1980s elements from large sections of the periodic system have been combined to produce multilayers, which has resulted in a large number of publications. A nonmagnetic interlayer with even better Kerr enhancing properties has been found: platinum. Co/Pt multilayers have a Kerr rotation of up to 0.5° at about 300 nm (4.2 eV), are insensitive to corrosion, and owing to the high reflectivity they have a higher figure of merit than the rare-earth (RE) element/transition metal (TM) layers applied in contemporary MO drives. The rewritability is smaller than for RE/TM layers, owing to the higher Curie temperature of Co/Pt multilayers. This Curie temperature is between 300 °C and 400 °C for a good Co/Pt medium. Owing to the high writing temperature that is required, the layers are annealed during each writing process, which can result in a decreasing figure of merit when the material is rewritten many times. Magnetic multilayers have been actively investigated since a perpendicular magnetic anisotropy was found in Co/Pd and Co/Pt multilayers (Carcia *et al*. 1985a). MO applications of Co/Pt and Co/Pd multilayers arose at the end of the 1980s (Zeper *et al*. 1989b, Ochiai *et al*. 1989), with the study of CoNi/Pt multilayers following (Mes *et al*. 1993, Hashimoto *et al*. 1993, Van Drent 1995).

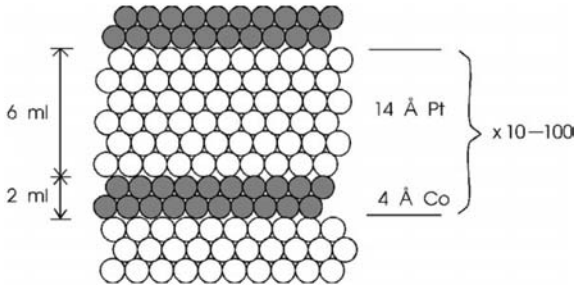

***Figure 1***
Schematic of part of a multilayer structure. The bilayer consisting of a cobalt and a platinum layer is repeated $N$ times with typically $10 \leqslant N \leqslant 100$.

The Co/Pd, Co/Pt, and CoNi/Pt multilayers discussed in this article meet most of the requirements of the next generation of MO media. MO media use wavelengths from about 820 nm to 680 nm. At shorter wavelengths, the detection of smaller bits is possible as the size of the smallest light spot depends on this wavelength. Reducing the wavelength by a factor of two will increase the density by a factor of 4. Reduction of the wavelength can be achieved with a laser generating blue–green light or by frequency doubling. The Curie temperature is an important system parameter, but the media should also have a large Kerr rotation, perpendicular anisotropy, square hysteresis loop for maximum read signal, and a large coercivity to preserve the written information and allow stable small domains/bits. By tailoring the deposition process, selecting the materials, and designing the layer structure it is possible to make multilayers that feature a high MO output at short wavelengths, good magnetic properties, and a Curie temperature between 250 °C and 300 °C. A comparison between an RE/TM MO recording medium and a Co/Pt one is shown in Fig. 2 by plotting the Kerr rotation. It can be clearly seen that the rotation at smaller wavelengths is much better for the multilayer configuration.

The potential application of Co/Pt and Co/Pd multilayers has motivated numerous studies on their fundamental magnetic, MO, and practical MO recording properties. Co/Pt multilayers are more attractive for MO recording than Co/Pd multilayers because the Kerr effect of the former is larger. The perpendicular magnetic anisotropy (PMA) obtained in magnetic multilayers is mainly attributed to the interface anisotropy. A large Kerr rotation of Co/Pt multilayers at short wavelengths is attributed to polarization of platinum (Weller *et al.* 1993). A large coercivity, $H_c$ (e.g., 3 kOe), with a square hysteresis loop can be obtained in Co/Pt multilayers by many deposition techniques, e.g., using an etched $SiN_x$ underlayer (Suzuki *et al.* 1992). The $T_c$ for Co/Pt multilayers is higher than that of RE/TM media, which leads to a requirement for a higher writing temperature, and results in a smaller number of write/erase cycles before film degradation occurs (Carcia *et al.* 1991a, 1991b). Therefore, it is important to reduce the Curie temperature without significantly reducing the PMA and Kerr rotation. This can be achieved by adding nickel into the cobalt layer to produce a CoNi/Pt multilayer that shows a lower Curie temperature and improved MO recording properties (Mes *et al.* 1993, Hashimoto *et al.* 1993, Hashimoto 1994). Furthermore, a key attribute of MO disks based on RE/TM alloys is their lower optical noise because of their amorphous properties. In contrast, Co/Pt multilayers are crystalline with an average grain size of about 5–10 nm, which causes disk noise as much as 5–7 dB higher than that for RE/TM media (Hashimoto *et al.* 1993). One of the sources of the disk noise is attributed to polarization variations owing to surface roughness and dispersion of the magnetization axis (Hashimoto *et al.* 1993). Therefore, to reduce disk noise, multilayers must be prepared with a smooth surface and small grains having high homogeneity and high degree of the texture along the growth direction.

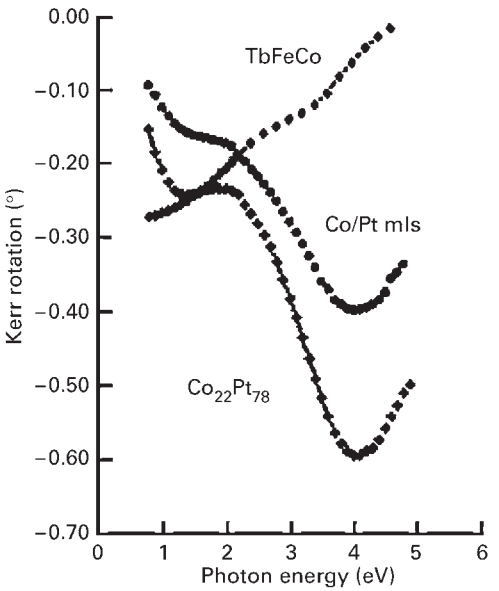

***Figure 2***
Kerr rotation spectra of a 100 nm thick $Co_{22}Pt_{78}$ alloy, a $77 \times (3$ Å Co/10 Å Pt) multilayer, and a 100 nm thick $Tb_{23.5}(Fe_{90}Co_{10})_{76.5}$ film (Weller *et al.* 1992a).

## *1. Deposition of Multilayers*

Multilayer systems as mentioned above can be prepared by vacuum deposition technologies such as e-beam deposition and sputtering. Because for commercialization a cost-effective manufacturing process is necessary the sputtering process is the most common technology.

Figure 3 shows a schematic of a (magnetron) sputtering system that has been used for the deposition of Co(Ni)/Pt(Pd) multilayers. There are more (at least two) "sputtering guns" mounted in a vacuum chamber. The sputtering guns can be operated using either radio-frequency (RF) or d.c. power. The target material is eroded from the target surface by the incoming positive inert gas ions such as argon, krypton, or xenon (purity 99.999%). Using a different sputter gas has an influence on the structure especially the interface structure of the multilayer. Heavier gas (xenon) reduces the chemical interdiffusion between the magnetic and platinum layer but increases the roughness at the interface compared with using lighter argon gas

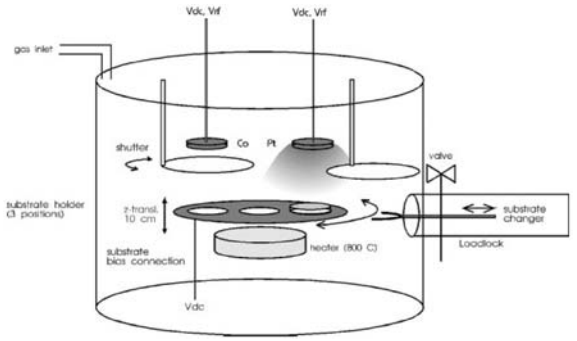

***Figure 3***
Schematic of the magnetron sputtering system used for the deposition of multilayers.

(Carcia *et al.* 1990, Donnet *et al.* 1996). In this system, RF sputtering leads to slow erosion compared with d.c. sputtering and gives more stable and reproducible results than d.c. sputtering. Therefore, RF sputtering has been used for thin magnetic targets (cobalt or CoNi, 1.5 mm) and d.c. sputtering for thick nonmagnetic targets (platinum and palladium, 3 mm). In most cases, a rather low power of 50 W or 100 W is applied for both RF and d.c. sputtering. For the system in Fig. 3 the frequency of the RF power supply is 13.56 MHz and the reflected power is tuned to be as low as possible ($<1$ W). The deposition pressure during sputtering varies from system to system. For the system in Fig. 3 most of the samples are deposited at $P_{Ar} = 1.6 \times 10^{-2}$ mbar and $4.0 \times 10^{-2}$ mbar. During sputtering the substrates can be heated to a few hundred degrees. Also a d.c. bias can be applied to the substrate table to realize a bias sputter deposition that influences the thin-film growth. Moreover the substrate can be sputtered, etched and cleaned before it is deposited. A base pressure of $10^{-9}$ mbar can be obtained by warming the chamber with the substrate heater. The substrate can be transferred through a load-lock without breaking the vacuum of the process chamber. As a result, the process chamber can be pumped down to a base pressure better than $5 \times 10^{-8}$ mbar. For sputtering as well as for e-beam evaporation the deposition rates (measured on the substrate) are 1–6 $\text{Å s}^{-1}$. Furthermore, the shutter time, the table rotation, and sputtering pressure are fully controlled by a computer.

## 2. *Thin-film Growth by Sputtering*

A transmission electron microscopy (TEM) cross-section of a typical CoNi/Pt multilayer is shown in Fig. 4. This multilayer structure is prepared on a silicon substrate. The first layer is a relatively thick platinum seed layer to obtain a good crystallographic orientation. For this particular purpose the multilayer

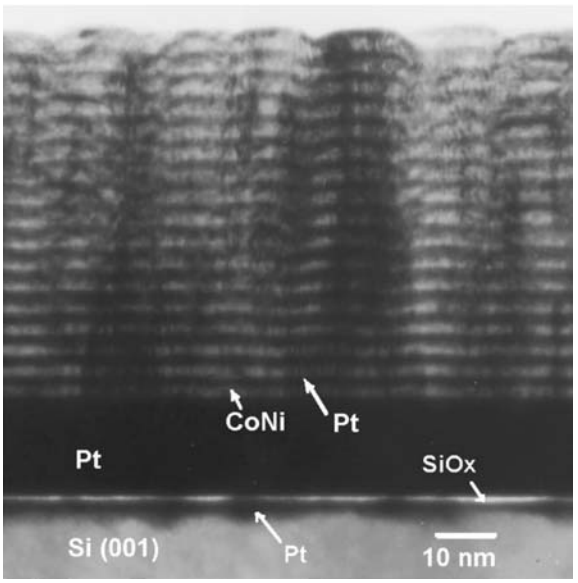

***Figure 4***
Typical structure of Co(Ni)/Pt multilayers. A cross-sectional TEM image of a $Co_{0.5}Ni_{0.5}$/Pt multilayer with a composition of (Si/24 nm Pt/(3.8 nm CoNi/1.5 nm Pt) $\times$ 17).

is made much thicker to demonstrate the growth more clearly. At the bottom, the layers are smooth and flat owing to the smooth and flat surfaces of the substrate and the platinum seed layer. A native $SiO_x$ layer (a bright line) can be seen on the surface of the silicon substrate. The platinum atoms can also be seen in the silicon substrate as indicated in the dark area (platinum silicide formation). Moreover, it clearly shows that the whole stack is composed of individual CoNi (bright) and platinum layers (dark).

In the sputtering process the kinetic energy of the incident atoms plays an important role in the growth of the thin-film microstructure. Consideration of the incident flux energy should include both the sputtered atoms and the gas neutrals reflected from the target. The latter arise from ions, which are accelerated through the plasma sheath and are neutralized on reflection at the target. On their way from the target to the substrate both types of atom are thermalized in the sputtering gas. Their incident energy is therefore considerably lower than their initial kinetic energy. The degree of thermalization is strongly dependent on the deposition pressure, target to substrate distance, target composition, and sputtering gas. Following the calculations of Somekh (1984), the kinetic energy of the incident atoms has been estimated for the case of sputtering of platinum and CoNi. The results are shown in Table 1. Because there is only a small difference in the energies of sputtered platinum with respect to Co/Ni atoms, no discrimination has

***Table 1***
Estimated energies of argon neutrals reflected from the targets, $E_{Ar,Pt}$ and $E_{Ar,CoNi}$, and of the sputtered atoms themselves, $E_{atoms}$, bombarding the substrate as a function of deposition pressure.

| $p$ (μbar) | $E_{Ar,Pt}$ (eV) | $E_{Ar,CoNi}$ (eV) | $E_{atoms}$ (eV) |
|---|---|---|---|
| 6 | 90 | 6 | 10 |
| 12 | 50 | 4 | 6 |
| 36 | 8 | 0.5 | 0.1 |

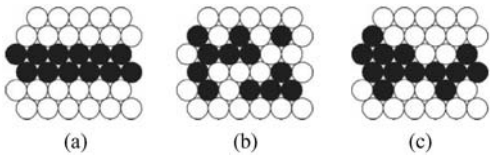

***Figure 5***
Schematic of three different types of interfaces in multilayers: (a) atomically sharp and smooth; (b) (non-ordered) alloyed; (c) atomically rough.

been made between these two. Clearly, the energetic bombardment of the reflected argon neutrals is dominant when depositing platinum but drastically decreases with increasing argon pressure. The energy of the deposited atoms decreases as well, by as much as two orders of magnitude over this range of argon pressure. Owing to the large variation in the energy of the incident atoms, thin-film growth can be expected to be strongly dependent on the deposition pressure, especially in the case of platinum.

In the case of CoNi/Pt multilayers, Bijker *et al.* (1996) have reported strong effects of the deposition pressure on the microstructure of the multilayers. At high deposition pressure, voids appear in the thin film. The cause of void formation is the high degree of scattering of the sputtered atoms combined with their very low kinetic energy. Obviously, the state of the interfaces in such multilayers will also depend on deposition pressure. Under high-energy bombardment at low argon pressure or at low deposition energies at high argon pressure, alloyed rough interfaces may be expected (see Fig. 5).

The interface conditions between the ferromagnetic layer (Co, CoNi) and nonferromagnetic layer (Pt, Pd) are also strongly dependent on crystallographic structure. In the case of $Co_{50}Ni_{50}$ and platinum they are both f.c.c. metals, but have a lattice mismatch of approximately 10%. Although epitaxial growth cannot be expected, a strong correlation between the textures of the two layers may exist. The interface will then be incoherent and both layers have different and/or inhomogeneous (in-plane) lattice spacing. For Co/Pt multilayers where f.c.c. to h.c.p. phase transitions may occur in the cobalt layer, several interesting growth features have been revealed by x-ray diffraction (XRD) and high-resolution electron microscopy. Both the interface structure and the crystallographic phase are also highly dependent on the designed layer geometry (i.e., number of bilayers, individual layer thickness, with or without underlayer, etc.). The multilayer structure always exhibits additional superlattice peaks in the diffraction patterns. The periodicity is not related to the crystallographic lattice parameters but to the artificial modulation of the multilayer itself. The structures are always analyzed by both low- and high-angle XRD measurements. The low-angle patterns refer more to the chemical modulation of the multilayers owing to their longer length scale. Carcia (1988) provides information about the interdiffusion of Co/Pd and Co/Pt from low-angle XRD patterns and concludes that Co/Pd sputtered layers do have a sharper chemical interface than Co/Pt layers. The multilayers (Co/Pt, Co/Pd, and CoNi/Pt) grow preferentially with 111 f.c.c. planes normal to the direction of growth. Figure 6 shows a typical high-angle XRD pattern of a $Co_{50}Ni_{50}$/Pt multilayer deposited at an argon pressure of 12 μbar. Two peaks are observed. The largest peak is present between the Pt(111) and $Co_{50}Ni_{50}$(111) lattice positions and indicates a good (111) texture in both the platinum and $Co_{50}Ni_{50}$ layer. Since (111) texture is absent in single $Co_{50}Ni_{50}$ thin films, it may be concluded that the platinum promotes (111) texture in the $Co_{50}Ni_{50}$ layer. The origin of the "multilayer" peak is the artificial layer modulation and its position corresponds to the average lattice spacing in the multilayer.

The dependence of the texture on the deposition conditions can be discussed by analyzing various multilayers by XRD. Figure 7 shows the low-angle

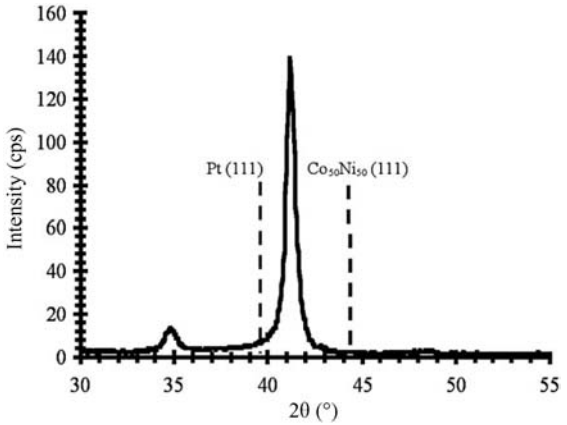

***Figure 6***
High-angle XRD pattern of a Pt (0.8 nm)/($Co_{50}Ni_{50}$ (0.7 nm)/Pt (0.8 nm)) × 26 multilayer.

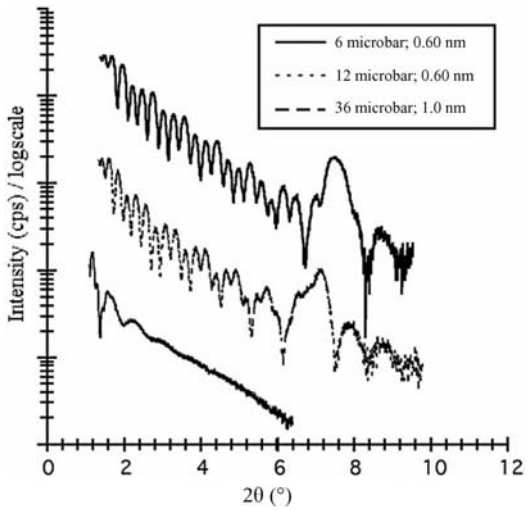

*Figure 7*
Low-angle XRD patterns of $Co_{50}Ni_{50}$/Pt multilayers deposited at different pressures (6 μbar, 12 μbar, and 36 μbar and various thickness of CoNi layer as indicated in the legend).

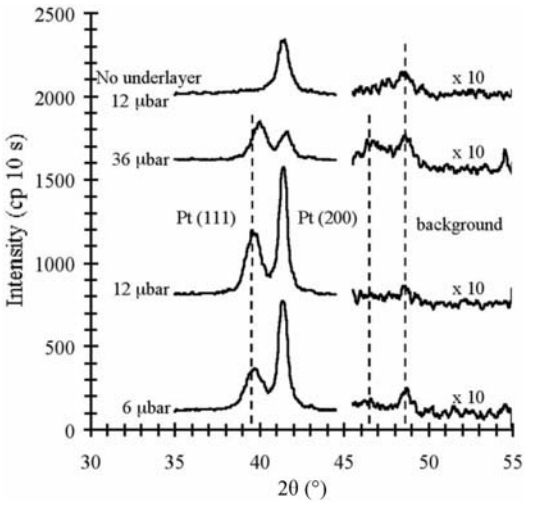

*Figure 8*
High-angle XRD patterns of $Co_{50}Ni_{50}$/Pt multilayers with $t_{CoNi} = 6$ Å. The platinum textures (1110) and (200) are indicated around 40° and 46° (for more details see text).

XRD patterns of three $Co_{50}Ni_{50}$/Pt multilayers deposited at different argon sputter pressures. For multilayers deposited at 6 μbar and 12 μbar, the first-order Bragg peak owing to the layer modulation is clearly present. The surface roughness obtained from GIXA simulations (the glancing incidence x-ray analysis (GIXA) program is commercial software from Philips Analytical, Almelo, The Netherlands) follows the trend observed for single platinum thin films.

Figure 8 shows high-angle XRD patterns of four different multilayers with a CoNi thickness of 0.6 nm and platinum thickness of 0.7 nm and consisting of 17 multilayers. They are prepared at three different argon pressures of 6 μbar, 12 μbar, and 36 μbar on a 10 nm seed layer. The upper figure is for a sample deposited at 12 μbar, prepared without a seed layer, and consists of nine multilayers.

The diffraction patterns of multilayers deposited on platinum underlayers at 6 μbar and 12 μbar are very similar. The platinum underlayers show good (111) texture and no (200) texture is observed. The multilayers deposited on top of these underlayers also show good (111) texture. The underlayer, multilayer, and satellite peaks have approximately equal intensity. Apparently, microstructural features such as the local variations in thickness (interface roughness) and strain of the individual layers are similar in both conditions. The texture of the platinum underlayer for multilayers deposited at 36 μbar is poor and similar to that of single platinum thin films. The Pt(111) peak of the underlayer is reduced and also the Pt(200) peak is observed. Moreover, the intensity of the multilayer peak is reduced and no satellite peaks are present. This might point to a simple reduction of (111) texture of the multilayers, but also to the presence of larger interface roughness and/or different intralayer strain may contribute to this effect.

The main peak in the diffraction pattern of the multilayer without underlayer is considerably smaller than that of multilayers with underlayer. Probably, the (111) texture is less owing to the bad initial growth as reported for single platinum thin films. This may also explain why the satellite peaks are less sharp. Then, after several bilayers, the interface roughness and interlayer strain seems to be not much different from multilayers deposited with thick underlayers.

## 3. Magnetic Properties of Multilayers

The most import magnetic properties are magnetization, anisotropy, switching characteristics, coercivity, and the Curie temperature. These are discussed below.

### 3.1 Magnetization

Certain materials that are not ferromagnetic in their bulk state can become ferromagnetic if placed in close contact with a magnetic "host" material. This happens for platinum and palladium combined with cobalt. Consequently, it has been shown that the magnetization of Co/Pt and Co/Pd multilayers is

enhanced relative to the value of pure cobalt. This is not a new phenomenon because the ferromagnetic polarization of platinum and palladium in diluted alloys with cobalt and iron is well known. It has been reported that e-beam deposited Co (0.3 nm)/Pt (1 nm) layers (Lin *et al.* 1991) have 30% higher magnetization ($1850\,\mathrm{kAm^{-1}}$) than the pure cobalt value ($1422\,\mathrm{kAm^{-1}}$). Up to $0.6\,\mu_B$ induced magnetization to interface palladium is explained in Broeder *et al.* (1987) and $0.9\,\mu_B$ in Carcia *et al.* (1985a). The induced magnetization depends strongly on how perfect is the interface from a structural as well as from a chemical point of view. The polarization in multilayers seems to be lower than in the alloys, which can be understood by defining the multilayer as a two-dimensional structure. Being magnetic, platinum and palladium also may contribute to the MO activity. The Kerr effects measured at short wavelengths (around 300 nm or 4 eV) for Co/Pt multilayers are much larger than expected, larger even than the Kerr effects measured for a single infinitely thick cobalt layer. The enhancement cannot be attributed to multiple reflections (in the way that dielectric coatings enhance a MO layer (Gamble *et al.* 1985)) because this would result in a noticeable reduction of the reflectivity of the multilayer. Typically the reflectivity is high ($R = 0.4$–$0.7$ (Zeper 1991)). Another explanation could be that the cobalt layers are so thin that the effect of the reduced number of neighbors becomes apparent. The average magnetic moment per cobalt atom in the bulk is about $1.9\,\mu_B$, but it might be influenced by the reduced symmetry. Freeman and Wu (1991) calculated enhancements of magnetic moments at the metal surfaces of cobalt, nickel, and iron. The maximum enhancement found for nickel is 23% for a f.c.c. Ni(001) surface, while for cobalt it is 13% for a f.c.c. Co(001) surface. Because very large enhancements are observed (up to a factor of 5 more rotation and ellipticity than is expected from the cobalt alone) the MO activity of platinum should also be considered.

### 3.2 *Magnetic Anisotropy*

The origin of perpendicular coercivity is found in the magnetic anisotropy. For the magnetic anisotropy representation a phenomenological formula (Carcia *et al.* 1985a, Draaisma *et al.* 1987) can be written:

$$K_{\mathrm{eff}} = K_{\mathrm{v}} + 2K_{\mathrm{s}}/t_{\mathrm{m}}$$

where $K_{\mathrm{eff}}$ is the measured effective anisotropy (including the shape anisotropy, $-\frac{1}{2}\mu_0 M_{\mathrm{s}}^2$), $K_{\mathrm{v}}$ and $K_{\mathrm{s}}$ are the contributions of the volume and interfacial anisotropy of the Néel type, and $t_{\mathrm{m}}$ is the individual layer thickness of the magnetic layers. The result $K_{\mathrm{eff}} > 0$ indicates the easy magnetization axis is perpendicular to the film surface, while $K_{\mathrm{eff}} < 0$ indicates

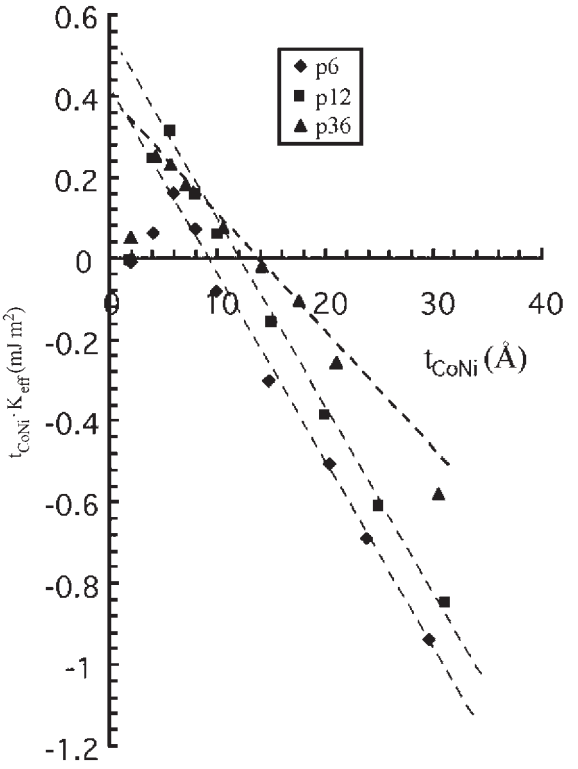

***Figure 9***
Effective magnetic anisotropy (expressed as) $t_{\mathrm{CoNi}} \times K_{\mathrm{eff}}$ vs. $t_{\mathrm{CoNi}}$ for multilayers sputtered with an argon pressure of 6 μbar, 12 μbar, and 36 μbar.

the easy magnetization axis is in the film plane. Figure 9 shows the effective anisotropy of three types of CoNi/Pt multilayers deposited at various argon sputter pressures. They all have a platinum thickness of about 0.7 nm, a platinum seed layer thickness of 10 nm, and consist of 17 bilayers.

Compared to multilayers deposited at intermediate pressure, the interface anisotropy decreases for lower deposition pressures. This may be explained by considering the more energetic bombardment of the multilayer during growth at lower pressure (Carcia *et al.* 1990). This is in agreement with the XRD analysis where no differences between the crystallographic structure of both series is revealed. For multilayers deposited at 36 μbar the interface anisotropy seems to increase with $t_{\mathrm{CoNi}}$. A likely explanation is the presence of significant interface roughness owing to the low deposition energies of the sputtered atoms (see Table 1). The consequence is that the effective interface area increases with $t_{\mathrm{CoNi}}$ and that the measured interface anisotropy should be corrected for this area. Unfortunately, this is not possible. Assuming that for $t_{\mathrm{CoNi}} = 30$ Å the measured interface

anisotropy is "saturated," it may be concluded that for pressures larger than 12 μbar the true interface anisotropy still increases with pressure. Apparently, this effect dominates the expected reduction of interface anisotropy owing to the presence of (200) grains. Note that the interface roughness is (at least) around the thickness of the platinum layer, i.e., 8 Å. Therefore, the interface anisotropy should also be corrected for the effective platinum coverage, which would give an even larger value. The interface roughness may also explain the apparent decrease of magneto-elastic anisotropy for larger $t_{CoNi}$. Owing to the large interface roughness and thin platinum layer, the growth of the $Co_{50}Ni_{50}$ layer may be inhomogeneous. Therefore, also strain effects may be inhomogeneous in the $Co_{50}Ni_{50}$ layer. Quantification of these effects is very difficult. The interface structure as a function of deposition pressure has been further characterized (Kirilyuk *et al.* 1998) with magnetization-induced second harmonic generation (MSHG). In general the magnitudes of $K_v$ and $K_s$ depend on the degree of (111) f.c.c. texture of the multilayer. This texture is promoted by using platinum seed layers between the multilayer and the substrate. The explanation of the origin of the perpendicular anisotropy in this type of multilayer is still a matter of debate, although in-depth discussions have been published (Chappert and Bruno 1988, Draaisma *et al.* 1987).

### 3.3 *Coercivity, Nucleation, and Saturation Field*

In the case of our multilayers, where the magnetization is reversed by domain wall motion, the origin of coercivity is presumably the imperfection of the layers (Honda *et al.* 1991, Suzuki *et al.* 1992). Magnetically inhomogeneous regions act as pinning centers for the domain walls and thereby hamper their movement through the layer. Suzuki *et al.* (1992) estimated the size of these pinning sites for Co/Pt multilayers with high coercivity and squareness by measurement of $H_c$, $K_u$, and $M_s$ as function of temperature (T = 5–400 K). Using the temperature-dependent data in a simple model, Kronmüller *et al.* (1986) found a pinning site diameter of 4 Å for a sample with well-defined [111] orientation and good interfacial sharpness (determined by low- and high-angle XRD) while this diameter increased to 16 Å and 31 Å for less perfect structures. As the magnetic polarization of platinum decays quickly with the distance from the interface, the pinning sites must be located in and nearby the cobalt layers. Therefore, the values of 4 Å and 16 Å are not surprising. The 31 Å diameter pinning site estimate might be due to inhomogeneity in the film plane, in addition to the variation along the film normal (Suzuki *et al.* (1992). When the nucleation field, $H_N$, is large it can hide both coercivity, $H_C$, and saturation field, $H_S$ (Zeper *et al.* 1991). On the left-hand side of Fig. 10 the nucleation can be clearly seen as large shoulders occur. At the shoulders the nucleation energy delays the creation of reversed domains. At field $H_N$ a steep transition occurs as here the field is high (low) enough to create the first domains, which immediately stripe out to achieve the energy balance between applied field, part of the layer that is reversed, and the corresponding demagnetizing field. The dotted lines illustrate that first $H_C$ and then $H_S$ will be increased when the nucleation field becomes larger. When the perpendicular anisotropy is high, and the layer is very thin, the hysteresis loop is almost rectangular, as shown on the right-hand side of Fig. 10. Here the coercivity is about the same as the nucleation field. A small tail is found just before $H_S$ and therefore it is assumed that $H_S$ is not "hidden" in this case.

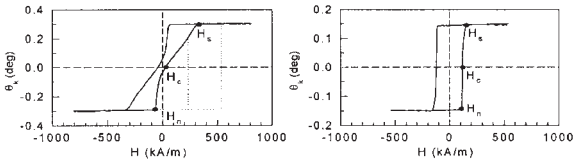

***Figure 10***
Kerr hysteresis loops of two multilayer samples. Left: sputtered Co/Pt multilayer with clear nucleation field, $H_N$, coercivity, $H_C$, and saturation field, $H_S$. The dotted lines illustrate how $H_C$ and $H_S$ can be hidden when the nucleation field is higher. Right: sputtered $Co_{50}Ni_{50}$/Pt multilayer with unity squareness, where $H_C$ is hidden.

For MO recording, where most of the disk is magnetized in one direction, $H_N$ (not $H_C$) has to be larger than the writing field. The rectangular ratio $r = H_N/H_C$ should be as close to unity as possible, while $H_C$ should be large. The small pinning sites that are responsible for the coercivity are generated during the sputtering process. Extensive literature about practical rules of thumb to control coercivity is available for Co/Pt multilayers. Initial experiments produced layers with too low a coercivity (300–500 Oe or 25–40 kA m$^{-1}$), but several ways have been found to enhance coercivity such as by tailoring the argon pressure during deposition, growing the right seed layer, optimizing the multilayer thickness, etc. As mentioned above, the multilayers should have a perpendicular anisotropy, which means an easy axis of magnetization perpendicular to the film surface. The perpendicular anisotropy only occurs if the cobalt or CoNi layers are very thin (Carcia 1988, Carcia *et al.* 1985a, Draaisma *et al.* 1987, Meng 1996, Van Drent 1995).

Figure 11 shows the Kerr rotation hysteresis loops of one series of Co/Pt multilayers with varying cobalt layer thickness, $t_{Co}$, from 2 Å to 12 Å. The platinum layer thickness and number of bilayers are kept constant, i.e., $t_{Pt} = 7$ Å and $N = 9$. As shown in the loops, the magnetic properties of Co/Pt multilayers are very

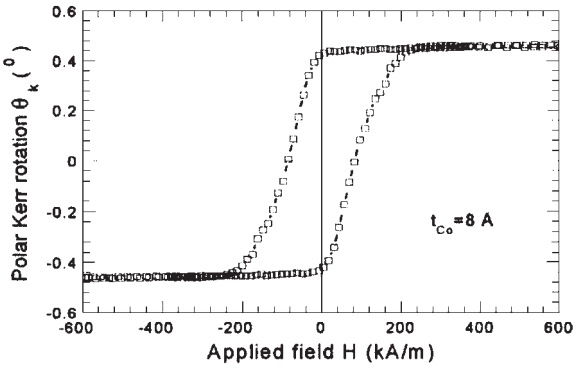

***Figure 11***
Polar Kerr loops of Co/Pt multilayers with varying cobalt layer thicknesses (series C). The compositions of films are (Si/16 nm Pt/($t_{Co}$/7 Å Pt) × 9). The measurements are carried out at room temperature and $\lambda = 300$ nm.

sensitive to $t_{Co}$, which relies on the sensitivity of the PMA on $t_{Co}$. For thin cobalt layers the loops are square and the remanent magnetization is equal to the saturation magnetization. The perpendicular coercivity becomes smaller. Similar observations have been made for CoNi/Pt layers (Meng *et al.* 1996c).

*(a) Effects of the platinum seed layer on the coercivity*

The platinum seed layer contributes to the important effects that increase the perpendicular magnetic anisotropy and the perpendicular coercivity of the multilayers because of the improvement of the f.c.c. ⟨111⟩ texture (see Fig. 12) (Meng *et al.* 1996b).

Furthermore, a platinum seed layer (thicker than the Kerr information depth) is required for the measurement of the Kerr spectra in order to avoid any influence from the substrates. However, with disks for MO applications, the platinum seed layer must be as thin as possible in order to allow the light to be transmitted through the seed layer without a significant decrease in the light power on the multilayers. Much research has been devoted to the selection of the best seed layer material (Hashimoto and Ochiai 1990), and the seed layer thickness dependence of virtually every multilayer parameter (Zeper 1991). Deposition of the seed layer at elevated temperatures (Shiomi *et al.* 1993b), applying a bias voltage to the substrate table (Honda *et al.* 1991], the influence of soft etch steps on both substrates (Chang and Kryder 1994) and seed layers (Suzuki *et al.* 1992), and the application of transparent ZnO or $SiN_x$ seed layers (Carcia *et al.* 1993, Suzuki *et al.* 1992) have been reported. Transparent seed layers such as ZnO (refractive index $n \sim 2$) enable MO recording from the substrate side, and, when the seed layer thickness is properly chosen, they can act as enhancement layers.

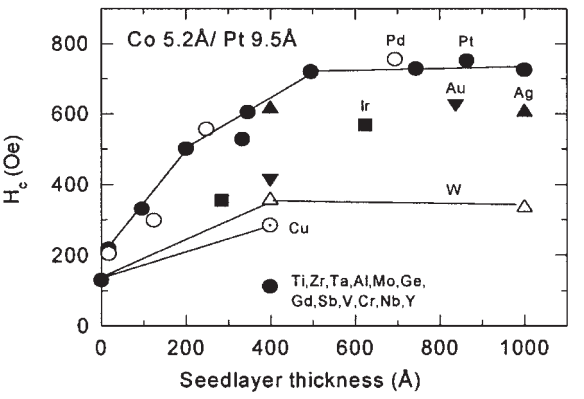

***Figure 12***
Dependence of coercivity on seed layer material and seed layer thickness (after Hashimoto and Ochiai 1990).

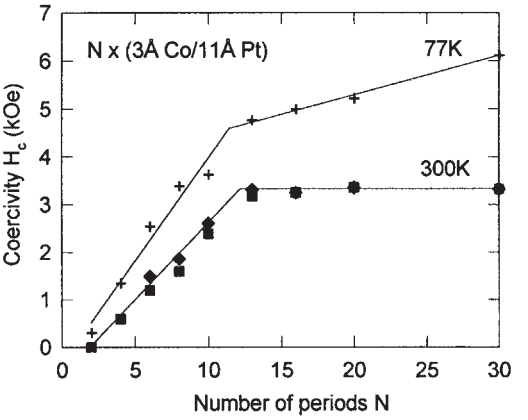

***Figure 13***
Thickness-dependent coercivity at 77 K and 300 K. Series of sputtered $N \times$ (3 Å Co/11 Å Pt) multilayers as a function of the number of bilayers $N$ (2 [$N$] 30) measured in the perpendicular direction with polar Kerr and/or AGFM (300 K data) and VSM (77 K data) loops (Weller *et al.* 1992a).

*(b) Multilayer thickness and coercivity*

When the number of bilayers is increased the coercivity will generally also increase. A good example is given by Weller *et al.* (1992b) where they present the coercivity as a function of the number of bilayers, $N$ (Fig. 13) for $N \times$ (3 Å Co/11 Å Pt) multilayers sputtered with argon at a pressure of 20 μbar on a 80 nm underlayer of $SiN_x$ sputtered at 4 μbar.

Obviously the coercivity increases fast with increasing $N$ when $N < 13$, while it stays constant (300 K) or increases more slowly (77 K) for $N > 13$. An attempt has been made to relate the sharp kink in coercivities around $N = 13$ to the average grain size

(determined from the width of the f.c.c. (111) central Bragg peak in $\theta$–$2\theta$ XRD) and to the degree of orientation (measured by the width, $\Delta\theta$, of the rocking curve of the same f.c.c. (111) peak). The average grain size increases smoothly from $D = 7$ nm at $N = 6$ to $D = 15$ nm at $N = 30$ and therefore there is no relationship with the grain size. $\Delta\theta$ does decrease with increasing $N$, and shows a weak kink between $N = 8$ and $N = 10$. Here too the correlation with $H_C$ is not very convincing. In a study of Zeper *et al.* (1991) the slope of the coercivity vs. $N$ also flattened above $N = 10$, but a sharp kink was not found. Also, Meng (1996) found for CoNi/Pt multilayers an increasing $H_C$ until $N = 16$.

### 3.4 Curie Temperature

In the thermo-optic writing process a small spot of the medium is heated (by irradiation of laser light) to such a temperature that the coercivity is low enough that the magnetization can be switched by a small magnetic field. In ferromagnetic materials this temperature is close to the Curie temperature ($T_c$) and therefore $T_c$ is taken as a design parameter, although it might be useful to define a temperature where coercivity becomes zero. A striking example is given by Lin and Do (1990) for a $23 \times (3$ Å Co/10 Å Pt) multilayer (see Fig. 14), where $T_c$ is about 330 °C while the coercivity becomes zero at about 260 °C, a difference of 70 °C!

Zeper *et al.* (1989a) reported differences of 15–30 °C for Co/Pt multilayers with comparable thickness, while this difference increased to 70 °C for a $21 \times (3.6$ Å Co/16.3 Å Pt) multilayer. Carcia *et al.* (1991b) found a decrease of 30 °C for a (4 Å Co/9 Å Pt) multilayer and 50 °C for (4 Å Co/19 Å Pt). Apparently this difference increases with increasing interlayer thickness, so it might be attributed to a decreasing ferromagnetic coupling between the layers. The Curie temperature should preferably be about 450–500 K (180–230 °C). At the lower end it is limited by the environment temperature range to which the medium is subjected and at the upper end by interdiffusion, and thus medium degradation (measured by write–erase cyclability experiments) becomes important. A lower $T_c$ also decreases power requirements for the diode laser in the recorder. Bulk cobalt has a $T_c$ of 1388 K, which is much too high for any type of thermomagnetic recording. The Curie temperatures that are reported for Co/Pt multilayers depend strongly on the layer thickness involved. The dependence on the number of bilayers, $N$ (by coupling through the interlayers), becomes small above $N = 8$, according to a model calculation for Co/Pt multilayers (Bruno 1991). Figure 15 shows various Curie temperatures reported in the literature for Co/Pt multilayers. Here sputtered and evaporated layers with high and low $N$ (where $N > 8$) are all shown on the same graph.

The agreement between the different data sets is generally good and apparently the different preparation methods do not influence $T_c$ strongly. The Curie temperatures reported by Bloemen *et al.* (1991) are extrapolated from temperature-dependent measurements. These extrapolated values are much higher than the values reported by other authors. The reported $T_c$ increases with increasing cobalt thickness. Very thin cobalt layers may not be continuous, thereby lowering $M_s$ and thus $T_c$. These layers also suffer

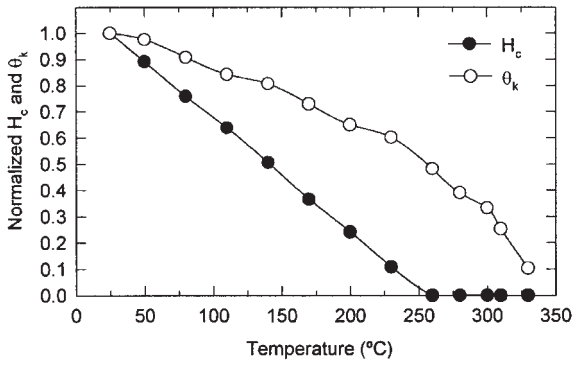

***Figure 14***
Temperature dependence of normalized coercivity and saturated Kerr rotation for a $23 \times (3$ Å Co/10 Å Pt) multilayer (after Lin and Do 1990).

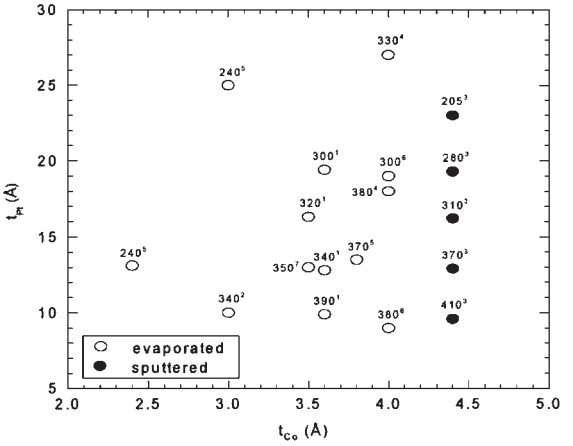

***Figure 15***
Curie temperatures (°C) reported in the literature for Co/Pt multilayers with varying cobalt and platinum thickness. The small figures above the temperatures denote the following references: 1, Zeper *et al.* (1989b); 2, Lin and Do (1990); 3, Hashimoto (1994); 4, Bloemen *et al.* (1991); 5, van Kesteren and Zeper (1993); 6, Carcia *et al.* 1991a); 7, Mes *et al.* (1993).

from a lower MO output. The increase of Curie temperature with increasing magnetic layer thickness is also in accordance with the random-phase approximation Green function calculations of Bruno (1991) in which he estimates the Curie temperature for ultrathin h.c.p. (0001) cobalt films as a function of the number of atomic planes. $T_c$ of the multilayer decreases with increasing platinum thickness. For a palladium interlayer this effect can be entirely attributed to the strong ferromagnetic coupling through the interlayer, which has a strong exchange-enhanced susceptibility. This coupling is an order of magnitude smaller for platinum interlayers and therefore the strong decrease in Curie temperature with platinum layer thickness cannot be attributed to this coupling (Bruno 1991). Therefore, this platinum thickness dependence might be due to interdiffusion between cobalt and platinum, which are known to form solid solutions. When gold is chosen as the interlayer (gold is insoluble in cobalt, and therefore sharp interfaces are expected) there is almost no dependence of Curie temperature on the gold thickness (Bloemen *et al.* 1991). This result supports the interdiffusion mechanism. Co/Pt layers with good MO properties and good perpendicular anisotropy generally are composed of about 3.5–4.5 Å cobalt and 10–15 Å platinum. The $T_c$ of such a layer is 350–400 °C. The coercivity will vanish at a lower temperature, say 50 °C lower, and therefore the layer has to be heated to 300–350 °C in the writing process. This temperature is higher than desirable. Annealing at 200 °C can lower coercivity (Lin and Do 1990), and therefore the Curie temperature should be lowered by about 100 °C. This could be done by changing the composition of the magnetic layers. This change should not drastically lower the magnetic moment of the magnetic layers because the Kerr rotation scales with the magnetic moment. One way to keep the magnetic moment high is to alloy the cobalt layers with another magnetic element. It has been found that $T_c$ for CoNi/Pt multilayers decreases with decreasing CoNi thickness but increases with decreasing platinum thickness (Meng *et al.* 1996a).

### 3.5 *Thermomagnetic Written Bits*

Multilayer disks consisting of Co/Pt have not only been prepared in research laboratories but also commercially (Lin and Do 1990, Sumi *et al.* 1991, Zeper *et al.* 1990, and Hashimoto *et al.* 1990). In MO recording the final bit-size is determined by the properties of the media as well as the writing laser beam. The domain (bit written by laser modulation) becomes smaller as the laser power decreases. This has been measured for Co/Pt multilayer disks (e.g., Greidanus *et al.* 1989) as well as for CoNi/Pt (Meng *et al.* 1996a).

Figure 16 shows an example of written bits in a multilayer with a composition of 1.2 nm platinum seed layer (0.55 nm CoNi/1.2 nm Pt) × 20. The written domains change in size as a function of the laser power. In order to achieve regularly written domains, a large perpendicular coercivity with a square hysteresis loop is required. The optimum thickness in Co(Ni)/Pt multilayers prepared in the author's laboratory has been determined to be about $t_{Co}$ (or $t_{CoNi}$) = 5 Å, $t_{Pt} = 10$ Å, and $N = 10$. An argon sputtering pressure of $1.6 \times 10^{-2}$ mbar is preferred. The typical magnetic parameters in an optimum CoNi/Pt multilayer are $H_C = 113\ \mathrm{kAm^{-1}}$, $\Theta_{K,310} = 0.3°$, and $T_c = 255$ °C.

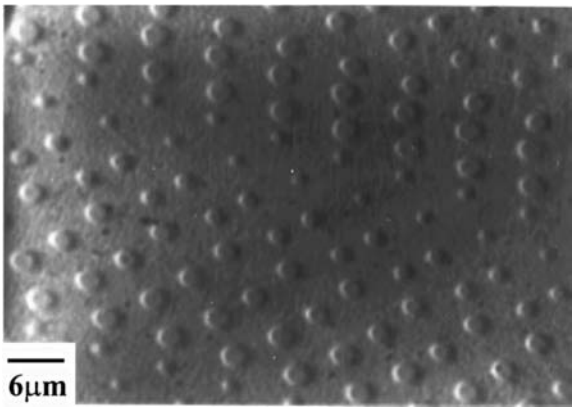

***Figure 16***
Lorentz microscopy image of written domains in a $Co_{0.5}Ni_{0.5}$/Pt multilayer with a composition of 12 Å Pt/(5.5 Å CoNi/12 Å Pt) × 20 (sample I) deposited at an argon pressure of $4.0 \times 10^{-2}$ mbar. The domains shown are written with laser powers of 2.5 mW, 5.0 mW, 7.5 mW, and 10 mW. The writing is performed with a pulse duration of 0.24 μs and a bias field of $50\ \mathrm{kAm^{-1}}$.

#### (a) *Thermal stability*

RE/TM multilayers are sensitive to oxidation while Co/Pd and Co(Ni)/Pt multilayers are very corrosion resistant. It has been shown (Hashimoto and Ochiai 1990, Zeper *et al.* 1991) that a Co/Pt multilayer does not show large changes in $H_C$ and Kerr rotation after being stored for 200 hours at 80 °C and 75% relative humidity. Another important point is the stability of the multilayer structure during thermomagnetic writing. During writing the whole multilayer stack is heated many times locally to much higher temperatures than 80 °C. Various studies (den Broeder *et al.* 1997, Wright *et al.* 1992, Shiomi *et al.* 1993a, Meng 1996) have reported on the structural and chemical changes (diffusion) and changing of the magnetic properties as a function of annealing temperature up to 500 °C. For all multilayers a general result is that below 300 °C only very small changes are observed. Above this temperature depending on the thickness

and preparation technologies changes are reported and at temperature higher than 400 °C a large interdiffusion takes place and perpendicular anisotropy is very much affected. In the case of CoNi/Pt multilayers two remarkable results have been found during annealing. One is enhancement of coercivity in the annealed multilayers with thinner CoNi layers. Another is enhancement of Kerr rotation in the annealed multilayers having thicker CoNi layers. Based on the reports it is advisable to choose multilayers with switching temperature below 300 °C. In the case of Co/Pt multilayers this means that the cobalt layer must be made thinner, which means that the Kerr rotation becomes smaller. CoNi/Pt multilayers are at least from these viewpoints a better solution.

## 4. Conclusions

The multilayer structures of Co/Pt are tested and used in very much detail for applications in short-wavelength MO recording. Research on CoNi/Pt multilayers started much later. Based on the published results a remarkable difference between Co/Pt and CoNi/Pt multilayers is the lower Curie temperature in CoNi/Pt. The lower $T_c$ results in lower values for the magnetic properties of CoNi/Pt multilayers but thermomagnetic writing can be more easily performed than in Co/Pt multilayers. The optimal thickness for Co/Pt magnetic layers, regarding magnetic and MO properties, is about 3 Å for cobalt layers, whereas it is 5–6 Å for $Co_{50}Ni_{50}$ layers. In the Co/Pt case, the thinnest platinum layer that still gives a squareness of unity is about 5 Å for 3 Å cobalt layers, and about 7 Å for 5 Å cobalt layers (Hashimoto *et al.* 1990). In the CoNi/Pt case, thinner platinum layers could be applied (down to 2.9 Å platinum for 5 Å $Co_{40}Ni_{60}$ magnetic layers) where the perpendicular anisotropy is still high, the magnetic hysteresis loop has unity squareness and is almost rectangular. The highest Kerr rotation $(\Theta_K)$ is found for a 100 Å Pt + 17 × (5 Å $Co_{50}Ni_{50}$/5.9 Å Pt) multilayer sputtered at 40 μbar argon pressure on a Si(111) substrate. The Kerr rotation is 0.48° at 4.6 eV (270 nm), but calculations indicate (Van Drent 1995) that the peak is shifted to higher photon energies because this multilayer is optically thin. According to the calculations, the peak would be 0.46° at 3.8 eV for an optical thick layer (100 instead of 17 repetitions). The calculations also indicate that increasing the seed layer thickness of this sample from 100 Å to 400 Å will shift the peak position back to 4.0 eV, while the Kerr rotation decreases by about 0.01°. The figure of merit (FOM = $R^{1/2}|\Theta_K|$, where $R$ is the reflectivity) is a measure of the MO performance of a given medium. The FOM for CoNi/Pt is calculated for a layer with the highest Kerr rotation.

In Fig. 17 the FOM for the thin CoNi/Pt sample is denoted by open circles. The corresponding reflectivity

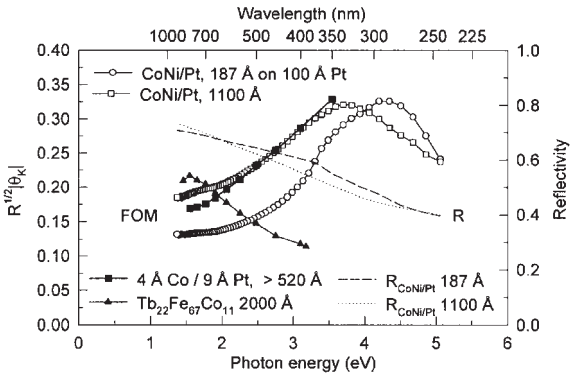

*Figure 17*
FOM, $R^{1/2}|\Theta_K|$, for several MO layers. Open circles denote the FOM for a 100 Å Pt + 17 × (5 Å $Co_{50}Ni_{50}$/5.9 Å Pt) multilayer on a silicon substrate. The corresponding reflectivity is denoted by the dashed line. Open squares denote the FOM for 100 instead of 17 repetitions. The dotted line denotes the corresponding reflectivity. The FOM for a $N \times$ (4 Å Co/9 Å Pt) with $N > 40$ is denoted by filled squares (Zeper 1991). The filled triangles denote the FOM for a conventional MO medium: a 2000 Å $Tb_{22}Fe_{67}Co_{11}$ layer (Hashimoto *et al.* 1990).

is drawn as a dashed line. As this sample is optically thin, comparison to other media is not straightforward. To compare several media, the media should be optically thick, without enhancement layers. Therefore the Kerr rotation, reflectivity, and FOM for a hypothetical 100-bilayer medium based on the thin CoNi/Pt sample are calculated. The MO Voigt constant of the polarized platinum is determined from the measurement data, and a prediction for the Kerr rotation and reflectivity of a 100-bilayer medium is made using this constant. The FOM for the 100-bilayer medium is denoted by open squares, the corresponding reflectivity by the dotted line (Fig. 17). For both $N = 17$ and $N = 100$ the calculated reflectivity is lower by 5–10% than the values measured by Zeper (1991) (not shown in Fig. 17).

These values are compared to the FOM for $N \times$ (4 Å Co/9 Å Pt) with $N > 40$ calculated from measured data (Zeper 1991) (filled squares). The FOMs of the Co/Pt and the 100-bilayer CoNi/Pt multilayer overlap in the region 2.4–3.3 eV (375–520 nm). At 3.5 eV the FOM of the Co/Pt multilayer is slightly higher than that for the CoNi/Pt simulation. From these results it is clear that the MO performance of CoNi/Pt multilayers can be made comparable to that of Co/Pt multilayers in the wavelength range of interest. For comparison the FOM of a 2000 Å $Tb_{22}Fe_{67}Co_{11}$ layer (Hashimoto *et al.* 1990) is drawn (filled triangles). The advantage of the multilayers at short wavelengths is evident.

# Magneto-optic Recording Materials: Chemical Stability and Life Time

Thin amorphous rare earth transition metal (RETM) alloys such as (Gd,Tb)–(Fe,Co) and (Gd,Dy)–(Fe,Co) are commonly used as a storage layer in the field of magneto-optical (MO) data storage. These alloys exhibit very good recording properties such as high carrier-to-noise ratio (CNR) and low required write/erase laser powers and fields (Raasch 1993, Raasch *et al*. 1994a, 1994b). Amorphous layers can be prepared by rapid quenching from a liquid phase, evaporation, or sputtering and show a 5–15% lesser density than their crystalline counterparts, depending on composition and preparation conditions (Klahn *et al*. 1990). Amorphous layers have no grain boundaries and composition can be varied continuously. Their advantages compared to polycrystalline materials led to the technical breakthrough of RETM layers in the field of MO data storage. The storage capacity of MO disks has been dramatically increased compared to the first products in 1988. This trend will continue over the next years opening a wide range of applications. The long-term stability is one essential requirement for storage layers.

The stability of RETM films is endangered by crystallization of the amorphous phase, by structural relaxation processes within the amorphous phase, and by selective reactions of the rare earth (RE) atoms, where oxygen is the most critical element. Degradation processes can be monitored by the change of important magnetic properties such as magnetic anisotropy $K_u$, required magnetic field to reverse the magnetization $H_c$, Curie temperature $T_C$, compensation temperature $T_{comp}$, and saturation magnetization $M_s$ as a function of aging time. The general dependencies of those parameters on composition and preparation conditions are listed in Landolt–Börnstein (Hansen 1988).

## 1. Crystallization and Structural Relaxation of Thin Amorphous RETM Layers

The amorphous phase is a metastable state, of which the free energy $E_{am}$ is larger than that of the crystalline state $E_{cr}$. This energy difference is the reason for a phase transition towards the crystalline phase, but a reduction of $E_{am}$ may not result in a better stability. Furthermore, the mobility of atoms, represented by the activation energy d$E$, dominates the stability of the amorphous phase. For instance, a $Gd_{0.62}Co_{0.38}$ alloy exhibited $dE = 3.3\,eV$ while $E_{am} - E_{cr} = 0.4\,eV$ (Buschow 1985). The required energy for atomic rearrangement follows the sequence transition metal (TM) = Fe, Mn, Co, and Ni as well as going from RE = La to RE = Lu. For $RE_{1-x}TM_x$ alloys (RE = Gd, Tb; TM = Fe, Co) with $x = 0.3$–$0.8$, $T_{cr}$ ranges between 500 K and 900 K with a maximum of $x = 0.35$ ($T_{cr} = 600\,K$) for Gd–Co alloys (Hansen 1988) and of $x = 0.70$ ($T_{cr} = 900\,K$) for magnetron-sputtered GdTb–Fe alloys (Klahn *et al*. 1987). The higher $T_{cr}$ of Fe alloys contradicts the former expectations and shows the importance of the preparation process.

It must be taken into consideration that layers sputtered at low argon pressure exhibit an ideal amorphous structure with a small number of crystallization grains and a density close to crystalline layers resulting in a reduced mobility of atoms (Klahn *et al*. 1990). In addition, the heating rate influences $T_{cr}$ which will decrease with decreasing heating rate. The correlation between both parameters is described by Kissinger (1957). A contribution of heating rate implies the possibility of structural changes within the amorphous phase below $T_{cr}$. These processes are known as structural relaxation processes effecting the near range ordering due to a limited atomic mobility. It is very difficult to comment on the importance of structural relaxation on stability of RETM alloys because this effect has to be separated from oxidation. Nevertheless, Klahn *et al*. (1987) found that structural relaxation mainly affect the coercive energy (required energy to reverse the magnetization), while

other magnetic properties remained nearly constant. This process performs on a logarithmic time scale. The required time to half the coercive energy on an aging temperature of 150 °C was estimated to be about 17 years though for lower temperatures it would be much longer.

## 2. Corrosion Kinetics of Thin Amorphous RETM Layers

A large number of elements are able to react with a bare RETM layer. As oxygen is the most critical element, this article will be mainly restricted to oxygen. Klahn *et al.* (1987, 1990) prepared unprotected GdTb–Fe layers of 100 nm thickness on glass substrates by magnetron sputtering and oxidized the samples in a hot dry climate chamber. Oxygen depth profiles were determined after 15 hours by secondary-ion mass spectroscopy (SIMS) as a function of aging temperature. Directly after preparation the layers exhibited a surface oxide layer of about 10 nm thickness consisting of $Tb_2O_3$ and $\alpha$-$Fe_2O_3$. Beneath the surface, a layer was detected with an oxygen saturation level of 25%, enough to oxidize the RE atoms completely and not effecting the TM atoms. The thickness of this partially oxidized layer increases with time and temperature. The remaining layer is magnetically still unaffected. The binding energies for RE–O (Gd–O, 716 $kJmol^{-1}$; Tb–O, 707 $kJmol^{-1}$; and Dy–O, 611 $kJmol^{-1}$) are much larger than for TM–O (Fe–O, 410 $kJmol^{-1}$ and Co–O, 368 $kJmol^{-1}$) (Weast 1976). This leads to a strong preference of oxidation of the RE atoms. The energy differences enable a reduction of oxidized TM atoms by RE atoms. Saito *et al.* (1986) established that the oxide of GdTb–Fe consists of RE oxide and b.c.c. Fe clusters.

If the oxygen exposure at higher temperatures continues after complete oxidation of the RE atoms the totally oxidized surface layer will grow into the particular oxidized bulk. The oxidation process can be characterized by an Arrhenian temperature dependency with an activation energy $E_a = 0.3 \pm 0.1$ eV, which shows only a weak dependency on composition and preparation (Klahn *et al.* 1990). The oxidation speed decreases considerably with increasing Co content. The most affected quantity is the magnetic anisotropy. Mergel *et al.* (1993) listed data of different additives and its influence on $K_u$, where a distinction between additives with a metallic bond and those with covalent bonds has to be made. An addition of only 2 at.% oxygen or 4–8 at.% nitrogen will destroy the anisotropy totally. Instead of this, up to 20 at.% of Bi, Pb, Al, Be, or Cr are still acceptable from this point of view (see Sect. 3). Nevertheless, a dilution of the magnetic system will effect $T_C$, $T_{comp}$, $M_s$, and Kerr rotation. The influence of several common additives regarding magnetic and recording properties is discussed elsewhere in more detail (Raasch *et al.* 1995, Raasch 1996).

## 3. Aging Behavior of Magneto-optical Storage Disks

The weak chemical stability of RETM layers requires additional measures to enhance the environmental stability of the MO layer stack, especially when the MO layers are grown on plastic substrates. Two methods can be applied separately or simultaneously: (i) the use of protective layers, such as SiN or AlN or (ii) doping active elements directly to magnetic layers in order to protect them from further corrosion by passivation of chemical reactions with air or water. If protective layers are grown perfectly, a long-term stability of more than 50 years is obtained. The possibility of local defects within these layers will cause corrosion of the MO layer and can be prevented by using a limited amount of additives though this must be restricted to elements with a metal bond. The magnetism of RETM alloys is caused by the localized 4*f* electrons of the RE and the delocalized 3*d* electrons of TM. Therefore, a differentiation must be made between elements with partly and fully occupied *d* shells. The addition of metals with partly occupied *d* shell (Ti, Cr, Nb, Zr, Hf, Ta, and Pt) shows positive effects on the chemical stability. But the large negative effect on the magnetic properties, such as $T_C$ and Kerr rotation, can not be compensated. Elements with fully occupied *d* shells (Be, Al, and In) show only a minor influence on magnetic properties. In particular, TbFeCo–In layers with In contents of up to 25 at.% exhibit sufficient magnetic properties. Therefore, recording performance simultaneously to a substantial improved environmental stability compared to nondoped RETM layers (Raasch 1996), proven for 150 hours at 85 °C and 85% relative humidity. The later values represent common accelerated aging test conditions.

# Magneto-optic Recording: Overwrite and Associated Problems

In the thermomagnetic write process, the magnetic storage layer is locally heated to its Curie temperature ($T_C$) by a focused laser beam. A magnetic domain is formed during cooling with its magnetization parallel to the direction of the external write field. This process is assisted by the demagnetizing field. Two modes to write information are applied: magnetic field modulation (MFM) and laser intensity modulation (LIM). With MFM, the laser power is kept constant and the magnetic field is switched according to the bit stream. The main issue here is to get sufficiently fast field switching (Lin 1990). With LIM, the laser intensity is modulated under constant external magnetic field. The data rate is higher than with MFM. However, only new domains are written. The old domains have to be erased before, in a separate run, so that there is no direct overwrite.

Two main schemes have been proposed to achieve direct overwrite with laser intensity modulation (LIM–DOW). Both use specifically designed storage media, i.e., a single layer with suitable magnetic properties and exchange-coupled multiple layers (ECMLs), respectively. Circular domains in an exchange-coupled double layer, ECDL, are sketched in Fig. 1.

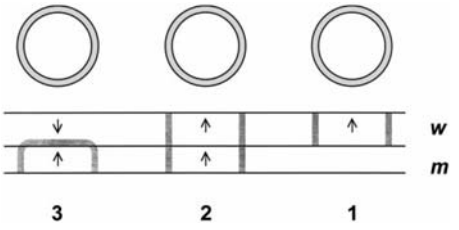

***Figure 1***
Circular magnetic domains in an exchange-coupled double layer consisting of a write layer *w* and a memory layer *m*. Top view and cross-section. The numbers designate the three steps in DOW.

## 1. Force Equilibrium at the Domain Wall

The total energy of a cylindrical domain is given by the sum of three energies: wall energy, Zeeman, and demagnetizing energy (Mergel 2000). The radial forces on the domain wall are obtained by differentiating with respect to the radial coordinate $r$. The pressure on the wall, i.e., the force $f_t$ per unit area of domain wall, is obtained by dividing the radial force by $2\pi rh$, where $h$ is the height of the domain, i.e., in general the thickness of the corresponding layer:

$$f_t = 2\mu_0 M_s[H_a(r) + H_{d1}(r) + (H_{d2}(r))] - \left[\frac{\sigma_w}{r} + \frac{\partial\sigma_w}{\partial r} + \left(\frac{\sigma_i}{h}\right)\right] \quad (1)$$

The resulting expressions have the dimension of energy density. The first square brackets enclose the external write field, $H_a$, and the demagnetizing fields, $H_{d1}$, due to the domain in one layer, and $H_{d2}$ if there is a second layer. $H_{d2}$ favors parallel orientation of the magnetization in the two layers. The demagnetizing field, $H_{d1}$, always acts expanding and is given by:

$$H_{d1}(r) = M_s\left(\frac{1}{1 + 3r/2h}\right) \quad (2)$$

Under LIM–DOW conditions, the applied field, $H_a$, always represents an expanding force. Domain erasure is driven by the contracting wall forces summarized in the second set of square brackets in Eqn. (1). The last term in Eqn. (1), $(\sigma_i/h)$, arises from an interface wall and has only to be taken into account in exchange-coupled layers.

## 2. Single-layer DOW

In a single layer, Eqn. (1) applies without the terms $(H_{d2}(r))$ and $(\sigma_i/h)$. The collapse of domains is achieved by heating to a temperature where the contracting domain wall forces overcome the sum of the

expanding forces, due to the demagnetizing and external write fields, and the coercive field. This is possible if the coercive forces are only moderate, e.g., for GdTb–FeCo, but not for Tb–FeCo, the standard composition. Domain erasure is fostered when the underlayers that are deposited onto the disk before the MO layer are polished because then the wall pinning strength is reduced. Furthermore, the demagnetizing field must be small. The best performance (CNR = 32 dB) in a standard recorder was obtained for 24–25 at.% rare-earth content yielding low magnetization at the erase temperature (Schultz *et al.* 1993).

The principle of single-layer DOW leads to a dilemma. For erasure, on the one hand, the domain walls have to move. During the write process, on the other hand, they must not move because moving domain walls become jagged and increase the write noise (Mergel 2000). This dilemma leads to contradicting requirements for the different steps of recording which could not be solved. For easy and complete domain erasure, materials with low coercive field and low magnetization are needed. Then, however, a write field higher than specified for standard recorders, 200 Oe (16 $kAm^{-1}$), is needed in order to write domain patterns with a high signal-to-noise ratio. The high field is necessary to assure a force equilibrium with $f_t = 0$ during domain formation in the write process. If $f_t \neq 0$ and the coercive field is low, the domain walls move. However, moving domains become jagged. The write noise increases and the storage density is reduced. Therefore, attempts to achieve a sufficiently high signal-to-noise ratio under realistic recording conditions failed and single-layer DOW has not been implemented on practical disks.

## 3. DOW in an Exchange-coupled Double Layer

Domains in an exchange-coupled double layer (ECDL) are thermomagnetically created in the three steps illustrated in Fig. 1. An ECDL for direct overwrite consists of a *write layer*, w, into which domains are thermomagnetically written during the write process (step 1) and a *memory layer*, m, into which the domains are copied during cooling below its $T_C$ (step 2). Now common domains extend through both layers. The original domains in the write layer are then erased at room temperature by an initializing field, $H_{ini}$, of several kOe provided by a permanent magnet (step 3). The reversal of the magnetization of the write layer creates magnetic interface walls.

Domain erasure is supported by the existence of an interface wall. The term ($\sigma_i/h$) in Eqn. (1) represents the strongest contracting force due to the small value of $h$ as compared to $r$. The write temperature is above the $T_C$ of the memory layer, m, such that there is no interface wall during the write process. The contracting forces are much smaller than during erasure such that the dilemma of single-layer overwrite is avoided.

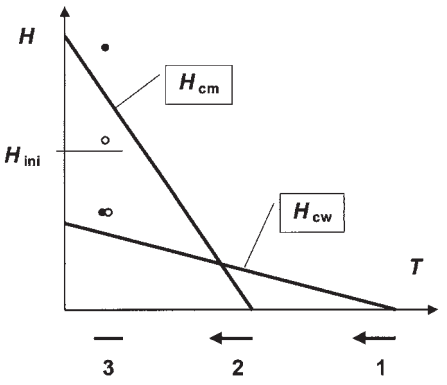

*Figure 2*
Coercive field of the two layers, write layer, w, and memory layer, m, in an ECDL that allows direct overwrite. The temperature regions of the three steps of DOW are indicated below the $T$ axis. The open circles refer to a P-ECDL and the closed circles refer to an A-ECDL (compare Fig. 4).

Such a write mechanism is possible if there is a cross-over of the $H_c = H_c(T)$ curves of the two layers, as illustrated in Fig. 2 (Saito 2000). At room temperature, the initializing field, $H_{ini}$, must be between the critical switching fields for the two layers. The creation and annihilation of the interface walls modifies the limits of the write ($H_{write}$) and initializing ($H_{ini}$) fields as will be discussed later.

Direct overwrite is achieved by switching the laser power between an erase and a write level. At the erase level, the magnetic layers are heated to a temperature where the coercive energy of the storage layer is reduced below the interface wall energy. The domains are annihilated by outside-in wall motion. At the write level, new domains are written into the write layer.

In order to control the exchange coupling, a thin intermediate layer is interposed between the storage and the write layer. A material with small anisotropy constant, $K_u$, is chosen such that the wall energy, $\sigma = 4\sqrt{(AK_u)}$, becomes smaller than in the adjacent layers. Then, the interface wall is located the intermediate layer. This allows a wider range of compositions of the other layers. The thickness of the intermediate layer is about 10 nm corresponding to typical wall thicknesses in RE–TM alloys (Mergel 2000).

## 4. Exchange-coupled Multilayers with a Permanent Magnetic Layer

The external initializing magnet in step 3 can be replaced by an additional permanent magnetic layer, p. The essential parameters of a typical layer stack for such a case are summarized in Table 1 Tsutsumi

***Table 1***
Composition and properties of a LIM–DOW multilayer.

| Layer | Composition | Thickness (nm) | $T_C$ (°C) | $H_c$ (kOe) |
|---|---|---|---|---|
| m, memory | $Tb_{24}Fe_{70}Co_6$ | 30 | 200 | 12 |
| i, intermediate | $Gd_{32}Fe_{48}Co_{20}$ | 10 | | |
| w, writing | $Dy_{25}Fe_{51}Co_{24}$ | 30 | 280 | 10 |
| s, switching | $Tb_{17}Fe_{79}Co_4$ | 10 | 170 | 2 |
| p, permanent, initializing | $Tb_{24}Fe_{17}Co_{59}$ | 30 | >300 | 8 |

Source: Tsutsumi (1993).

(1993). The layer, p, is separated from the write layer, w, by a switching layer, s, that couples w and p when room temperature is approached. The switching layer has a low $T_C$ so that p is decoupled from w during the write process. There are constraints on the thickness of the layers. The total stack should not be thicker than 150 nm to assure sufficient write sensitivity. The thickness of the memory layer should be bigger than 30 nm in order for the MO readout signal not to be affected by the other layers.

## 5. *Reversal Mechanisms in Exchange-coupled Layers*

So far, the principal mechanisms of LIM–DOW have been explained. For a discussion of associated problems, the phenomena occurring in exchange-coupled multilayers must be discussed in more detail (Mergel 1993, 2000, Tsunashima 2000, Kobayashi *et al.* 1981).

The reversal mechanisms in ECDLs are complicated. A great variety of hysteresis loops are observed. They are determined by the interface wall energy density, $\sigma_i$, the magnetization, $M_{sz}$, the coercive field, $H_{cz}$, and the thickness, $d_z$, of the layers. The different layers are denoted by the index, $z$. A magnetic reversal takes place when the balance of coercive, Zeeman, and wall energy densities yields a negative value:

$$0 > 2\mu_0 d_z(H_{cz} + v|H_a|)M_{sz} + w\sigma_i, (v,\ w = \pm 1) \quad (3)$$

$$0 > (H_{cz} + v|H_a|) + wH_{\sigma z} \quad (4)$$

$$H_{\sigma z} = \frac{\sigma_i}{2\mu_0 d_z M_{sz}} \quad (5)$$

with $v = +1$ or $-1$ when the magnetization is rotated against [ag] or into [in] the external field, respectively, and with $w = +1$ or $-1$ when an interface wall is created [c] or annihilated [a] by the process, respectively.

The abbreviations in the square brackets [a, c, ag, in] are used to designate magnetic reversal processes. Eqns. (3) and (4) can only be fulfilled when $v$ or $w$ or both are negative. Three processes are, therefore, allowed and all play a role in LIM–DOW (Mergel 1993)

(i) [c, in, z] Creation of an interface wall by rotation of $M_s$ into the external field.

(ii) [a, in, z] Annihilation of the interface wall with rotation of $M_s$ of layer $z$ into the external field.

(iii) [a, ag, z] Annihilation of the interface wall with rotation of $M_s$ against the external field.

An example of a hysteresis loop of an ECDL is given in Fig. 3(c). The isolated layers are represented by (a) and (b). When the two layers are exchange coupled the following changes may be observed:

(i) Reversal of layer 1 by [a, in, 1] may occur by motion of the interface wall. In such a case, the hysteresis curve becomes sheared.

(ii) The reversal fields are shifted to lower or higher values because domain walls are annihilated or created, respectively.

(iii) Minor loops are not symmetric to zero field but are centered around a value given by

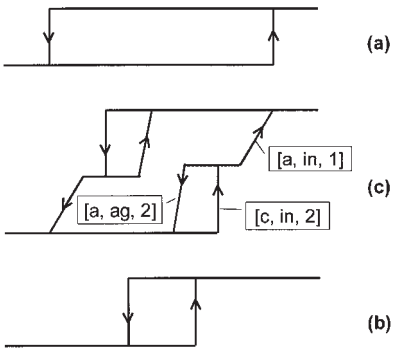

***Figure 3***
Hysteresis loop of an exchange-coupled double layer (b). Single layers (a) layer 1 and (c) layer 2.

$$H_a = \frac{\sigma_i}{\mu_0 M_{sz} d_z} \quad (6)$$

where $M_{sz}$ and $d_z$ are magnetization and thickness, respectively, of the reversing layer, $z$. The first two effects have to be taken into account when predicting recording properties of ECDLs from the properties of the isolated layers. The interface wall energy can be determined from Eqn. (6).

In ferrimagnetic RE–TM alloys, the TM moments alone determine the exchange-coupling whereas the magnetization, $M_s$, that interacts with the external magnetic field, is given by the difference of the TM and RE submagnetizations ($M_{TM} - M_{RE}$). This defines two types of ECDLs (see Fig. 4), A and P. In P-type double layers, $M_s$ is parallel or antiparallel to $M_{TM}$ in both layers. In A-type double layers, $M_s$ is

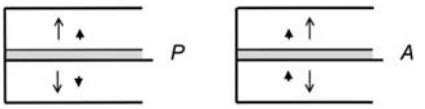

*Figure 4*
Two types of ECDLs, A and P, based on ferrimagnetic materials. The thin and bold arrows refer to the TM moments and the total magnetization, respectively.

parallel to $M_{TM}$ only in one layer and interface walls exist at infinite external field.

We now apply the reversal systematics to derive the conditions for the LIM–DOW mechanism in ECDLs.

Writing: Avoid [a, ag, w]
Copying: Enable [a, in, m] for P or [a, ag, m] for A, respectively.
Initialization: Enable [c, in, w]: $H_{ini} > H_{cw} + H_{\sigma w}$
Stable domains after initialization:
Avoid [a, in, m], $H_{ini} < H_{cm} - H_{\sigma m}$ for P, inside a circular domain
Avoid [c, in, m], $H_{ini} < H_{cm} + H_{\sigma m}$ for A, outside a circular domain.

The restrictions for the initialization field are indicated in Fig. 2 by circles. The upper limit is higher for A-ECDLs.

## 6. Media Design

In order to achieve reliable operation, the composition and the thickness of the various layers in a LIM–DOW medium have to be chosen appropriately. In the following, the requirements for the design of a five-layer stack and their implications for the chemical composition of suited RE–TM alloys are schematically summarized. For a typical example see Table 1.

In the memory layer, m, the domains must remain stable under the high initializing field. This implies a high $H_c$ which is achieved by choosing terbium as the dominant rare-earth element. Terbium has a strong spin-orbit coupling that leads to a large anisotropy constant, $K_u$. $H_c$ increases with $K_u$ with a power between 0.5 and 4. The $T_C$ in the memory layer, m, must be lower than in the write layer, w. Cobalt has a stronger exchange-coupling than iron and leads to a higher $T_C$ in RE–TM alloys. Therefore, w, contains more cobalt than m.

The intermediate layer must have a small wall energy in order for the interface wall to be situated in this layer. This is achieved by a high gadolinium content. Due to lack of spin orbit coupling, gadolinium leads to a low anisotropy constant, $K_u$, and a low interface wall energy, $\sigma_i = 4\sqrt{(AK_u)}$.

In the write layer, the force on the domain wall must be small during the write process in order to avoid domain wall motion that leads to jagged domain boundaries. Dy–FeCo is easily optimized to meet these requirements (Raasch 1993).

The initializing layer must keep a permanent magnetization. A high $H_c$ and a high $T_C$ are needed. They are obtained by high concentrations of terbium and cobalt.

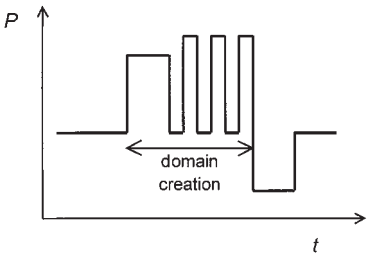

*Figure 5*
Laser power modulation pattern for DOW on ECMLs in order to avoid thermal interference.

## 7. Write Pulse Modulation

The temperature profile on the disk is influenced by heat flow from neighboring marks written before or after the considered mark. Therefore, the mark shape depends on the information pattern, and more domain length jitter is generated. This decreases the signal-to-noise ratio and consequently the storage density. The problem could be solved by modifying the modulation scheme of the laser power as shown in Fig. 5 (Saito 2000, Sect. 8.3.5). An assisting power is applied, heating the track to a medium temperature, and shutoff for some time after a domain has been written. This reduces the additionally introduced heat when a domain is written. The write pulse is replaced by a sequence of short pulses such that the write process takes place at a lower temperature.

## 8. Concluding Remarks

The principle of single-layer DOW leads to contradicting requirements for the different steps of recording. For erasure, on the one hand, the domain walls have to move. During the write process, on the other hand, they should not move because moving domain walls become jagged and increase the write noise. This dilemma could not be solved and the attempts to achieve a sufficiently high signal-to-noise ratio under realistic recording conditions failed.

A typical layer stack for DOW in exchange-coupled layers comprises five layers: a write, a memory, and an initializing layer together with two intermediate layers. The initializing layer has a permanent magnetization. Domain erasure is supported by an interface wall between the write and the memory layer. During the write process, the write layer is magnetically

decoupled from both the initializing and the memory layer and the dilemma of single-layer DOW is avoided.

The relevant magnetic properties like $T_C$ and magnetic wall energy density can be tuned separately for every layer by the composition of the RE–TM alloys. Therefore, overwrite with ECMLs can be implemented in practical disks and yields a good recording performance.

## Magneto-optic Recording: Total Film Stack, Layer Configuration

The currently used rare-earth transition-metal (RE–TM) recording media suffer from two main disadvantages: the RE elements oxidize easily and the polar Kerr effect and consequently the signal strength of the magneto-optic readout decrease significantly at shorter wavelengths. Pt/Co multilayers have advantages relative to RE–TM media in both aspects.

The larger Kerr effect of Pt/Co below a wavelength of 450 nm promises a higher storage density in future recording with blue lasers. However, the recording performance is also determined by several other properties:

- the write sensitivity within the specified ranges of the magnetic field and the laser power
- the magnetic stability of the written domains
- the noise level to get a high signal-to-noise ratio and low error rates
- degradation of the disk after repeated read/write cycles (see *Magneto-optic Recording Materials: Chemical Stability and Life Time*).

In this article, the recording-relevant properties of Pt/Co multilayers are discussed and compared with those of RE–TM media.

### 1. Magnetic Properties of Pt/Co Multilayers in Comparison with those of RE–TM Films

The saturation magnetization $M_s$ and the coercive field $H_c$ of Pt/Co multilayers are displayed in Fig. 1 as a function of temperature together with $M_s$ of a typical amorphous RE–TM film.

Pt/Co multilayers generally exhibit a higher $T_C$ than amorphous RE–TM films. They need a higher laser power for the thermomagnetic write process and their signal-to-noise ratio of written domains degrades more rapidly with the number of write/erase

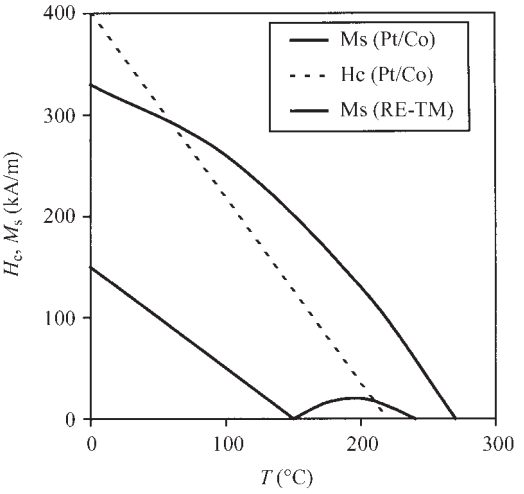

*Figure 1*
Saturation magnetization $M_s$ and coercive field $H_c$ of a typical (Pt/Co) multilayer as a function of the temperature. For comparison, $M_s(T)$ of a typical RE–TM composition is also shown.

cycles. The Pt layers are typically 0.9 nm thick (five atomic layers). Reducing their thickness lowers $T_C$, as desired, but also the Kerr angle $\Theta_K$ due to less magnetic matter in the total film and thus diminishes the potential advantage of the (Pt/Co) multilayers. Reducing $T_C$ by alloying Ni to Co avoids this problem but still reduces $\Theta_K$ at the readout temperature by about 25%.

The $M_s$ of Pt/Co is larger than that of the RE–TM alloys used for MO recording. This leads to stronger demagnetizing effects. The magnetic domains tend to form subdomains and their boundary tends to become curved. Both effects increase the noise of written marks (the write noise). The magnetization of the ferrimagnetic RE–TM alloys is controlled by the choice of the compensation temperature where $M_s = 0$.

The coercive field $H_c$ of Pt/Co multilayers vanishes at about 50 °C below $T_C$. Wall motion during the first stage of the cooling in the thermomagnetic write process is to be expected. This is a principal disadvantage for recording because wall motion results in jagged domain boundaries and in an increase of the domain length jitter (Mergel 2000, Sect. 6.6).

For MO readout the magnetization must be perpendicular to the substrate. The effective perpendicular anisotropy constant $K_{eff}$ achieves its maximum when the Co layer thickness corresponds to two atomic layers (0.4 nm). In that case all the Co atoms are forming part of Pt/Co interfaces. It was found that a pronounced (111)-f.c.c. texture of the multilayer is needed to get a large $K_{eff}$ but is alone not sufficient. The most decisive feature is the sharpness of the interfaces (Bertero and Sinclair 1994). Any chemical intermixing reduces $K_{eff}$.

The magnetization $M_s$, the Kerr angle $\Theta_K$, the Curie temperature $T_C$, and to a large extent, the anisotropy constant $K_{eff}$ are material properties determined on the subnanometer scale whereas the strength of $H_c$ is strongly determined by the microstructure of the films on the 10 nm scale.

Large values of $H_c$ are obtained for exchange-decoupled grains in combination with a large $K_{eff}$. The exchange-decoupling can be achieved by a discontinuous microstructure or when the grain boundaries consist of a nonmagnetic phase.

$K_{eff}$ and $H_c$ are sensitive to the details of the deposition process. Evaporated films are characterized by a pronounced (111)-f.c.c. texture with flat interfaces leading to a high $K_{eff}$. Furthermore, they exhibit a porous columnar structure with physically separated, exchange-decoupled columns or grains so that $H_c$ is large.

The microstructure of Ar-sputtered films is strongly influenced by energetic bombardment by reflected (at Pt) Ar neutrals. This leads to a low $H_c$ due to a dense structure and to a low $K_{eff}$ due to irregular interfaces between Pt and Co (Bertero and Sinclair 1994). Better results are obtained when the films are sputtered with the heavier noble gases Kr or Xe, leading to less severe bombardment, or when they are deposited on well chosen and prepared underlayers.

## 2. *Influence of Underlayers on the Microstructure*

A cross-section of a typical MO disk is shown in Fig. 2. There is a capping layer only in some disk designs. Usually a protective layer is deposited on top of the layer stack.

### *2.1 Pt Underlayers*

Pt/Co multilayers exhibit good properties when grown as a (111)-f.c.c. stacking sequence. As the stable phase of Co at room temperature is h.c.p., growth must start with a Pt layer. The thicker this underlayer, the better the (111) texture. However, for substrate-incident readout, the underlayer reduces the signal due to absorption. To give an example, a 5.5 nm thick Pt underlayer diminishes the readout signal (carrier) by 3.5 dB (van Kesteren *et al*. 1991).

The best magnetic properties of Ar-sputtered (at 1.6 Pa) Pt/Co multilayers were obtained on ultrathin ($d_{Pt}$ about 3 nm), discontinuous Pt underlayers (Carcia *et al*. 1996). The latter were prepared by d.c. magnetron sputtering followed by ion etching under an rf-bias field. The largest $H_c$ (3.5 kAm$^{-1}$) and the largest $K_{eff}$ ($1.2 \times 10^7$ erg cm$^{-3}$, 1.2 MJ m$^{-3}$) were obtained for $d_{Pt} = 3.3$ nm before etching. For this thickness the most pronounced superstructure features were observed in x-ray diffractograms. The microstructure of the (Pt/Co) film comprised small (10–20 nm) grains separated by voids and resembled that observed in vapor-deposited films. The etching of the underlayer likely sputtered away some Pt atoms leaving behind highly (111) textured and flat Pt

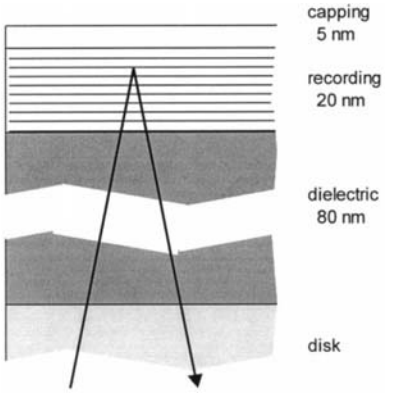

***Figure 2***
Layer stack comprising a (Pt/Co) recording layer. Not all disk designs comprise a capping layer. There is generally a protection layer on top of the stack.

mesas that served as independent nucleation centers for the multilayers.

For thicker or thinner underlayers the Pt/Co multilayers are structurally less coherent. On thicker underlayers the surface structure becomes continuous. When the underlayers are thinner, the grains are separated but the surface becomes very rough.

### *2.2 Dielectric Layers*

The stack design usually contains a dielectric layer with an index of refraction $n \approx 2$ to get an enhancement of the magneto-optic effects by interference. For RE–TM media only nitrides like $Si_3N_4$ or AlN can be used due to the tendency of the RE elements to oxidize. For Pt/Co, oxides are also possible and ZnO and $In_2O_3$ have been attempted. The dielectric underlayers influence the magnetic properties of the Pt/Co multilayers deposited on them. $K_{\text{eff}}$ increased to more than $7 \times 10^6$ erg cm$^{-3}$ (0.7 MJ m$^{-3}$) when the underlayer (ZnO and $In_2O_3$) was sputter-etched at $-100$ V (Carcia and Suzuki 2000).

ZnO is the most effective in creating a (111)-f.c.c. texture and prevents degradation of the recording properties upon annealing above 300 °C. It has a hexagonal structure and grows preferentially with its c axis (0001) perpendicular to the substrate. The mismatch between the ZnO(0001) and the (Pt/Co)(111) f.c.c. planes is only 1.6% and the multilayers grow epitaxially on ZnO.

The structural and magnetic properties of sputtered (Pt/Co) multilayers depend on the ZnO deposition temperature $T_{\text{ZnO}}$ (Carcia *et al.* 1993). $K_{\text{eff}}$ was maximum when ZnO was deposited at 150 °C. For $T_{\text{ZnO}} \leqslant 200$ °C a continuous microstructure was observed and the magnetic reversal was by wall motion. For $T_{\text{ZnO}} = 500$ °C the microstructure is particulate with a better (111)-f.c.c. texture and the magnetization reverses by coherent rotation within the separated grains. However, the perpendicular anisotropy is reduced, correlated with a severe multilayer roughening. This proves that the quality of layering is more important for a large $K_{\text{eff}}$ than the texture.

## *3. Magnetization Reversal*

### *3.1 Magnetic After-effect*

In magnetic after-effect experiments, a magnetically saturated specimen is subjected to an inverse magnetic field with a value smaller than $H_c$ and the magnetic relaxation (slow reversal) is observed as a function of the lag time.

For $(Co_{0.6}Ni_{0.4})$[0.5 nm]Pt[$\geqslant$0.6 nm] multilayers sputtered on a Pt buffer layer, the magnetic after-effect depends on the sputter pressure (Meng *et al.* 1999). Sputtering at low Ar pressure results in dense films. The reversal is dominated by wall motion indicating that the wall propagation field is smaller than the nucleation field. The magnetization pattern is characterized by concatenated small domains. In discontinuous films, grown at high Ar-pressure, a homogeneous nucleation all over the film is observed. Domain wall motion is inhibited and the magnetization reversal occurs by coherent rotation in the isolated grains. The hysteresis curves are sheared, according to the distribution of nucleation energies.

### *3.2 Mark Structures*

The marks in Pt/Co layers can be investigated by scanning magnetic force microscopy (van Kesteren *et al.* 1991). In this technique, a ferromagnetic tip is scanned across the object surface to obtain an image of the magnetization pattern. Pt/Co layers are well suited because they need no protection layer, in contrast to RE–TM layers. This has the advantage that the parameters measured in a recorder, namely the writing conditions and the carrier and noise levels, can be directly related to the magnetic microstructure of the domains on the same disk.

For layers with high magnetization, marks were written even without an applied field, a consequence of the demagnetizing field in the heated area. They contained subdomains because the decrease of the magnetostatic energy is larger than the increase of the total wall energy. Subdomains decrease the readout signal. They furthermore lead to fluctuations in the readout signal and an increase of the write noise. With increasing external field, the subdomains disappear, the carrier increases, and the noise decreases.

For laser intensity modulation, a uniform magnetization of the written marks was only observed for an external write field $H_{\text{ext}} > 30$ kA m$^{-1}$ (375 Oe). On these disks, magnetic field modulation always produced irregular domains. This was attributed to the lack of a wall gradient force. The wall gradient force is due to the temperature profile and tends to shift the domain wall into regions of higher temperature, i.e., to the center of the hot spot. This effect balances the expanding demagnetizing force and favors circular domains. For constant laser power, the temperature gradient is much smaller than for modulated laser power.

## *4. Recording Experiments*

In order to estimate the recording performance of a disk, a *carrier* is written. A carrier consists of periodically written marks and produces a signal with 50% duty cycle (up and down signal have the same length). The readout signal is analyzed in a spectrum analyzer. The carrier-to-noise ratio (CNR) is determined as the ratio of the signal and the noise at the write frequency. It depends on the linear velocity of the disk and the residual bandwidth of the spectrum analyzer.

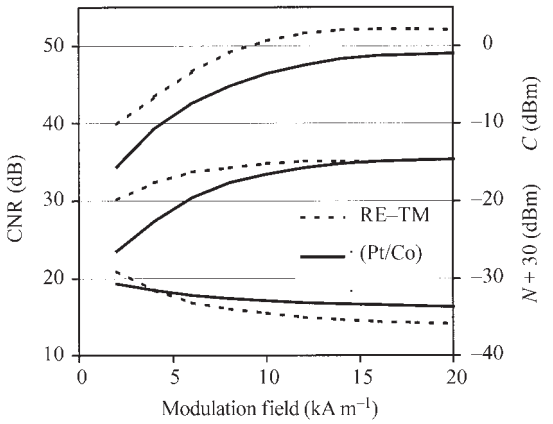

***Figure 3***
Carrier $C$ and noise $N$ of a Pt/Co and a GdDyFeCo medium. Laser wavelength 780 nm. Schematically after Teragaki *et al.* (1993).

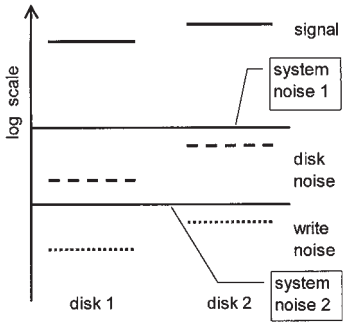

***Figure 4***
Comparison of signal and noise levels for two competing MO media. Disk 1 has the higher signal level whereas disk 2 has the lower disk noise level. It depends on the level of the system noise which disk exhibits the higher CNR. The CNR is given by the distance between the signal and the highest noise level.

### *4.1 Magnetic Field Sensitivity*

In Fig. 3, the recording performance of (Pt/Co) and GdDyFeCo media is compared (Teragaki *et al.* 1993). The carrier of Pt/Co saturates at a higher modulation field, 200 Oe (16 kA m$^{-1}$), instead of 100 Oe (8 kAm$^{-1}$) for GdDyFeCo. The reason is the higher $M_s$ leading to stronger demagnetizing effects. The higher magnetic field $H_{wr}$ is necessary to obtain complete marks without subdomains although the magnetic reversal starts at a lower field due to a higher Zeeman energy $\mu_0 M_s H_a$.

A high magnetic field sensitivity was obtained in high-$M_s$ films when the formation of subdomains was suppressed by a thin (2–5 nm) RE–TM capping layer, RE-rich and with a high $T_C$ ($>280\,^{\circ}$C, Ishida *et al.* 1997). This works for $Tb_{14}Fe_{82}Co_4$ ($H_{wr} = 100$ Oe) and for Pt/Co (140 Oe). The CNR obtained with a light wavelength $\lambda = 680$ nm was 2 dB higher for the RE–TM medium. The ferrimagnetic RE–TM-based media have the advantage that the magnetization in the recording relevant temperature region can be optimized towards best recording performance by the choice of the compensation and the Curie temperatures.

### *4.2 Competition of Carrier-to-noise Ratios*

For Pt/Co multilayers, the readout signal at smaller wavelengths is higher than for conventional RE–TM alloys due to a stronger Kerr effect. However, this does not imply automatically a better performance of Pt/Co media and a higher storage density on these media in "blue" recording. The performance of a drive-medium system depends not only on the signal level but also on the various noise levels of the disk and the system noise.

A competition between two disk families, one with a higher signal level, the other with a lower medium noise level is illustrated in Fig. 4. For a large system noise ("1"), disk 2 with the higher signal level yields a relatively better performance, whereas disk 1 with the lower medium noise performs better for a lower system noise ("2"). Therefore, the various noise sources have to be considered in detail when predictions on the recording performance of a medium class are made.

### *4.3 Noise Sources*

The *system noise* is measured on a stationary disk and arises from the light source, the detector, and the electronic circuit. In the first recording experiments with a green laser, the detector noise was initially very strong but its influence on the CNR could be reduced by increasing the laser intensity. Later a specially designed PIN photodetector with a high sensitivity was used (Kaneko *et al.* 1993).

The *disk noise* is the difference between the noise of the rotating and the stationary disk in a magnetically initialized state without magnetic marks. It originates from fluctuations of the polarization due to spatial fluctuations of the magneto-optical properties of the recording layer or due to the roughness of underlayers or the substrate. In Fig. 3, the disk noise is larger for the Pt/Co medium. This is due to additional polarization noise introduced by a nonperfect (111) texture of grain orientations.

The *write noise* is the additional noise measured on a rotating disk with written marks. Both subdomains in the mark and irregularities of the mark edge contribute to the write noise. A higher write noise is expected for Pt/Co media because the domain length jitter is about 40 nm (Teragaki *et al.* 1993) compared

to 15 nm in the best RE–TM media (see Mergel 2000).

The sum of write and disk noise is called *medium noise*. It arises from geometrical irregularities on the disk. As it is readout by the optical system, it is subjected to the optical transfer function. As a consequence, the CNR depends on the mark length that determines the spatial frequency at which the CNR is measured. This effect is important when judging the relative performance of RE–TM and (Pt/Co) media. For marks shorter than 0.5 $\mu$m, Pt/Co performs better because the medium noise is suppressed below the system noise by the optical transfer function (Kaneko *et al*. 1993). This corresponds to ''system noise 1'' in Fig. 4. RE–TM performs better for longer marks due to a lower medium noise, ''system noise 2.'' Therefore, RE–TM media are expected to perform better even for shorter marks when the system noise is reduced (Mergel 2000).

### 5. Concluding Remarks

Pt/Co media exhibit a high magnetization such that a higher magnetic field is necessary to suppress demagnetizing effects and to obtain saturated marks. The modulation field can be reduced by a thin RE–TM capping layer with high $T_C$ on top of the recording layer. Then, however, the advantage of intrinsic corrosion resistance is lost.

A discontinuous microstructure with exchange-decoupled grains is necessary to obtain a high coercive field $H_c$. This can be achieved by ion-etched Pt nucleation layers on top of the dielectric layer. Ion-etched dielectric underlayers can promote the spatial coherence and the flatness of the interfaces of Pt/Co multilayers, the key feature to obtain a large perpendicular magnetic anisotropy. ZnO is especially effective because the mismatch of the lattices is only 1.6% and enables heteroepitaxial growth.

The higher signal level of Pt/Co for shorter wavelengths is counteracted by a currently higher medium noise level, both relative to RE–TM. In such a situation, the measured signal-to-noise ratios depend on the details of the recording and readout process. The currently reported domain length jitter is 40 nm as compared to 15 nm for RE–TM resulting in a higher write noise. Therefore, a higher storage density than for RE–TM media cannot be expected in ''blue'' recording when the system and disk noise are suppressed below the write noise by improved disk manufacturing.

The reason for the large jitter is the temperature dependence of the coercive field, $H_c(T)$. $H_c(T)$ vanishes at 50 °C below the Curie temperature such that the domain walls can easily move in the first stage of the cooling in the thermomagnetic write process and become jagged under nonoptimal recording conditions.

## Magneto-optical Disks: Thermal Effects

In thermomagnetic recording on magneto-optical (MO) data storage media, focused light energy is directed to a moving magnetic film structure to control the local temperature distribution. The magnetic material typically has a strong native anisotropy which

restricts the magnetization alignment perpendicular to the film plane, or nearly so. Owing to the strong temperature dependence of the magnetic properties of the medium, domain reversals that represent a pattern of recorded data can be induced, usually with the aid of an external bias magnetic field. Subsequent to recording, readout of written data is performed by reflecting a focused beam of reduced power from the impressed domain pattern to interrogate the magnetic state of the recorded track by using the MO Kerr effect (see *Faraday and Kerr Rotation: Phenomenological Theory*). The resultant heating of the medium during reading may or may not be instrumental for the proper performance of the readout function, depending on the design of the medium.

## 1. Regime of Thermal Transport in MO Recording

Much has been published on thermal performance of MO media (McDaniel and Victora 1997, Mansuripur 1995). Normally, the thermal physics involved in treating recording and readout is well within the limits of classical heat conduction in homogeneous media. Therefore, the well-known analysis of classical references (Carslaw and Jaeger 1959) applies, and the complications of microscale heat transport or phase change can be ignored. Even with these simplifications, an MO media designer routinely uses numerical analyses of heat conduction by computer simulation due to the relatively complicated thin film and disk substrate structures involved. Non-numerical thermal analysis methods for moving multilayer thin film stacks, even those on planar substrates, may be too complicated or lack generality for routine engineering design practice (Madison and McDaniel 1989).

Heat conduction in the solid MO film structures obeys the standard diffusion-like differential equation:

$$\nabla^2 T - \frac{1}{\kappa}\frac{\partial T}{\partial t} = \frac{Q(x,y,z,t)}{k} = A\exp\{-\beta^2[(x-vt)^2 + y^2]\} \times \exp(-\alpha z)\Psi(t) \quad (1)$$

Here $T(x,y,z,t)$ is the temperature field of interest, $\kappa = k/\rho c$ is the thermal diffusivity, $k$ is the thermal conductivity, $\rho$ is the material mass density, $c$ is the material mass specific heat, $v$ is the moving media velocity, and $Q$ is the thermal power input per volume. In the case of laser beam heating for recording on a typical MO medium thin film structure as shown in Fig. 1, $Q$ should be represented as the Poynting vector energy deposition rate from absorption of the incident electromagnetic beam. The far right side of Eqn. (1) can be used for a simplified case in which a moving beam of Gaussian profile undergoes Beer's law absorption in a single, thick film. $\alpha$ is an absorption coefficient, $\beta$ is an inverse beam size parameter, and $\Psi(t)$ is an incident beam power-versus-time profile.

Heat diffusion in a thin film structure is frequently described using characteristic lengths and times for the thermal transport described by $L = (\kappa t)^{0.5}$ and $t = L^2/\kappa$. The various film materials in typical MO media structures have very different diffusivities, as indicated in Table 1. Therefore, characteristic lengths and times are most applicable to either single films, or as effective values derived from numeric analyses that weigh together composite results from a realistic, but more complicated structure. Characteristic times in thermal diffusion analysis can also be estimated by relating heat flow to an electrical circuit analogue. If

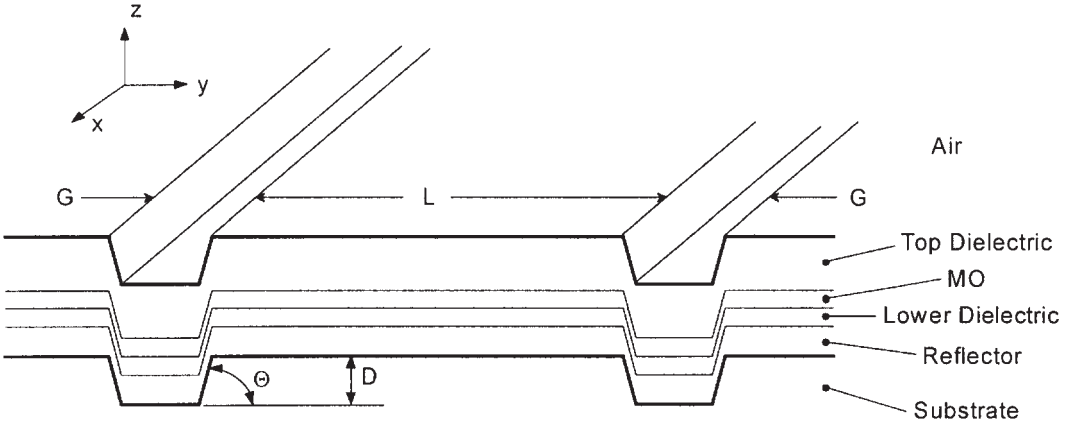

***Figure 1***
First-surface film stack geometry deposited on a grooved substrate. The geometry of the recording track (land $L$), the inter-track groove $G$, the groove depth $D$, and the groove side wall angle $\Theta$ help control heat diffusion.

***Table 1***
Materials and their properties for a nominal quadrilayer MO structure (see Fig. 1).

| Material | Thickness (nm) | $n$ | $k_{opt}$ | $k$ (W m$^{-1}$K$^{-1}$) | $c$ (J kg$^{-1}$K$^{-1}$) | $\rho$ (kg m$^{-3}$) | $\kappa$ ($10^{-6}$ m$^2$s$^{-1}$) |
|---|---|---|---|---|---|---|---|
| Air | $\infty$ | 1 | 0 | 0.03 | 1150 | 1.15 | 22.7 |
| SiN | 85 | 2.02 | 0.01 | 2.0 | 740 | 3400 | 0.79 |
| MO | 20 | 2.4 | 3.6 | 7.0 | 360 | 7900 | 2.46 |
| AlX | 40 | 1.8 | 6.8 | 25 | 900 | 2700 | 10.3 |
| Polycarbonate | $\sim 10^6$ | 1.58 | 0 | 0.15 | 300 | 1200 | 0.42 |
| glass | $\sim 10^6$ | 1.5 | 0 | 1.0 | 860 | 2300 | 0.51 |

one relates temperature to voltage, heat flux to current, thermal resistance $R_{th} = L/kA$ (where $L$ and $A$ are effective conductive path length and cross-sectional area, respectively) to electrical resistance, and heat capacity ($cm$, with $m$ the heat conductor's mass) to electrical capacitance, then the time for the charging of an electrical RC network ($t = RC$) becomes $t = R_{th}cm$. This leads again to the expression $t = L^2/\kappa$.

We note that the thermal constants of the thin films shown in Table 1 may differ considerably from those of the corresponding bulk material, and they may be adjusted considerably by altering the film compositions or deposition processes. One expects higher phonon and electron scattering in thin films due to the effects of layer boundaries and film growth morphology.

In thermomagnetic recording, the thermal energy deposited by an incident light beam should provide locally concentrated heating so that well-controlled magnetic domain reversals are established along a data track. Lateral heat spreading due to media motion (distributed dosing) and thermal diffusion must be limited to enable high resolution writing without excessive cross-write and cross-erase of previously recorded adjacent information. The means available to aid in this purpose are (i) surface topography of the thin films and substrate, (ii) thermal design of the thin film stack, and (iii) the writing strategy employed to apply the radiant energy. In Fig. 1, thermal confinement grooves provide an example of (i), while (ii) is illustrated by the reflector film, which can serve as a heat-sinking layer to minimize lateral heat diffusion. Regarding writing strategy (iii), probably the most important fundamental to remember in the heating of moving thin film structures with focused light beams is the following: *The most efficient heating with the highest resultant thermal gradients is always achieved through the use of short duration, low duty-cycle irradiation pulses* (McDaniel and Victora 1997, McDaniel 1999).

## 2. *Fundamentals of Thermal Design for MO Disk Thin Film Structures*

It is evident from Eqn. (1) that the *minimum* lateral extent of a heated region on the MO medium is the width of the incident focused light beam. Disk motion under the beam and lateral thermal diffusion can only enlarge the heated zone. Therefore, to achieve high-resolution, high-performance recording, the MO disk designer must counteract these tendencies with a combination of means as indicated in the previous section. Fortunately, each of the three avenues for control of lateral heat spreading (topography, film design, writing strategy) can be accurately modeled with a numerical computer simulation. The most powerful and flexible of the simulation tools for this purpose provides a solution $T(x,y,z,t)$ in two steps. First, the three-dimensional geometry of the substrate with film coatings (see, for example, Fig. 1) is exposed to a radiant impulse from a prescribed focused beam, and a fully time-developed "thermal impulse solution" is obtained from a finite-element or finite-difference solver operating on Eqn. (1). As long as the thermal problem is defined to be *linear* (material thermal properties independent of temperature; no material phase changes), superposition of the impulse solution in space and time with appropriate weighting according to the input light beam power–time profile will yield the desired final solution $T(x,y,z,t)$, even for a moving beam (McDaniel and Victora 1997, Mansuripur 1995).

Substrate and film topography departing from perfect planarity can increase the impedance to lateral heat flow. This is particularly true if the dominant thermal conduction path(s) is(are) altered or interrupted. For example, in Fig. 1 the side walls of the thermal confinement grooves are likely to have reduced thickness film layers (as measured normal to the local surface) if the incident material species during deposition travel predominantly in the $-z$ direction. Consequently, it is expected that lateral heat conduction can be shaped with features such as those depicted in Fig. 1 (McDaniel 1999), Peng and Mansuripur 2000).

Next, consider the film design issues. The basic physics of thermal transport involves optical absorption of the incident radiation (depending on how film stack reflectance $R$ and absorbance $A$ are split, given the constraint $R + A \approx 1$ in an opaque structure) on a time scale of $< 10^{-12}$ s, followed by diffusion of the

resultant thermal energy by conduction in all directions on time scales ranging from $\sim 10^{-10}$ to $10^{-6}$ s. Light absorption occurs predominantly in the first film that the incident light encounters that has a large value of $k_{opt}$ (see Table 1). Heat sinking to a reflector layer at the base of the film stack is made increasingly effective by (i) increasing the heat capacity (volume) of the reflector, (ii) increasing the thermal conductivity of the reflector, and (iii) decreasing the thermal resistance between light absorption location and the reflector.

Intuitively, we expect an effective heat sink layer to increase the heat flow in the axial ($-z$) direction away from the light absorption zone, and to diminish the lateral flow. Surrounding the thin, but relatively high thermal conductivity MO layer with insulating dielectric films further suppresses the relative importance of lateral heat flow. Simple analysis of characteristic times for these respective flow directions tells us that the axial channel is at least an order of magnitude faster than the lateral flow channel. This is the primary reason that radiation power input by short-duration, low duty-cycle pulses couples energy efficiently to the fast axial flow channel, and minimizes the (detrimental) effect of the slow lateral flow channel in spreading heat.

### *3. Issues in Advanced MO Film Designs and Limits of Thermomagnetic Writing*

Advanced MO film designs for the attainment of higher performance or areal recording density usually have more complex magnetic film structures than that shown in Fig. 1. In these cases, there typically are two or more magnetic layers with thermally controlled magnetic coupling to each other. Examples of these design structures include light-intensity modulated direct overwrite (LIM-DOW), magnetically induced super-resolution (MSR), and magnetic amplification MO system (MAMMOS). The total thickness of the metallic magnetic layers in these designs ($\sim$50–100 nm) is much greater than that of the simple, single-layer structure illustrated in Fig. 1 and Table 1. Consequently, the effectiveness of a design strategy utilizing a heat-sinking layer at the base of the film stack is significantly compromised. The incident light is totally absorbed in the thick magnetic layers, and the resultant heat will diffuse laterally with diminished control from the more distant underlying heat sink.

Another inevitable trend for high-performance MO storage media will be the necessity to increase the recording and playback rate. Data throughput rates for rotating memory products are driven higher by increasing the disk rotation rate or increasing the linear bit density along the track, or both. Notice that the former strategy increases the relative linear speed of the write/read beam and the storage medium, while the latter requires improved along-track writing and reading resolution. The resolution limitations when using an optical stylus whose lateral extent is $W \sim \lambda/NA$ (wavelength/numerical aperture) are well known and obvious. But increasing the linear speed of recording combines with the higher linear bit density to shorten the bit transit time to $\tau \sim L_{bit}/v$. Eventually, $\tau$ becomes shorter than the shortest thermal characteristic time of the recording medium, regardless of the aggressiveness of the film thermal design or the writing strategy. At this point, one has lost control of shaping the thermal environment for thermomagnetic writing, and the viability of a recording process based on impressed thermal gradients becomes questionable.

## Magneto-optical Effects, Enhancement of

The fundamental magneto-optical Kerr and Faraday effects, described phenomenologically in *Faraday and Kerr Rotation: Phenomenological Theory*, are intrinsically very small. However, with modern light sources and signal-processing techniques the various phenomena, discovered originally by Michael Faraday and John Kerr (Faraday 1845, Kerr 1877), can be easily observed. Indeed, with optical modulation techniques, it is possible to detect magneto-optic signals associated with thin layers of magnetic materials that are effectively one atom thick or less. However,

for commercial applications aimed at mass markets, such as magneto-optic memories, the costly use of sophisticated electronic detection techniques and the need to read magnetically stored information very rapidly requires one to optimize the sensitivity with which magneto-optical signals can be detected. The relationship between the size of the magneto-optical effects and the sensitivity with which they can be detected is discussed below. The influence that the various optical and magneto-optical parameters of the material have on the detection process is determined and various techniques are outlined for increasing the size of magneto-optical effects and, in particular, maximizing the sensitivity with which they can be detected. In this article it is not possible to treat all magneto-optic configurations (see *Faraday and Kerr Rotation: Phenomenological Theory*) and we shall concentrate on the polar Kerr effect at normal incidence, since this is most applicable to the developments in magneto-optic data storage systems. However, much of the underlying philosophy of enhancement applies to the alternative situations and, where appropriate, this will be pointed out.

In most instances, whether one is working in reflection (Kerr effect) or transmission (Faraday effect), the magneto-optical signal arises from a magnetization-sensitive polarization change, usually from a linear state to an elliptical state, with the major axis of the polarization ellipse rotated slightly with respect to the incident polarization direction. This of course only applies to the *polar* and *longitudinal* cases and not to the *transverse* case. It is shown in *Faraday and Kerr Rotation: Phenomenological Theory* that the polarization ellipse is the result of the combination of two orthogonal vectors, one optical and the other magneto-optical. These are the Fresnel reflection coefficient, $r$, and the Kerr coefficient, $k$, respectively. Under normal circumstances, in thin absorbing films, the condition $|k| \ll |r|$ applies, with the result that a very small, complex magneto-optical rotation, $\hat{\theta}_k$, may be defined as

$$\hat{\theta}_k = \theta_k + i\varepsilon_k \approx \frac{k}{r} = \left|\frac{k}{r}\right| \cos \Delta_k + i\left|\frac{k}{r}\right| \sin \Delta_k \qquad (1)$$

where $\Delta_k$ is the phase difference between $k$ and $r$, and $\theta_k$ and $\varepsilon_k$ are the Kerr rotation and ellipticity, respectively. Intuitively, it seems obvious that the larger this complex rotation the easier it is to detect, and in general this is true. However, as is shown below, one may reduce the reflection coefficient, $r$, to a value comparable to $k$ with the result that very large rotations could, in principle, be obtained, albeit with very low accompanying reflectivity. It should be made clear, however, that despite the large effective magneto-optical rotations that would result, it is undesirable to have this accompanied by a sample surface that reflects little or no light at all. The role of sample reflectivity, $R(=|r|^2)$, and the associated magnitude of complex Kerr rotation in determining the sensitivity by which a magneto-optic signal can be detected are clearly of importance, and the way in which each contributes to determining the signal-to-noise ratio in any detection system requires careful attention.

### 1. Signal-to-noise Ratio

In magneto-optic recording systems, the most common detection method is one that relies on differential detection (Egashira and Yamada 1974) employing two balanced detectors, as shown schematically in Fig. 1. For simplicity the incident radiation is not shown in this diagram. At any given moment the two detectors are, to a very good approximation, balanced in their output by having almost equal light intensities falling on them. The advantage of such a system is that variations in the intensity of the radiation source (often a laser diode) are effectively removed from the differentially amplified output of the two detectors. After traversing the polarizing beam-splitting optics of the system, magneto-optical rotations, induced by magnetization changes in the sample surface, cause small imbalances in the amplified output and this becomes the detected signal. Accompanying this is a series of noise levels whose origins may be fundamental (shot noise), electronic (detector and amplifier noise), or associated with fluctuations of the laser light source. It is the ratio of the signal to the noise level that determines the degree of precision with which the magneto-optical effects can be detected. Atkinson *et al.* (1991) have shown that for such a system the signal-

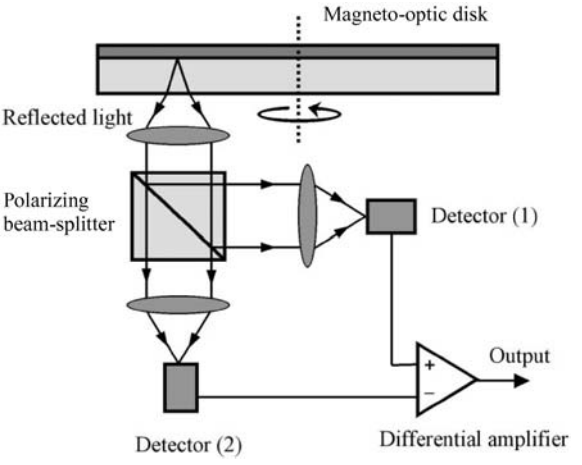

***Figure 1***
Schematic diagram of a magneto-optic differential readout system.

to-noise power ratio is given by

$$\mathrm{SNR} = \frac{P\psi_k^2 R(1-R)^2 \cos^2 \Delta_k}{\varepsilon + \sigma R + (\lambda+\mu)\psi_k^2 R(1-R)^2 \cos^2 \Delta_k} \quad (2)$$

where

$$|k| = \psi_k(1-R) \quad (3)$$

$P$ is a constant related to the optical read power and quantum efficiency and gain of the detectors, $\varepsilon$ is the electronic noise, $\sigma$ determines the shot-noise level, proportional to disk reflectance, and $\lambda$ and $\mu$ are the laser feedback and medium noise, both of which are assumed to come through the differential detection system in proportion to the Kerr signal.

An important parameter in Eqns. (2) and (3) is $\psi_k$, known as the potential Kerr coefficient. This parameter, introduced by Gamble *et al.* (1985), may be understood through Eqn. (3) as being the maximum possible amplitude of the Kerr coefficient, produced when the overall system reflectance is reduced to zero. The principles of increasing SNR through magneto-optic enhancement now reduce to three simple requirements. These are to maximize the value of $\psi_k$ for the particular magnetic medium; to ensure zero ellipticity ($\cos \Delta_k = \pm 1$); and to do this for a system reflectance that maximizes Eqn. (2) or is compatible with the practical needs of providing sufficient optical feedback for the purposes of tracking. Depending on the levels of the various noise sources, the intensity reflectance can lie between the limits of zero and 33% and is typically 10–20%.

## 2. Maximizing the Kerr Effect

The most important aspect of magneto-optic enhancement is the maximization of the potential Kerr coefficient and this may be accomplished by the use of a quadrilayer system, as shown in Fig. 2. Enhancement is produced through the use of a high-reflectance mirror placed behind a film of the magnetic medium that is thin enough to allow transmission of the incident radiation. The thickness, $d_M$, of the magnetic film must therefore be much less than the optical skin depth determined by the absorption coefficient of the material at the design wavelength, $\lambda_0$. It is the thickness; the refractive index, $n$ ($= n' + in''$), and magneto-optic parameter, $Q$ ($= Q' + iQ''$), of the magnetic layer; and the reflectance of the mirror that are important in maximizing $\psi_k$. Indeed its value is unaffected by any optical layers in the system that lie on the side of incidence (e.g., the incident layer).

The mirror itself must satisfy two important requirements: it must have a high-amplitude reflectivity, $|r_m|$, into air; and the phase change, $\rho_m$, on reflection from the mirror should be controllable.

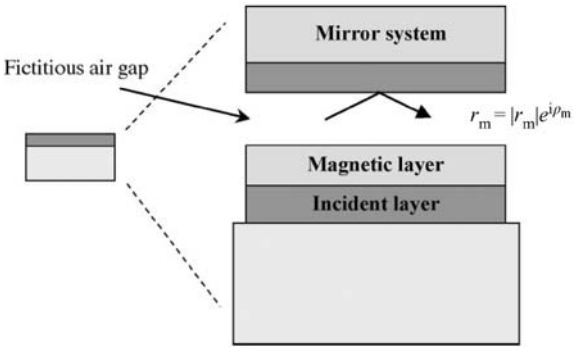

***Figure 2***
Quadrilayer structure for a magneto-optic disk, showing the reflectivity, $r_m$, of the mirror system into a fictitious air gap.

This is most easily achieved using an opaque aluminum film separated from the magnetic layer by a low refractive index spacer layer. The spacer layer has little effect on the reflectivity but its thickness, $d_s$, provides control over $\rho_m$. It can be shown that the potential Kerr coefficient for such a system is given by (Gamble *et al.* 1985)

$$\psi_k = (1+\Gamma^2)^{1/2} G|Q|/4 \quad (4)$$

where

$$\Gamma = \frac{n''}{n'} \quad (5)$$

and

$$G = G(n', n'', d_M, r_M, \lambda_0) \quad (6)$$

$G$ is a complex gain function derived by Gamble *et al.* (1985). The form of the function can be described graphically by a three-dimensional plot showing how $G$ varies with $|r_m|$ and $\rho_m$. A typical plot for an absorbing magnetic layer is shown in Fig. 3. It is important to note that this function does not change much with $d_M$, providing $d_M <$ skin depth, and that many optically absorbing media show similar plots. Even more important to note is that $G$ is a maximum for the largest value of $|r_m|$ but that there is quite a range of values of $\rho_m$ over which $G$ remains relatively high. It is this flexibility in $\rho_m$ that allows us to proceed with simple designs for enhancement.

## 3. Quadrilayer

At this point there are two ways of proceeding. In the first, called a quadrilayer (Atkinson *et al.* 1991), the thicknesses of the magnetic and spacer layers are adjusted to give a zero reflectance into the medium of the incident layer. This almost always requires a magnetic layer thickness that is less than the skin

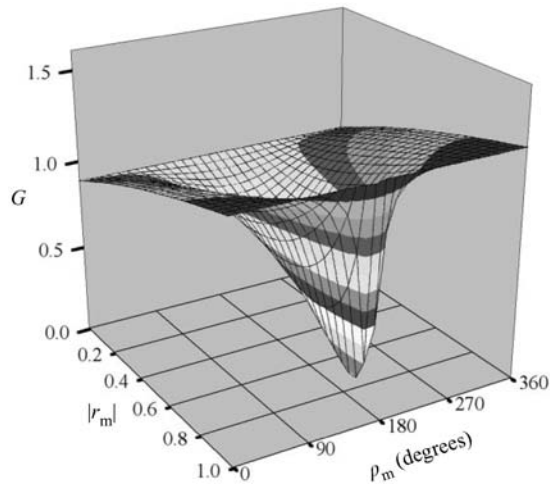

***Figure 3***
Typical gain function for an absorbing material with $d_M <$ skin depth.

depth and since there is considerable flexibility in the required value of $\rho_m$, the maximum value of the potential Kerr coefficient is usually achieved quite easily. Having reduced the reflectance from the top of the magnetic layer/mirror system to zero, only the magneto-optical Kerr coefficient, $k$, remains. The desired finite reflectivity, $r$, is returned to the system from the single upper surface of the incident layer and is determined by the refractive index of the material of this layer. This combines with the Kerr coefficient to produce a complex Kerr rotation in the usual way. However, the phase, $\Delta_k$, between $k$ and $r$ can be adjusted by varying the thickness of the incident layer and in this way can be set equal to zero or $\pi$. This may be done without affecting the value of either $k$ or $r$.

## 4. Trilayer

An alternative to the quadrilayer and one that is more practical and adequate for most purposes is the *trilayer* (Atkinson 1993), where the incident layer shown in Fig. 2 is omitted. In this case the overall reflectivity is controlled by the thicknesses of the magnetic and spacer layers. Thus, there are only two variables of the system that can be adjusted to maximize $\psi_k$, obtain a particular reflectance, and maintain a zero ellipticity. Theoretically it is rarely possible to satisfy all three conditions simultaneously. However, by sacrificing a small percentage in $\psi_k$ and hence maximum Kerr rotation, zero ellipticity can be obtained for a range of reflectances.

The design procedure, based on the use of CoPt, is illustrated graphically in Fig. 4. This shows how the intensity reflectance, $R$, of the three-layer system

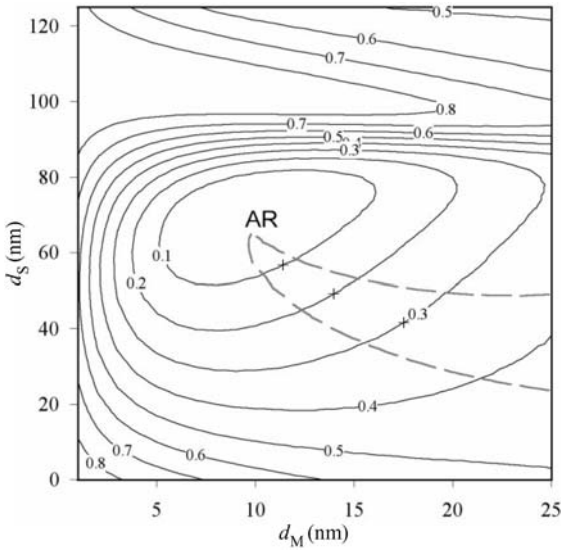

***Figure 4***
Reflectance (—) and cos $\Delta_k$ (- - -) contours as a function of the thicknesses of magnetic and spacer layers ($\lambda_0 = 350$ nm).

***Table 1***
Optical and magneto-optical parameters of materials at $\lambda_0 = 350$ nm.

| Material | $n'$ | $n''$ | $Q'$ | $Q''$ |
|---|---|---|---|---|
| CoPt | 1.38 | 2.84 | −0.0138 | 0.008 |
| $SiO_2$ | 1.48 | 0 | 0 | 0 |
| Al | 0.38 | 4.23 | 0 | 0 |

varies with the thicknesses $d_M$ and $d_s$. Also shown in Fig. 4 is a single contour (dashed line) within which $|\cos \Delta_k| > 0.99$. The optical and magneto-optical constants used to generate these contour maps are given in Table 1.

Figure 4 demonstrates how the reflectance of the system can be controlled and that, as required for the quadrilayer design, an antireflection condition can be produced at the point marked AR. It is worth pointing out that the Kerr rotation for such a point would be $\pm 90^\circ$, although the reflectivity of the system would be very low indeed. More important is the area within the dashed contour corresponding to cos $\Delta_k = -0.99$. Within this region three designs have been marked (+) that would give zero ellipticity for reflectances of 10%, 20%, and 30%.

What is not clear from these figures is the extent to which the designs will achieve optimization of the Kerr rotation through the maximization of the potential Kerr coefficient. In order to check this aspect of the design one must compare the resulting

***Table 2***
Trilayer designs corresponding to the three points marked (+) in Fig. 4.

| $R$ (%) | $d_M$ (nm) | $d_s$ (nm) | $\lvert k\rvert \times 10^2$ | $\theta_k$ (°) | $\psi_k/\psi_{k\max}$ (%) |
|---|---|---|---|---|---|
| 0.1 | 11.4 | 56.3 | 0.9 | 1.69 | 96.9 |
| 0.2 | 14.1 | 48.9 | 0.8 | 1.01 | 97.2 |
| 0.3 | 18.1 | 42.5 | 0.7 | 0.72 | 96.5 |

value of $\psi_k$ using Eqns. (4)–(6) and compare this with the absolute maximum possible value, $\psi_{k\max}$. This can be calculated using the same equations combined with the maximum possible value of the $G$ function, $G_{\max}$, which is obtained for a perfect mirror and is given by (Gamble *et al*. 1985)

$$G_{\max} = (1 - \Gamma^{-2})^{1/2} \tag{7}$$

Because of the insensitivity of the gain function to the mirror reflectance over a range of $\rho_m$ values, it is quite common for the potential Kerr coefficient to be within a few percent of the maximum that would be possible if the design were perfect. This is shown in Table 2 for the three designs marked (+) in Fig. 4 for $R = 0.1$, 0.2, and 0.3.

It may be noted that the extra complexity that would be needed to achieve the perfect enhancement does not usually warrant the additional effort since errors during fabrication of such multilayer systems are likely to lead to imperfections in performance.

## 5. *Enhancement Process*

It is useful to obtain a physical understanding of why enhancement of the magneto-optical Kerr effect occurs in the multilayer systems described above. There are two simple reasons for this. First, the overall reflectance is reduced and this clearly leads to an increase in Kerr rotation even if the Kerr coefficient remains unchanged. More importantly, however, for any chosen value of system reflectance, the Kerr coefficient has been increased to the maximum possible value that the intrinsic properties of the magnetic material will allow. This is accomplished through multiple interactions of the radiation with a thin film of the material. This is achieved using a high-reflectance mirror in such a way that all radiation not reflected from the system is absorbed by the magnetic layer. This maximizes the magneto-optic interaction of the incident radiation with the system.

These points are illustrated in Fig. 5, which shows the electric field amplitude and differential absorptance throughout a simple trilayer structure. The design actually corresponds to that indicated in Fig. 4 for $R = 0.1$ at a wavelength of 350 nm. It

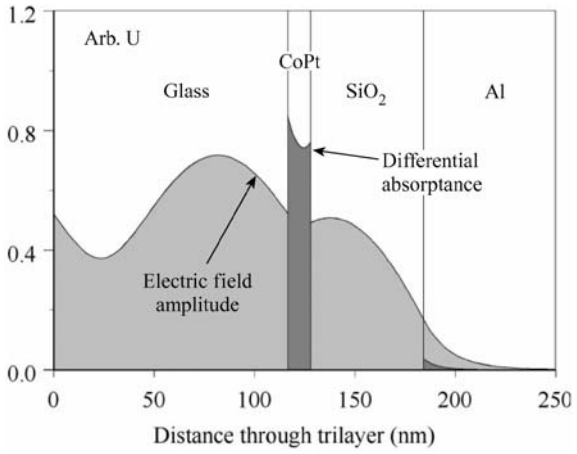

***Figure 5***
Electric field amplitude and differential absorptance as a function of distance through a trilayer designed for $R = 0.1$.

should be noted that the curve represents the amplitude of the electric wave through the various layers and should not be thought of as a traveling wave. In the incident medium (glass) therefore, we see a standing wave with nonzero nodes resulting from combination of the incident wave and the reflected wave that corresponds to the 10% reflected energy. The fields gradually decrease through the spacer and become very low within the highly reflecting aluminum mirror.

Differential absorptance indicates the variation of optical absorption throughout the system and the total dark area in Fig. 5 corresponds to the total absorption by the trilayer. Most important is the fact that virtually all of the radiation not reflected by the system is absorbed in the magnetic layer. Very little is lost to the mirror, either by absorption or in transmission. It is this fact that results in maximization of the potential Kerr coefficient since all radiation not reflected from the system is available to stimulate the magneto-optical effect.

## 6. *Longitudinal and Transverse Effects*

The general principles of enhancement, outlined above for the normal incidence polar Kerr effect, also apply to the longitudinal and transverse effects. In such cases one is working at oblique incidence and account must be taken of the orientation of the polarization state of the incident radiation with respect to the plane of incidence. The longitudinal case has been considered in some detail by Keay and Lissberger (1968). In the transverse case, the effect is usually described in terms of the ratio of the magnetization-sensitive reflectance change, $\Delta R$, to the

usual isotropic intensity reflectance, $R$, for P-polarized radiation. It is clear that enhancement can be obtained through the control of the reflectivity of the P-polarized state and maximization of the interaction of the radiation with the magnetic layer. The details for these cases will, to some extent, depend on the exact experimental arrangement being used to detect the effects.

### 7. Summary

An outline has been given of the means by which the normal incidence polar Kerr effect can be enhanced to improve the sensitivity with which it may be detected. The method relies on the use of three- or four-layer systems that control the reflectivity of the coating surface while, at the same time, maximizing the magneto-optical interaction of the radiation with the magnetic medium.

## Magneto-optics: Inter- and Intraband Transitions, Microscopic Models of

Magneto-optical methods are widely used to study the magnetic properties of materials. These experiments consider the response of a magnetic medium to

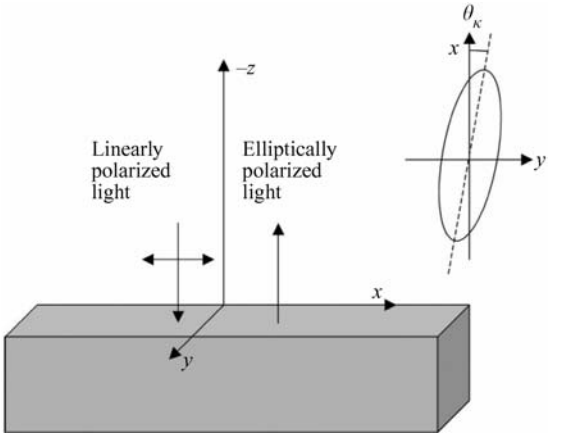

***Figure 1***
Schematic configuration of polar Kerr effect geometry.

the incident plane polarized light. When linearly polarized light is reflected or refracted it generally becomes elliptically polarized, as shown in Fig. 1. The main axis of the ellipse is rotated through angle $\theta_k$ with respect to the polarization direction of the incident light. The magneto-optical Kerr effect (MOKE) considers the reflected light, while the Faraday effect deals with the refracted light. $\theta_k$ is called the Kerr/Faraday rotation angle. The other important parameter is the ellipticity ($\eta_k$) of the outgoing light.

The discussion below deals primarily with the Kerr effect that can be easily extended to the Faraday effect. To make the analysis of this complex problem somewhat simpler we assume normal incidence of light and assume the $z$-axis to be normal to the surface of the sample. The light traveling through vacuum or air with refractive index $n=1$ is reflected from a sample with refractive index $n$. Let us consider the electric vector of the linearly polarized light.

$$E_{\text{inc}} = E_0 \hat{e}_x e^{ikz - i\omega t} \tag{1}$$

where $\hat{e}_x$ is the polarization vector along the $x$-axis, $k$ is the wave vector, $\omega$ is the frequency of the wave, and $E_0$ is the amplitude. This expression can be rewritten in terms of right and left circularly polarized light as follows:

$$E_{\text{inc}} = E_r + E_l \tag{2}$$

where

$$E_{r/l} = E_0(\hat{e}_x \pm i\hat{e}_y)e^{ikz - i\omega t} \tag{3}$$

This wave has equal right and left components.

Using the boundary conditions, the following relation is obtained for the incident, $E_{\text{inc}}$, and the

reflected, $E_{\text{refl}}$, electric vectors:

$$E_{\text{refl}} = \frac{1-n}{1+n} E_{\text{inc}} \tag{4}$$

Replacing $E_{\text{inc}}$ with its right-($n_r$) and left-($n_l$) circularly polarized components one gets

$$\begin{aligned} E_{\text{refl}} &= \frac{1-n_r}{1+n_r} E_{\text{inc,r}} + \frac{1-n_l}{1+n_l} E_{\text{inc,l}} \\ &= \frac{E_0}{2}\left[\frac{1-n_r}{1+n_r}(\hat{e}_x + i\hat{e}_y) + \frac{1-n_l}{1+n_l}(\hat{e}_x - i\hat{e}_y)\right] e^{ikz-i\omega t} \end{aligned} \tag{5}$$

which is elliptically polarized light if $n_r \neq n_l$. The Kerr rotation angle and ellipticity are given by

$$\begin{aligned} \theta_k &= \frac{\text{Re}(E_{\text{refl}}\hat{e}_y)}{\text{Re}(E_{\text{refl}}\hat{e}_x)} = \text{Im}\frac{n_r - n_l}{1 - n_r n_l}, \\ \eta_k &= \frac{\text{Im}(E_{\text{refl}}\hat{e}_y)}{\text{Re}(E_{\text{refl}}\hat{e}_x)} = \text{Re}\frac{n_r - n_l}{1 - n_r n_l} \end{aligned} \tag{6}$$

The positive sign of the Kerr angle is considered for the rotation from the $x$-axis to the $y$-axis. Keep in mind that the direction of propagation for the reflected beam is $-z$.

The corresponding parameters for the Faraday effect are

$$\begin{aligned} \theta_F &= \frac{1}{2c}\,\omega z \text{Re}(n_r - n_l), \\ \eta_F &= -\tanh\left(\frac{1}{2c}\,\omega z \text{Im}(n_r - n_l)\right) \end{aligned} \tag{7}$$

where $c$ is the speed of light and $z$ is the distance from the interface. These expressions are valid for $|n_r - n_l| \ll n_r$. We see from these equations that reflected and refracted waves are elliptically polarized due to the difference in the refractive indices of the medium for the left and right polarized light. The index of refraction is related to the dielectric constant $\varepsilon$ and conductivity tensor $\sigma$ as follows:

$$n^2 = \varepsilon = 1 + i\frac{4\pi}{\omega}\,\sigma \tag{8}$$

The left-handed ($-$) and the right-handed ($+$) components of the conductivity are given by

$$\sigma^{\pm}(\omega) = \sigma_{xx}(\omega) \pm i\sigma_{xy}(\omega) \tag{9}$$

and the conductivity tensor for a medium with threefold or higher rotational symmetry about the $z$-axis has the following form:

$$\sigma = \begin{pmatrix} \sigma_{xx} & \sigma_{xy} & 0 \\ -\sigma_{xy} & \sigma_{xx} & 0 \\ 0 & 0 & \sigma_{xx} \end{pmatrix} \tag{10}$$

Combining Eqns. (6), (8)–(10), the Kerr rotation parameters are given by

$$\theta_k = \text{Re}\,\frac{4\pi\sigma_{xy}}{\omega n(1-n^2)}, \quad \eta_k = \text{Im}\,\frac{4\pi\sigma_{xy}}{\omega n(1-n^2)} \tag{11}$$

We see from Eqn. (11) that a system gives rise to the Kerr effect if the off-diagonal component of its conductivity tensor, $\sigma_{xy}$, is not zero. Now, the Onsager reciprocal relation $\sigma_{ij}(M) = \sigma_{ji}(-M)$ along with Eqn. (10) gives $\sigma_{xy}(M) = -\sigma_{xy}(-M)$ and $\sigma_{ii}(M) = \sigma_{ii}(-M)$, where $M$ is the magnetization vector along the $z$-axis. Thus there is no Kerr rotation in a paramagnet or antiferromagnet because $\sigma_{xy}(M) = -\sigma_{xy}(-M)$ leads to an equal and opposite contribution for the identical spin-up and spin-down densities of states. Also, $\sigma_{ii}$ and $\sigma_{xy}$ have odd-power and even-power dependence respectively on $M$. As a result, the rotation parameters are linear functions of $M$ when the higher order terms are neglected. The Kerr rotation for the geometry considered here is known as polar Kerr rotation.

The conductivity tensor is determined by intraband and interband electronic transitions in response to the applied electromagnetic radiation. Thus the computation of the conductivity tensor requires the electronic states of the system. The electronic states are determined by the self-consistent solutions of the one-electron Schrödinger equations

$$(-\Delta + V_{\text{eff}})\psi_{\vec{k}\,\lambda} = E_{\vec{k}}\psi_{\vec{k}\,\lambda} \tag{12}$$

where $V_{\text{eff}}$ is the effective potential including spin–orbit interactions, $\vec{k}$ is the wavevector and $\lambda$ is the band index.

The Drude model is used to calculate the intraband contribution to the diagonal component of the conductivity tensor. The conductivity in this model is given by (Ziman 1972)

$$\sigma^{\text{intra}}(\omega) = \frac{\sigma_0}{1 - i\omega\tau} \tag{13}$$

where the d.c. conductivity $\sigma_0$ is related to the plasma frequency $\omega_p$ and the relaxation time $\tau$ of the band states by

$$4\pi\sigma_0 = \omega_p^2 \tau \tag{14}$$

The calculated band structure is used to compute $\omega_p$ using the following expression (Mazin *et al.* 1989):

$$\omega_p^2 = \frac{4\pi e^2}{\Omega} \sum_{\vec{k}\,\lambda} |V_{\vec{k}\,\lambda}|^2 \delta(E_{\vec{k}\,\lambda} - E_F) \tag{15}$$

where $\Omega$ is the volume of the primitive cell of the system and

$$V_{\vec{k}\,\lambda} = \langle \vec{k}\,\lambda | \nabla | \vec{k}\,\lambda \rangle \tag{16}$$

is the mean velocity of an electron in state $|k\lambda\rangle$ and $E_F$ is the Fermi energy.

$\sigma_0$ and $\omega_p$ are used to calculate $\tau$ and then $\sigma^{\text{intra}}(\omega)$.

The interband contribution to the conductivity tensor is related to matrix elements of the interaction potential between the electrons and the electromagnetic field given by:

$$H' = \frac{e}{mc}\vec{\pi}\cdot\vec{A} \tag{17}$$

where $A$ is vector potential and

$$\vec{\pi} = \vec{p} + \frac{\hbar}{4mc^2}\sigma\times\nabla V(r) \tag{18}$$

with $\sigma$ as the Pauli spin matrices and $\vec{p}$ as the electron momentum. The second term in $\vec{\pi}$ leads to the spin–flip transitions. It has been found to be negligible compared to the first term and is usually ignored. Treating $H'$ as a perturbation in the random phase approximation, without allowance for the local field effects, the imaginary part of the off-diagonal conductivity tensor is

$$\sigma_{2xy} = \frac{\pi e^2}{4m^2\hbar\omega\Omega}\sum_{\vec{k}\lambda\lambda'}\{|\langle\vec{k}\lambda'|\pi^-|\vec{k}\lambda\rangle|^2 - |\langle\vec{k}\lambda'|\pi^+|\vec{k}\lambda\rangle|^2\}\times\delta(\hbar\omega - E_{\lambda\lambda'}) \tag{19}$$

where $\pi^+$ and $\pi^-$ are electron momentum operators corresponding to right- and left-circularly polarized light and $|\vec{k}\lambda\rangle$ and $|\vec{k}\lambda'\rangle$ are occupied and unoccupied states, respectively (see for example Bennet and Stern 1965, Wang and Callaway 1974). The real part of the diagonal component of the conductivity tensor, $\sigma_{1xx}$, is given by a similar expression where $\pi^+$ and $\pi^-$ contributions are added. The Kramers–Kronig dispersion relations are used to find the other parts of these components.

The selection rules for the dipole matrix elements in terms of the orbital quantum numbers ($l$, $m_l$) are $\Delta l = \pm 1$ and $\Delta m_l = 1$ for $\pi^+$ and $\Delta m_l = -1$ for $\pi^-$. In the absence of spin–orbit interactions, $\pi^+$ and $\pi^-$ contributions in Eqn. (19) cancel each other exactly ($\sigma_{xy} = 0$) due to the degeneracy of the states with magnetic orbital quantum numbers $m_l$ and $-m_l$. As a result there is no Kerr rotation in such a system. Spin–orbit interactions lift the above mentioned degeneracy of the electronic states so that $\pi^+$ and $\pi^-$ contributions no longer cancel each other, giving a finite value for $\sigma_{xy}$. Thus a system must have spin moment (asymmetric spin-up and spin-down densities of states) with spin–orbit interactions to produce Kerr rotation.

The off-diagonal components of the conductivity tensor (Eqn. (19)) and hence the Kerr rotation (Eqn. (11)) is determined by the dipole matrix elements between the occupied and unoccupied electronic states of the same spin separated by the incident photon energy $\hbar\omega$. Since the Kerr parameters are proportional to the off-diagonal component of the conductivity tensor, one can qualitatively try to relate the features in the magneto-optic spectra by assuming the matrix elements in Eqn. (19) to be the same for all transitions. In this case $\sigma_{xy}$ is proportional to the joint density of states (JDOS) as follows:

$$\sigma_{xy}(\omega) \propto \frac{1}{\omega}\left[\int_{\omega_F-\omega}^{\omega_F} n^{\uparrow}(\omega')n^{\uparrow}(\omega+\omega')\mathrm{d}\omega' + \int_{\omega_F-\omega}^{\omega_F} n^{\downarrow}(\omega')n^{\downarrow}(\omega+\omega')\mathrm{d}\omega'\right] \tag{20}$$

where $n^{\uparrow,\downarrow}(\omega')$ and $n^{\uparrow,\downarrow}(\omega+\omega')$ are the spin-up($\uparrow$) and spin-down ($\downarrow$) densities of states (DOS) for the occupied and unoccupied states respectively and $\omega_F$ refers to the Fermi energy. It must be kept in mind that constant matrix element approximation is inadequate for a quantitative comparison of this rather weak effect.

The magneto-optical materials have been actively studied for several decades in terms of their applications as rewritable data storage devices. The large Kerr rotation allows the increase of signal to noise ratio and as a result the density of recording. Currently, materials with Kerr rotation of about 0.3° are used for magneto-optical recording. Research is now concentrated on materials with a Kerr rotation above 0.3°. Also, the Curie temperature ($T_c$) should be such that one can easily go above it to write and stay below it to read. Thus, along with the exchange parameters for appropriate $T_c$, a practical magneto-optical system must have large magnetization and spin–orbit interactions to produce a large enough Kerr rotation. One of the common ways to achieve this combination is by creating a mixture of 3*d* elements with large magnetization and heavy elements with large spin–orbit coupling. The materials currently in use are based on amorphous $(\text{Tb, Gd})_x(\text{Fe, Co})_{1-x}$ ($x = 0.2$–$0.3$) with Kerr rotation of about 0.2–0.3° around 633 nm wavelength of light (Bloomberg *et al.* 1996).

Finally, as an example of intraband and interband contributions to the Kerr parameters we consider MnBi, an interesting system with one of the largest Kerr rotations known. MnBi has a hexagonal structure with four atoms per unit cell. We have studied the Kerr effect in MnBi using the first-principle relativistic self-consistent band structure calculations. The large magnetization in this system comes from Mn($3.6\,\mu_B$) and Bi is responsible for the appreciable spin–orbit coupling (Sabiryanov and Jaswal 1996).

Figure 2 shows the spin-polarized DOS for MnBi. The major peaks in the DOS are due to the Mn *d*-states. The interband contribution to the Kerr rotation in MnBi comes primarily from *p* and *d* states ($\Delta l = \pm 1$). The Kerr-active region of the

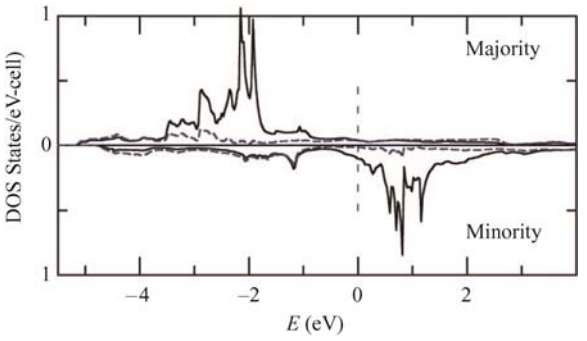

***Figure 2***
Spin-polarized total and projected DOS of MnBi. The zero on the energy axis corresponds to the Fermi energy.

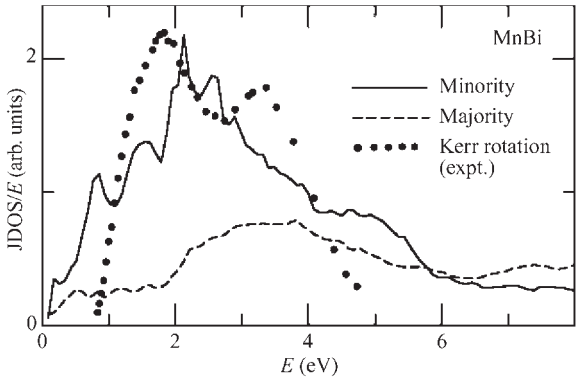

***Figure 3***
Spin-resolved JDOS of MnBi and the Kerr rotation data from Di *et al.* (1992).

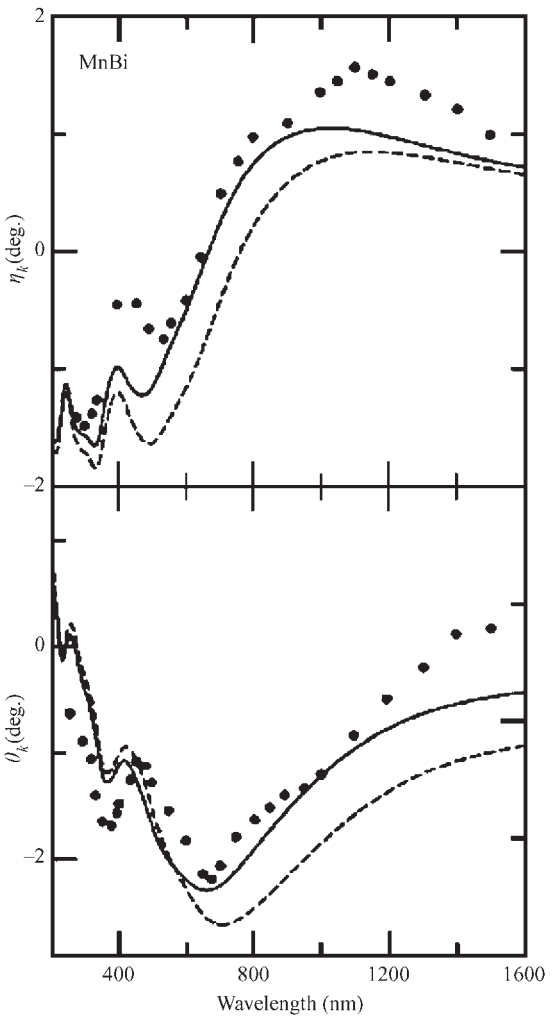

***Figure 4***
Kerr rotation ($\theta_k$) and ellipticity ($\eta_k$) for MnBi. Dots represent the experimental data at 85 K from Di *et al.* (1992). The full line gives the results with interband and intraband contributions while the dashed line corresponds to the interband contribution only.

electromagnetic spectrum for MnBi can be qualitatively seen from the JDOS (Eqn. (20)) for spin-up and spin-down states plotted in Fig. 3. Figure 3 also shows the experimental data for Kerr rotation for MnBi (Di *et al.* 1992). One can see from Fig. 3 that JDOS do a good job of predicting that the Kerr-active region of MnBi is centered around 2–3 eV. The minority spin JDOS has a large peak around 2 eV that arises from a modest peak around 1.4 eV below Fermi energy and a large peak at 0.6 eV above $E_F$ in the DOS of MnBi in Fig. 2. The transitions are between hybrid bands formed by Bi *p*- and Mn *d*-states. The majority-spin JDOS has a small broad peak around 3.3 eV. The transitions from hybrid Bi *p*- and Mn *d*-bands to more dispersed Mn and Bi *sp*-bands are responsible for the smaller second peak in the Kerr rotation angle around 3.3 eV.

For a quantitative comparison, the calculated Kerr rotation and ellipticity are compared with the experimental data in Fig. 4. First, overall there is good agreement between theory and experiment. The largest Kerr rotation of 2.3° is around 2 eV (630 nm). Figure 4 also shows the calculated Kerr rotation without an intraband contribution. We see that the intraband contribution is appreciable at longer wavelengths but becomes negligible below 600 nm.

In spite of the large Kerr rotation MnBi has not become a data storage device so far. This is because MnBi undergoes structural phase transition from a low-temperature hexagonal ferromagnetic phase to the high-temperature orthorombic paramagnetic phase near its Curie temperature. This makes it

unsuitable for recording applications. Scientists continue to make efforts to overcome this problem and enable the large Kerr rotation in MnBi to be exploited for data storage applications (Bandaru *et al*. 1998, Sabiryanov and Jaswal 1999).

## Magnetoresistance in Transition Metal Oxides

If the electrical resistance of a material depends on the strength of the magnetic field which it experiences, then the material is said to show the property of magnetoresistance (MR). This property has many useful applications: it enables magnetic field strength to be deduced from a relatively simple measurement of electrical resistance, and it allows magnetic fields to control the flow of current in a circuit, i.e., a magnetic switch. As recently as 1988, a 50% drop in the resistance of an Fe/Cr multilayer device in a field of 2 T at a temperature of 4.2 K was described as ''huge'' (Baibich *et al*. 1988). Since that time, considerable progress has been made towards producing a material that shows a larger effect at higher temperatures in weaker fields, with most of the recent research focusing on mixed-metal oxides containing manganese, for example $La_{1-x}Sr_xMnO_3$. The level of success has been such that the word used to describe the magnetoresistance has changed from huge, via giant (GMR), to colossal (CMR), although at the time of writing (2000) the cause of the enhancement is not fully understood. The oxides that have shown the most interesting behavior are described below; a number of more detailed reviews are available (Battle and Rosseinsky 1999, Bishop and Röder 1997, Ramirez 1997, Rao and Cheetham 1997).

### *1. Perovskites*

The seminal paper in the study of MR in mixed-metal oxides was concerned with $Nd_{0.5}Pb_{0.5}MnO_3$ (Kusters *et al*. 1989), a compound that adopts the relatively common, cubic (or pseudo-cubic) perovskite crystal structure. This structure has the general formula $ABO_3$, with the possibility of substitution on the A site (ideally 12-coordinated by oxide ions) to form $A_{1-x}A'_xBO_3$, or on the B site (6-coordinated) to form $AB_{1-x}B'_xO_3$. Many aspects of the behaviour of A-site substituted $Nd_{0.5}Pb_{0.5}MnO_3$, including the adoption of a perovskite-related structure, have subsequently been shown to be common among MR oxides. The majority of the compounds to be discussed below contain manganese in a mixed valence state, that is, the average oxidation state of the transition-metal cation lies between $+3$ and $+4$, and the average number of electrons in the 3*d* electron shell of each cation is therefore non-integral, lying between 4 and 3 for $Mn^{3+}$ and $Mn^{4+}$ respectively. At temperatures above 200 K, the valence electrons are localized and the electrical conductivity of $Nd_{0.5}Pb_{0.5}MnO_3$ is activated.

However, a transition from an insulating to a metallic state occurs on cooling through 185 K. This is typical of MR oxides, as is the fact that the Curie temperature ($T_C$), below which the material is ferromagnetic, coincides with the temperature of the metal–insulator (MI) transition. The coexistence of metallic conductivity and ferromagnetism is often accounted for in terms of the double-exchange mechanism (Zener 1951), which argues that the ease of transferring the extra electron associated with a $Mn^{3+}$ cation to a neighboring $Mn^{4+}$ cation, thus establishing a current, is greatest when the outer electrons on the two cations have parallel spins, and that ferromagnetic coupling of the atomic magnetic moments therefore reduces the electrical resistivity. The MR effect is greatest at temperatures slightly above $T_C$, where the application of a magnetic field

increases the degree of spin alignment in a material which is susceptible to short-range magnetic coupling, thus reducing the spin-scattering of the conduction electrons and effectively moving the MI transition to higher temperatures.

Hence, the resistivity of $Nd_{0.5}Pb_{0.5}MnO_3$ decreases by two orders of magnitude when it is subjected to a field of 11 T at 190 K, with $T_C = 184 \pm 1$ K. This reduction, although large enough to be useful, is occurring at too low a temperature and too high a field to be of practical benefit. In the late 1990s, a great deal of effort was expended in order to shift the region of maximum effect to higher temperatures and to reduce the value of the required field. The perovskites having the general formula $Ln_{1-x}A_xMnO_3$, where Ln is a metal from the lanthanide series and A is an alkaline earth (group II) metal, were studied in great detail. Changes in the value of $x$ produced changes in the mean oxidation state of the manganese cations, and hence changes in the population of the conduction ($3d$) band. They also caused a variation in the mean size of the cations, and hence subtle changes in the details of the crystal structure.

This chemical approach resulted (Urushibara *et al.* 1995) in the observation of 90% MR (defined as $-100[\rho(B)-\rho(0)]/\rho(0))$ at 300 K in $La_{0.875}Sr_{0.175}MnO_3$, albeit in a field of 15 T. Thus, the temperature problem was solved, but not that of the field strength. It should be noted that the oft-cited chemical similarity of the lanthanide elements cannot be assumed in this research area. The electronic phase diagrams of $Ln_{1-x}A_xMnO_3$ are very sensitive to the particular cations (Ln and A) involved, as well as to their concentration. Although perovskites containing manganese have dominated recent research into MR effects in oxide materials, a number of manganese-free systems have also been studied. One such system (Kobayashi *et al.* 1998) is $Sr_2FeMoO_6$, a perovskite with an ordered arrangement of two cations over the 6-coordinate sites. This compound is metallic with $T_C \sim 415$ K, and it shows 10% MR in 7 T at 300 K. Note that in analyzing magnetotransport data on these materials there is a need to distinguish between intrinsic MR and spin-dependent intergrain tunnelling effects (Hwang *et al.* 1996), the latter being important in low fields.

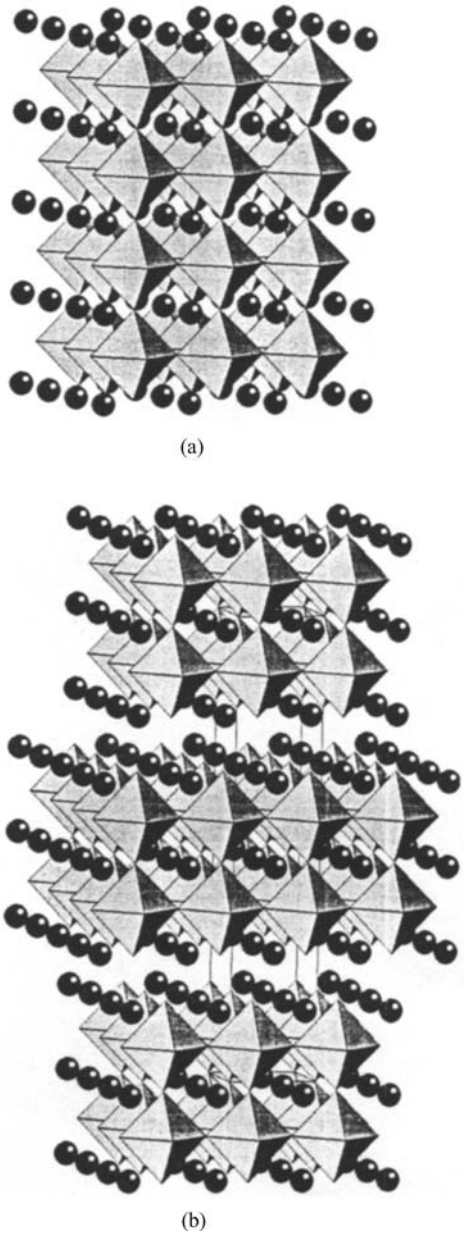

***Figure 1***
Crystal structures of the Ruddlesden–Popper phases having (a) $n = \infty$ (perovskite) and (b) $n = 2$. $MnO_6$ octahedra are shown, along with A site cations.

## 2. *n* = 2 Ruddlesden–Popper Phases

The perovskite phases described above are the $n = \infty$ members of the Ruddlesden–Popper family having the general formula $(A, A')_{n+1}(B, B')_nO_{3n+1}$. CMR has also been observed in compounds which correspond to the $n = 2$ member of the series (Fig. 1). In the case of $n = \infty$, a three-dimensional, infinite network of vertex-sharing $BO_6$ octahedra is present, with the A cations occupying interstices between the octahedra. For $n = 2$, the octahedral network is infinite in two dimensions, but it is broken into blocks, each only two (i.e., $n$) octahedra wide, along the third direction. The two-dimensional nature of this structure introduces anisotropy into the electronic properties of the oxides. $Sr_{1.8}La_{1.2}Mn_2O_7$ was one of the first $n = 2$ compositions to be studied from the

point of view of CMR (Moritomo *et al*. 1996). It was found to show a MI transition coincident with the Curie temperature, $T_C = 126\,K$, although the conductivity parallel to the infinite perovskite blocks was two orders of magnitude greater than that in the perpendicular direction.

MR was observed both parallel and perpendicular to the blocks, and the low-field effect was much stronger than had been observed in $n = \infty$ (La, Sr)$MnO_3$; in the two-dimensional material $\rho(0)/\rho(H) = 110\%$ in 0.3 T and $\sim 3000\%$ in 1 T. The chemical sensitivity of these systems is demonstrated by the behavior of $Sr_{1.6}La_{1.4}Mn_2O_7$, which, in contrast to that of $Sr_{1.8}La_{1.2}Mn_2O_7$, is markedly different parallel and perpendicular to the layers (Kimura *et al*. 1996), with the strongest magnetoresistance being in the latter direction. This has lead to comparisons being drawn between the multilayer devices described above and these Ruddlesden–Popper phases, which are now often referred to as "naturally-layered manganites." CMR has been reported in $n = 2$ compositions containing lanthanides other than lanthanum (Battle and Rosseinsky 1999). As in the case of the perovskites, the electronic properties are very sensitive to the atomic number and concentration of the lanthanide; CMR is not observed in compounds containing the smaller lanthanides. It has been shown that the microstructure of these compounds can be very complex (Sloan *et al*. 1998), with intergrowths of $n = \infty$ perovskite breaking up the regular $n = 2$ structure.

### 3. Other Ruddlesden–Popper Phases

There have been few reports of CMR in $n = 1$ ($K_2NiF_4$-like) phases, in which $Mn^{3+}/Mn^{4+}$ charge ordering appears to be common. The most promising system studied to date is perhaps $Ca_{2-x}Ln_xMnO_4$ ($0 < x < 0.2$, Ln = Pr, Sm, Gd, Ho), with 64% MR being observed in $Ca_{1.92}Pr_{0.08}MnO_4$ in 7 T at 40 K (Maignan *et al*. 1998). The $n = 3$ phases studied to date have shown lower MR ratios.

### 4. Pyrochlores

The observation of CMR in the pyrochlore $Tl_2Mn_2O_7$ (Shimakawa *et al*. 1996) increased the breadth of contemporary magnetotransport research. $Tl_2Mn_2O_7$ orders ferromagnetically at 142 K, and the MR is largest in this temperature region (86% in 7 T). However, the pyrochlore is metallic both above and below $T_C$, that is, the onset of ferromagnetic ordering is not accompanied by a MI transition. Furthermore, there is apparently no mixed valency on the manganese sublattice; only $Mn^{4+}$ is present. The CMR observed in this compound is therefore not readily explained by arguments based on double exchange, and it has been shown (Ramirez and Subramanian 1997) that the MR can be increased by doping with scandium to form $Tl_{2-x}Sc_xMn_2O_7$.

During the last decade of the twentieth century considerable progress was made in improving the magnetotransport properties of mixed-metal oxides. Perovskites that show a practically useful effect at room temperature have been identified; unfortunately the field needed to produce the effect is impractically large. RP phases show an effect at lower fields, but at temperatures too far below ambient to be useful. The remaining challenge is to find new materials that show a colossal effect at high temperatures. These new materials may or may not be perovskite-related, and they may or may not be manganese-based.

# Magnetoresistance, Anisotropic

The electrical conductivity of spontaneously magnetized materials depends on the relative orientation of the electrical current and the magnetization. This phenomenon, called anisotropic magnetoresistance (AMR) or spontaneous magnetoresistance anisotropy (SMA), was discovered by Lord Kelvin in the middle of the nineteenth century. However, intensive investigations on AMR started only in the 1950s with the work of Smit (1951) and van Elst (1959). Although technical applications of AMR were suggested in the 1970s, corresponding devices (sensors and read heads for hard disks) (Göpel *et al.* 1989) were not introduced commercially until about 20 years later.

The physical origin of AMR is the reduction of the symmetry of a magnetized material compared to its nonmagnetic state caused by the simultaneous presence of the magnetization and spin–orbit coupling. The first qualitative models to describe AMR were developed by Smit (1951) and Campbell *et al.* (1970) and have been extended subsequently by others. A parameter-free theoretical description of AMR has been published (Banhart and Ebert 1995).

## 1. Phenomenological Description

For a material that is homogeneously magnetized along the *z*-axis but otherwise isotropic, the conductivity tensor takes the following form (Kleiner 1966, Cracknell 1973):

$$\boldsymbol{\sigma} = \begin{pmatrix} \sigma_\perp & \sigma_H & 0 \\ -\sigma_H & \sigma_\perp & 0 \\ 0 & 0 & \sigma_\parallel \end{pmatrix} \tag{1}$$

with the corresponding resistivity tensor being given by

$$\boldsymbol{\rho} = \begin{pmatrix} \rho_\perp & \rho_H & 0 \\ -\rho_H & \rho_\perp & 0 \\ 0 & 0 & \rho_\parallel \end{pmatrix} \tag{2}$$

The tensor elements $\rho_\perp$ and $\rho_\parallel$ are called transverse and longitudinal electrical resistivity, respectively, with their average

$$\bar{\rho} = \tfrac{2}{3}\rho_\perp + \tfrac{1}{3}\rho_\parallel \tag{3}$$

giving the isotropic resistivity $\bar{\rho}$. Normalizing $\rho_\perp$ and $\rho_\parallel$ using $\bar{\rho}$ leads to the transverse and longitudinal magnetoresistivity, respectively:

$$\left(\frac{\Delta\rho}{\bar{\rho}}\right)_\perp = \frac{\rho_\perp - \bar{\rho}}{\bar{\rho}} \tag{4}$$

$$\left(\frac{\Delta\rho}{\bar{\rho}}\right)_\parallel = \frac{\rho_\parallel - \bar{\rho}}{\bar{\rho}} \tag{5}$$

The difference of these two quantities gives the AMR ratio

$$\frac{\Delta\rho}{\bar{\rho}} = \frac{\rho_\parallel - \rho_\perp}{\bar{\rho}} \tag{6}$$

The off-diagonal element $\rho_H$ of the resistivity tensor is called the Hall resistivity and represents the anomalous or spontaneous Hall effect (Karplus and Luttinger 1954, Smit 1955). The elements of the conductivity tensor $\boldsymbol{\sigma}$ are denoted in an analogous way to those of the resistivity tensor $\boldsymbol{\rho}$ with the following relationships between the various elements:

$$\sigma_\perp = \frac{\rho_\perp}{\rho_\perp^2 + \rho_H^2} \quad \sigma_\parallel = \frac{1}{\rho_\parallel} \quad \sigma_H = \frac{\rho_H}{\rho_\perp^2 + \rho_H^2} \tag{7}$$

$$\rho_\perp = \frac{\sigma_\perp}{\sigma_\perp^2 + \sigma_H^2} \quad \rho_\parallel = \frac{1}{\sigma_\parallel} \quad \rho_H = \frac{\sigma_H}{\sigma_\perp^2 + \sigma_H^2} \tag{8}$$

## 2. Basic Properties

In principle, the above definitions apply to a single-domain sample. For a multidomain sample one therefore has to apply an external magnetic field to align the magnetization. This may lead, for example, to a variation of $\rho_\perp$ and $\rho_\parallel$ with the field, as shown in Fig. 1 (van Elst 1959). Because the ordinary magnetoresistance is superimposed onto the spontaneous magneto-resistance the proper values $\rho_\perp^0$ and $\rho_\parallel^0$, corresponding to the single-domain state of the sample are obtained by an extrapolation of the high-field data to zero external field.

The simple form given above for the conductivity and resistivity tensors is not restricted to isotropic materials, but applies to any material for which the direction of the magnetization coincides with an at least three-fold rotational symmetry axis (Kleiner 1966, Cracknell 1973). Furthermore, it can be applied without modifications for polycrystalline materials. For less symmetric situations the shape of the tensors in Eqns. (1) and (2) will change. In particular, for single crystals one finds that the AMR varies if the

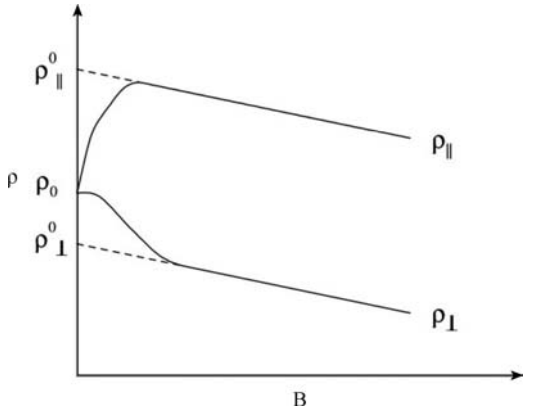

***Figure 1***
Dependency of the transverse and longitudinal electrical resistivity, $\rho_{\perp}$ and $\rho_{\parallel}$, respectively, on an external magnetic field, $B$.

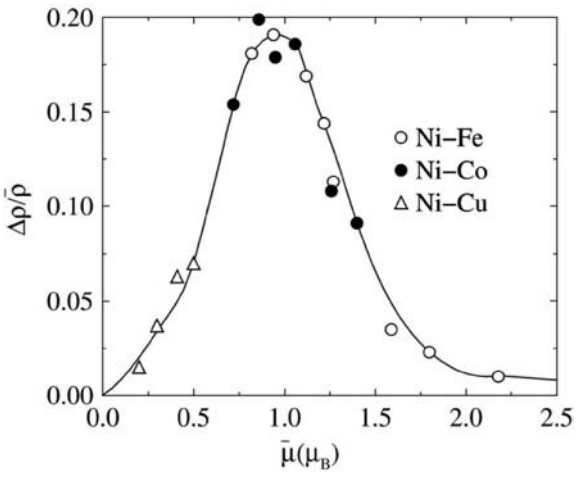

***Figure 2***
AMR ratio $\Delta\rho/\bar{\rho}$ at 20 K as a function of the average magnetic moment $\bar{\mu}$ for various 3d element alloys (after Wijn 1991).

orientation of the magnetization with respect to the crystal axis is changed (Becker and Döring 1939).

## 3. *Materials and Applications*

The AMR effect can be observed in principle in any spontaneously magnetized material. However, most experimental work has been devoted to systems based on the transition metals iron, cobalt, and nickel. In the search for materials with high AMR ratio, diluted and concentrated alloys among these elements, but also with other transition metals (e.g., chromium, vanadium, copper, palladium, and platinum) or non-transition elements (e.g., aluminum, silicon, tin) have been investigated (McGuire and Potter 1975, Dorleijn 1976). Among these systems the highest values for the AMR ratio $\Delta\rho/\bar{\rho}$ have been found for nickel-based alloys.

In particular, a rather simple empirical relationship between the AMR ratio $\Delta\rho/\bar{\rho}$ and the average magnetic moment $\mu$ has been found for concentrated binary nickel-based alloys (see Fig. 2 and below). This relationship implies that the AMR ratio can be optimized within certain limits by a suitable choice of the alloy partners and their concentration. An upper limit seems to be given by the data for NiCo alloys and NiFeCo alloys, which show AMR ratios of up to 30% at low temperatures. Unfortunately, the AMR ratio rapidly decreases with increasing temperature. For example, for $Ni_{81}Fe_{19}$ one has $\Delta\rho/\bar{\rho} = 20\%$ at $T = 20$ K, but only about 3% at $T = 300$ K.

The AMR effect has also been investigated for a number of amorphous alloy systems, e.g., Fe–Si, Fe–Zr, and Fe–V–B. These amorphous systems are attractive because they can be easily prepared as thin films by various techniques and because their isotropic resistivity $\bar{\rho}$ is in general almost temperature independent (see *Amorphous Intermetallic Alloys: Resistivity*). Unfortunately, $\bar{\rho}$ is normally quite high (of the order of 100 $\mu\Omega$ cm) leading to AMR ratios that are usually not much higher than 1%. In contrast to this property of transition metal-based amorphous systems, a very pronounced AMR effect with $\Delta\rho/\bar{\rho}$ up to 26% at low temperature has been found for ferromagnetic amorphous alloys based on uranium and antimony (Freitas and Plaskett 1990). This finding can be ascribed to the strong spin–orbit coupling of uranium (see below).

Although the maximum AMR ratio that can be achieved at room temperature is relatively small, it is nevertheless high enough to be exploited in sensor and storage technology (Göpel *et al.* 1989). Transition metal alloys are very suitable for this purpose, because they can easily be prepared by evaporation or sputtering deposition as thin films. In some cases the resistivity $\bar{\rho}$ of such films can be decreased by up to 30% by tempering. This increases the AMR ratio accordingly leading to a higher output signal for a given input power (Butherus and Nakahara 1985). Further important restrictions for applications are a low magnetostriction and a small coercivity field.

These requirements are extremely well fulfilled by permalloy that is free of magnetostriction at 81 at.% nickel. In addition, it has at this composition a very low coercivity field of about 100 $Am^{-1}$ and a low uniaxial anisotropy energy constant of about 200 $Jm^{-3}$. Although the AMR ratio for the NiFe–alloy system is highest for about 90 at.% nickel and although higher values for $\Delta\rho/\bar{\rho}$ are achieved by other transition metal alloy systems (see above), these suitable properties make $Ni_{81}Fe_{19}$ permalloy the most

commonly used AMR material for applications. According to this situation, industrial research and development aims to optimize the geometry and readout technique of AMR devices instead of searching for more efficient AMR materials (Eijkel and Fluitman 1990).

## 4. Phenomenological Theories

Transport phenomena in magnetic materials are in general discussed in the framework of two simplifying models (Rossiter 1987). The first is Matthiessen's rule that states that thermal and impurity scattering contribute independently to the electrical resistivity (see *Boltzmann Equation and Scattering Mechanisms*). The two-current model of Mott assumes that the scattering of electrons at impurities in a magnetized sample does not change the electron spin orientation relative to the magnetization, and that the scattering is different for majority and minority spin electrons. This implies that there are two independent currents in a magnetic material with two corresponding subband resistivities, $\rho^{\uparrow}$ and $\rho^{\downarrow}$, that add up to the total resistivity according to

$$\frac{1}{\bar{\rho}} = \frac{1}{\rho^{\downarrow}} + \frac{1}{\rho^{\uparrow}} \tag{9}$$

This approach clearly ignores spin-mixing, e.g., due to finite temperature magnon scattering. This effect is sometimes considered by introducing a parameter $\rho^{\uparrow\downarrow}$ that represents the rate of spin-flip transitions leading to (Fert and Campbell 1968)

$$\bar{\rho} = \frac{\rho^{\downarrow}\rho^{\uparrow} + \rho^{\uparrow\downarrow}(\rho^{\downarrow} + \rho^{\uparrow})}{\rho^{\downarrow} + \rho^{\uparrow} + 4\rho^{\uparrow\downarrow}} \tag{10}$$

The AMR originates from the different scattering rate of electrons that travel parallel or perpendicular to the direction of the magnetization. This is ascribed in general primarily to the spin–orbit coupling. Accordingly, it has been suggested that the AMR ratio can be expressed by (Campbell 1970)

$$\frac{\Delta\rho}{\bar{\rho}} = \gamma(\alpha - 1) \quad \text{with} \quad \alpha = \frac{\rho^{\downarrow}}{\rho^{\uparrow}} \tag{11}$$

where $\gamma$, primarily determined by spin–orbit coupling, describes the anisotropy of the spin-resolved resistivities according to

$$\rho_{\parallel}^{\uparrow} = \rho_{\perp}^{\uparrow} + \gamma\rho_{\perp}^{\downarrow}, \quad \rho_{\parallel}^{\downarrow} = \rho_{\perp}^{\downarrow} + \gamma\rho_{\perp}^{\uparrow} \tag{12}$$

In practice one determines the subband resistivities $\rho^{\uparrow(\downarrow)}$ and their ratio $\alpha$ indirectly by measuring deviations from Matthiessen's rule for the temperature dependence of the resistivity or for ternary alloys. The applicability of this model is shown in Fig. 3. Here experimental AMR ratios for various dilute nickel alloys are plotted as a function of experimental values for $\alpha$. Obviously, the data approximately lie on a straight line given by Eqn. (11), if $\gamma$ is chosen appropriately. However, for alloys for which $\alpha$ is close to unity, pronounced deviations from the behavior shown in Fig. 3 occur. Moreover, first-principles calculations have shown that the measured $\alpha$ is greatly reduced in comparison with values calculated on the basis of the two-current model because spin-mixing mechanisms are always present in real materials. These have been sometimes accounted for by using an extended version of Eqn. (11) (Campbell *et al.* 1970):

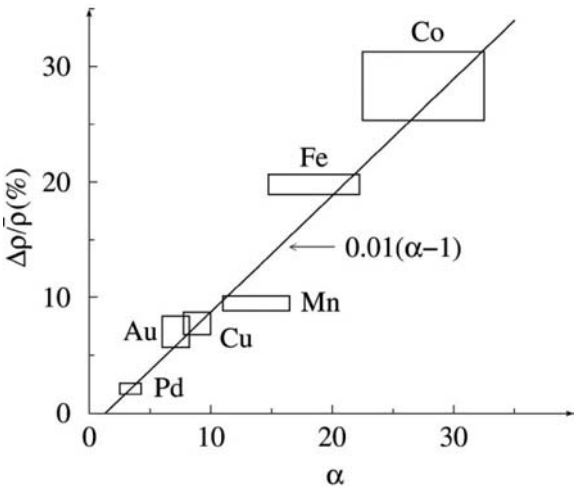

***Figure 3***
AMR ratio for various dilute nickel alloys NiX, with X = Pd, Au, Cu, Fe, Co (Campbell *et al.* 1970).

$$\frac{\Delta\rho}{\bar{\rho}} = \gamma\frac{(\rho^{\downarrow} - \rho^{\uparrow})\rho^{\downarrow}}{\rho^{\uparrow}\rho^{\downarrow} + \rho^{\uparrow\downarrow}(\rho^{\uparrow} + \rho^{\downarrow})} \tag{13}$$

## 5. Quantitative Models

The first step towards a quantitative description of AMR was the combination of the model described above with a calculation of the residual electrical resistivity of disordered alloys on the basis of Mott's two-current model (Akai 1977). This questionable approximation could be avoided by the development of a fully relativistic description for the AMR effect (Banhart and Ebert 1995). The starting point of this approach is the formulation of the conductivity tensor as a current–current–correlation function within the Kubo–Greenwood response formalism (Edwards 1958):

$$\sigma_{\mu\mu} = \frac{\hbar}{\pi V_{\text{cryst}}} Tr\langle j_{\mu}\text{Im}G^{+}(E_{\text{F}})j_{\mu}\text{Im}G^{+}(E_{\text{F}})\rangle_{\text{conf}} \tag{14}$$

A similar but somewhat more complex expression can be given for the off-diagonal elements $\sigma_{\mu\nu}$. In Eqn. (14) the underlying electronic structure of the system is described by the retarded electronic Green's function $G^+(E_F)$ for the Fermi energy $E_F$ (Butler 1985). In practice, this is calculated by means of multiple scattering theory.

Model calculations based on Eqn. (14) with the spin–orbit coupling manipulated reveal the role of this relativistic effect for AMR. Its major effect is to mix the minority and majority spin systems. As a consequence the two-current model in its strict sense is obviously not applicable. For the isotropic resistivity $\bar{\rho}$ it nevertheless gives reasonable results if the spin polarization at the Fermi level is not too high. This applies, for example, for the alloy systems $Co_xPd_{1-x}$ and $Co_xPt_{1-x}$, while for $Fe_xNi_{1-x}$ inclusion of the spin–orbit coupling increases $\bar{\rho}$ by up to an order of magnitude compared to a calculation based on the two-current model.

The model calculations also demonstrate that the AMR effect is indeed caused by the spin–orbit coupling with AMR increasing quadratically with its strength. In addition it is found that the spin–orbit coupling causes AMR nearly exclusively via the mixing of the spin systems. This implies in particular that contributions to the AMR due to the spin-diagonal part of the spin–orbit coupling can be neglected.

Use of the formalism described above leads for the conductivity tensor automatically to the structure given by Eqn. (1) that is required from symmetry considerations. As an example of its application, Fig. 4 shows results for the AMR ratio obtained for the alloy system $Co_xPd_{1-x}$ and $Co_xPt_{1-x}$ (without manipulating the spin–orbit coupling). The satisfying agreement implies that other possible sources of AMR, e.g., magnon scattering processes, can be neglected. Equation (14) has been exploited only to account for the residual resistivity caused by the chemical disorder in alloys. However, it also allows the incorporation of other mechanisms and supplies an appropriate basis to deal with the temperature dependency of AMR.

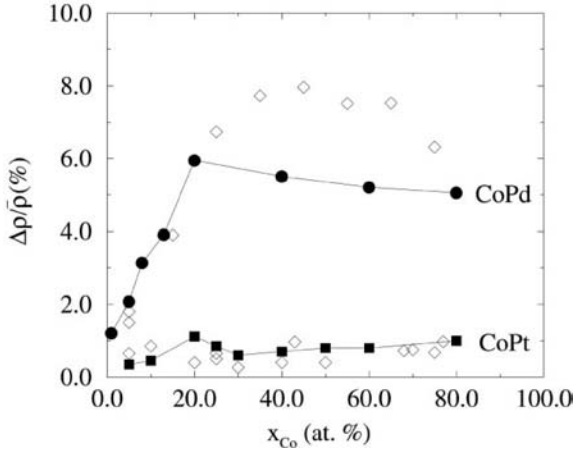

***Figure 4***
AMR ratio $\Delta\rho/\bar{\rho}$ for the alloy systems $Co_xPd_{1-x}$ and $Co_xPt_{1-x}$ at $T = 0\,K$ calculated by means of Eqn. (14) (filled symbols) and compared to experimental data (Ebert *et al.* 1996).

## 6. *Summary*

The AMR effect is a galvanomagnetic effect, which can be observed in any spontaneously magnetized material. Most experimental work that aimed to optimize the AMR ratio of materials applied in sensor and storage technology has been focused on transition metal alloys. For these systems, values for the AMR ratio of up to 30% have been found at low temperatures, with only a few percent remaining at room temperature.

A phenomenological description of the AMR effect is obtained by assuming an anisotropy in the transport properties, represented by a corresponding conductivity tensor. This anisotropy can primarily be ascribed to the presence of the spin–orbit coupling and the magnetic ordering. Starting from this, microscopic descriptions of the AMR effect have been developed. Most of this theoretical work has been based on Mott's two-current model together with the use of some parameters. Modern *ab initio* band structure calculations allow parameter-free calculations of AMR. Corresponding investigations essentially confirm the ideas of the previous more phenomenological work and supply a very detailed understanding for the physical mechanisms giving rise to AMR.

# Magnetoresistance: Magnetic and Nonmagnetic Intermetallics

The theory of the magnetoresistance of metals is concerned with the description of the motion of an electron under the combined influence of externally applied electric and magnetic fields (assuming thermal equilibrium, i.e., $\nabla T = 0$) in the internal periodic potential owing to the ionic lattice. As is discussed in *Boltzmann Equation and Scattering Mechanisms*, an external magnetic field influences the transport phenomena but does not contribute to a current in the same way as an electric field.

The Boltzmann theory will be used for the discussion of the general tendencies of the magnetoresistance.

Ohm's law for the electrical transport in metals in magnetic fields is given by

$$\vec{I} = \overleftrightarrow{\sigma}(T,\ \vec{B}) \cdot \vec{E} \tag{1}$$

where $\vec{I}$ is the electrical current density, $\vec{E}$ the electric field, and $\overleftrightarrow{\sigma}$ the temperature and magnetic field-dependent conductivity tensor. In the absence of an external magnetic field the conductivity becomes a scalar for a cubic lattice symmetry. If a magnetic field is applied this symmetry is broken, but the Onsager relationships still hold:

$$\sigma_{ij}(\vec{B}) = \sigma_{ji}(-\vec{B}) \tag{2}$$

The conductivity tensor, $\overleftrightarrow{\sigma}(\vec{B})$, for an isotropic (cubic) material with $\vec{B} = (0, 0, B\,\vec{e}_z)$ is given below from which the corresponding resistivity tensor, $\overleftrightarrow{\rho}(B)$, follows:

$$\overleftrightarrow{\sigma}(B) = \begin{pmatrix} \sigma_{xx}(B) & \sigma_{xy}(B) & 0 \\ -\sigma_{xy}(B) & \sigma_{xx}(B) & 0 \\ 0 & 0 & \sigma_{zz}(B) \end{pmatrix} \rightarrow$$

$$\overleftrightarrow{\rho}(B) = \begin{pmatrix} \rho_{\perp}(B) & \rho_H(B) & 0 \\ -\rho_H(B) & \rho_{\perp}(B) & 0 \\ 0 & 0 & \rho_{\parallel}(B) \end{pmatrix} \tag{3}$$

where $\rho_{\perp}$ and $\rho_{\parallel}$ are the resistivity in a transverse and a longitudinal external magnetic field, respectively, and $\rho_{\mathrm{H}}$ is the Hall resistivity.

The *transverse* and the *longitudinal magnetoresistance* are defined by (respectively):

$$\frac{\Delta\rho_{\perp}}{\rho} = \frac{\rho_{\perp}(T,B) - \rho(T,\ B=0)}{\rho(T, B=0)} \text{ and}$$

$$\frac{\Delta\rho_{\parallel}}{\rho} = \frac{\rho_{\parallel}(T,B) - \rho(T, B=0)}{\rho(T, B=0)} \tag{4}$$

## 1. Magnetoresistance in the Scope of the Boltzmann Formalism

In accordance with *Boltzmann Equation and Scattering Mechanisms* we assume that the electrons, moving through the periodic array of the ions in the lattice, can be described by Bloch waves. The semiclassical description of the movement of these packets is given by (see Eqn. (6) of *Boltzmann Equation and Scattering Mechanisms*):

$$\vec{v}_{\gamma} = \frac{1}{\hbar}\vec{\nabla}_k E_{n\sigma}(\vec{k}),\ \frac{\mathrm{d}\,\vec{k}}{\mathrm{d}t} = +\frac{e}{\hbar}[\vec{E} + (\vec{v}_{\gamma} \times \vec{B})] \tag{5}$$

where $\vec{E}$ and $\vec{B}$ are the electric and the magnetic fields, respectively, and $\vec{v}_{\gamma}$ is the velocity of a conduction electron.

We are looking for a distribution function as a solution of the Boltzmann equation under the simultaneous influence of an electric and a magnetic field. The Boltzmann equation can be written as:

$$\frac{\partial f}{\partial t} + \frac{e}{\hbar}[\vec{E} + (\vec{v}_{\gamma} \times \vec{B})] \cdot \vec{\nabla}_k f + \vec{v}_{\gamma} \cdot \vec{\nabla} f = \left(\frac{\partial f}{\partial t}\right)_{\mathrm{C}} \tag{6}$$

The term on the right-hand side of Eqn. (6) is the collision term, which is given by:

$$\left(\frac{\partial f}{\partial t}\right)_{\mathrm{C}} = \sum_{\gamma} \{ f(\gamma')[1 - f(\gamma)] P_{\gamma' \to \gamma} - f(\gamma)[1 - f(\gamma')] P_{\gamma \to \gamma'} \} \tag{7}$$

where $P_{\gamma' \to \gamma}$ is the quantum mechanical transition rate of an electron per unit time from state $\gamma'$ to state

$\gamma$. Focusing on stationary solutions only and considering small deviations from the equilibrium, a new function, $\Phi_\gamma$, is then defined through:

$$f = f_0 + f_1 \text{ with } f_1 = -\left(\frac{\partial f_0}{\partial \varepsilon_\gamma}\right)\Phi_\gamma \tag{8}$$

Equation (6) can be linearized, which then reads (see also Eqn. (36) of *Boltzmann Equation and Scattering Mechanisms*):

$$[C + \Omega]\Phi_\gamma = -e\left(\frac{\partial f_0}{\partial \varepsilon_\gamma}\right)\vec{v}_\gamma \cdot \vec{E} \tag{9}$$

where $C$ is the *collision operator* and $\Omega$ the *magnetic operator*. These operators are defined by (respectively):

$$C\Phi_\gamma = \frac{1}{k_B T}\sum_{\gamma'} W_{\gamma\gamma'}[\Phi_{\gamma'} - \Phi_\gamma] \tag{10}$$

$$\Omega\Phi_\gamma = -\frac{e}{\hbar}\frac{\partial f_0}{\partial \varepsilon_\gamma}(\vec{v}_\gamma \times \vec{B}) \cdot \vec{\nabla}_k \Phi_\gamma \tag{11}$$

where

$$W_{\gamma\gamma'} = f_0(\gamma')[1 - f_0(\gamma)]P_{\gamma' \to \gamma} = W_{\gamma'\gamma} \tag{12}$$

is the symmetric equilibrium transition probability in first order.

### 1.1 Solution of the Boltzmann Equation

A formal solution for the function $\Phi_\gamma$ of the linearized Boltzmann equation (Eqn. (9)) is given by:

$$\Phi_\gamma = -e[C + \Omega]^{-1}\left(\frac{\partial f_0}{\partial \varepsilon_\gamma}\right)\vec{v}_\gamma \cdot \vec{E} \tag{13}$$

For the current density it follows that:

$$\vec{I} = e\sum_\gamma \left(\frac{\partial f_0}{\partial \varepsilon_\gamma}\right)\vec{v}_\gamma \Phi_\gamma = -e^2 \sum_\gamma \left(\frac{\partial f_0}{\partial \varepsilon_\gamma}\right)\vec{v}_\gamma [C + \Omega]^{-1} \times \left(\frac{\partial f_0}{\partial \varepsilon_\gamma}\right)\vec{v}_\gamma \cdot \vec{E} = \overleftrightarrow{\sigma} \cdot \vec{E} \tag{14}$$

where $e$ is the charge, $\vec{v}_\gamma$ the drift velocity of the conduction electrons, and $\overleftrightarrow{\sigma}$ is the conductivity tensor.

### 1.2 Relaxation Time Approximation

In the scope of this concept the collision term is replaced by a function that is proportional to $f_1$. This function is a measure of the deviation from the thermal equilibrium in the conduction electron distribution weighted by the inverse relaxation time, $\tau_\gamma$:

$$\left(\frac{\partial f}{\partial t}\right)_C = -\frac{f - f_0}{\tau_\gamma} = -\frac{f_1}{\tau_\gamma} \tag{15}$$

which is equivalent to setting the collision operator of Eqn. (10) to:

$$C\Phi_\gamma = \left(\frac{\partial f_0}{\partial \varepsilon_\gamma}\right)\frac{1}{\tau_\gamma}\Phi_\gamma \tag{16}$$

The relaxation time, $\tau_\gamma$, can be anisotropic in k-space and different for each band.

## 2. Normal Magnetoresistance

The effect of an external magnetic field on the electrical resistivity can be considered as consisting of two parts. The first originates from the influence of the magnetic field on the conduction electron trajectories. In between collision events the Lorentz force deflects the electrons on their way through the specimen. This mechanism always increases the resistivity with the field. In the following it will be called "normal magnetoresistance." In practice one distinguishes between two limiting cases known as the "low"- and the "high"-field limit. Under usual experimental conditions with polycrystalline sample material one is always in the low-field limit where the conduction electron traverses a path in a plane perpendicular to the $B$-field and completes only a small arc before being scattered into another state in k-space. In order to provide an example of the influence of a magnetic field on the resistivity, $\rho(T)$ curves of $YAl_2$ at different magnetic fields are shown in Fig. 1. In inset (a) the temperature dependence of the resistivity at low temperatures in different external fields is given. Inset (b) shows the field dependence of the resistivity at different temperatures.

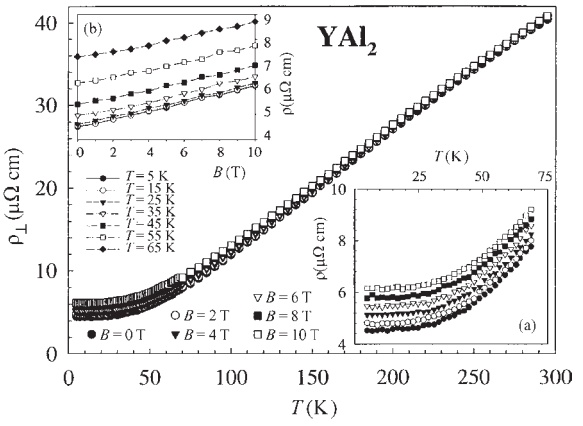

***Figure 1***
Temperature dependence of the resistivity of $YAl_2$ from 4 K to 300 K in transverse external magnetic fields of various strengths. Inset (a) shows details of the $\rho(B,T)$ curves at low temperatures. Inset (b) shows the field dependence of the resistivity for different temperatures.

### *2.1 Kohler Rule*

Before discussing the temperature variation of the normal magnetoresistance an important and useful rule, the Kohler rule, is discussed. This states that the magnetoresistance can be expressed as

$$\frac{\Delta\rho}{\rho} = \Psi\left(\frac{B}{\rho(B=0,T)}\right) \tag{17}$$

where $\Psi$ is a general function characteristic of a particular sample material. Rigorously, Eqn. (17) can be justified only if there is a single species of charge carrier (i.e., one conduction band model) and the relaxation time is the same at all points on the Fermi surface. Fortunately the Kohler rule has been found to be a good approximation in many cases where a single scattering mechanism dominates. In the inset of Fig. 2 a so-called Kohler plot of $YAl_2$ is shown, and it is clear that there are only small deviations from a universal curve at very low temperature ranges. Kohler plots for the two isostructural compounds $YAl_2$ and $YNi_2$ have been compared (Gratz *et al.* 1995). In $YNi_2$ a considerable deviation from the universal curve has been found at lower temperatures for all fields, this being associated with its high residual resistivity. This derives from the impurity scattering, which at low temperature is the dominant relaxation mechanism. However, as the temperature increases the phonon scattering with another relaxation time becomes the dominant scattering mechanism.

The temperature variation of the transverse magnetoresistance ($\Delta\rho_\perp/\rho$) of $YAl_2$ is shown in Fig. 2. $YAl_2$ is a representative example of many other nonmagnetic compounds, such as YAg, LuAg, $YCu_2$, and $LuCu_2$, which show qualitatively a similar temperature variation of $\Delta\rho_\perp/\rho$ as $YAl_2$ (Gratz *et al.* 2001). Figure 2 shows that as the temperature increases the influence of the external magnetic field on the resistivity decreases. The increase of $\Delta\rho_\perp/\rho$ with increasing field strength, $B$, at low temperatures is closely related to the $\rho_0$ value of the sample, and this may be highlighted with an example. The value of $\Delta\rho_\perp/\rho$ at 4.2 K and 10 T for a YAg sample (cubic CsCl structure, $\rho_0 = 1.8\,\mu\Omega$cm) is 18%. The $\Delta\rho_\perp/\rho$ value for an isostructural sample where 20% of yttrium has been replaced by lutetium ($Y_{0.8}Lu_{0.2}Ag$, i.e., $\rho_0$ has been increased to 3.6 μΩcm) is only about 6% at 10 T.

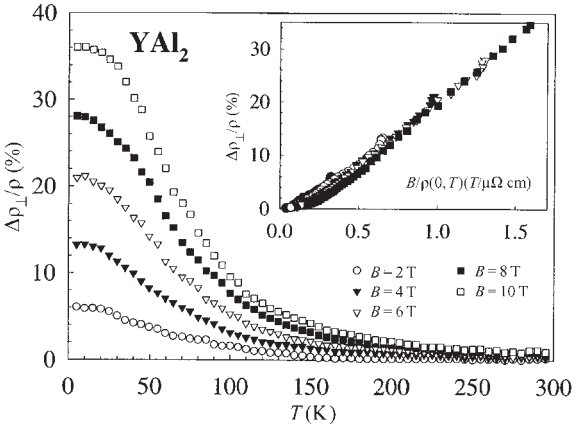

***Figure 2***
Transverse magnetoresistance of $YAl_2$ for various field strengths. Inset shows the Kohler plot for $YAl_2$.

### *2.2 Temperature and Field Dependence of the Normal Magnetoresistance*

There have been several successful attempts to calculate the temperature dependence of $\Delta\rho_\perp/\rho$ (e.g., Blatt 1968). In the following a short outline of the model and the underlying assumptions on which such a calculation is based are given (we make use of what is discussed in *Boltzmann Equation and Scattering Mechanisms*).

In accordance with Eqn. (36) of *Boltzmann Equation and Scattering Mechanisms*, we assume an external force, $X$, in the direction $X // \vec{e}_i$ with $i = x,y,z$:

$$(C+\Omega)\phi_{\gamma i} = Z_{\gamma i} = -\left(\frac{\partial f_0}{\partial \varepsilon_\gamma}\right) v_{\gamma i} X_i \tag{18}$$

Assuming for the moment that $\Omega = 0$, multiplying from the left by $\phi_{\gamma j}$, and summing over $\gamma$ we obtain:

$$\sum_\gamma \phi_{\gamma j} C \phi_{\gamma i} = \sum_\gamma Z_{\gamma i}\phi_{\gamma j} = \sum_\gamma \phi_{\gamma i} C \phi_{\gamma j} = \sum_\gamma Z_{\gamma j}\phi_{\gamma i} \tag{19}$$

(where the symmetry of the operator $C$ has been used).

The components of the conductivity tensor are given by:

$$\sigma_{ij} = -\frac{e^2}{\mathrm{Vol} X_i X_j}\sum_\gamma (Z_{\gamma i}\phi_{\gamma j} + Z_{\gamma j}\phi_{\gamma i} - \phi_{\gamma i} C \phi_{\gamma j}) \tag{20}$$

It can be shown that a functional of the form:

$$F_{ij}[\Phi] = -\frac{e^2}{\mathrm{Vol} X_i X_j}\sum_\gamma (Z_{\gamma i}\Phi_{\gamma j} + Z_{\gamma j}\Phi_{\gamma i} - \Phi_{\gamma i} C \Phi_{\gamma j}) \tag{21}$$

takes an extremal value for $\Phi = \phi$ and gives $\sigma_{ij}$ (see Eqn. (20)). Therefore, one can determine $\Phi$ using the variational principle with the functional given by Eqn. (21). Searching for the extremal value of this functional by varying $\Phi$ in a subspace one finally obtains an approximation for the conductivity tensor. The application of the variational principle is more

difficult if there exists simultaneously an external magnetic field. However, one can still find a functional which shows an extremal value. In this case one has to make use of the solution of the Boltzmann equation for the two opposite $B$-field directions $B^+$ and $B^-$ (see Eqn. (18)):

$$(C+\Omega)\phi^+_{\gamma i} = -\left(\frac{\partial f_0}{\partial \varepsilon_\gamma}\right) v_{\gamma i} X_i = Z_{\gamma i}$$
$$(C-\Omega)\phi^-_{\gamma i} = -\left(\frac{\partial f_0}{\partial \varepsilon_\gamma}\right) v_{\gamma i} X_i = Z_{\gamma i}$$

The conductivity tensor in the presence of an external magnetic field is similar to that in Eqn. (20) and is given by:

$$\sigma_{ij}(\vec{B}) = -\frac{e^2}{\mathrm{Vol} X_i X_j} \times \sum_\gamma [Z_{\gamma i}\phi^+_{\gamma j} + Z_{\gamma j}\phi^-_{\gamma i} - \phi^-_{\gamma i}(C+\Omega)\phi^+_{\gamma j}] \quad (23)$$

Equation (23) leads to the corresponding functional (see Eqn. (21)):

$$F_{ij}[\Phi^+_j, \Phi^-_j] = -\frac{e^2}{\mathrm{Vol}\ X_i X_j} \times \sum_\gamma [Z_{\gamma i}\Phi^+_{\gamma j} + Z_{\gamma j}\Phi^-_{\gamma i} - \Phi^-_{\gamma i}(C+\Omega)\Phi^+_{\gamma j}] \quad (24)$$

We use for the trial functions the ansatz:

$$\Phi^+_{\gamma i} = \sum_{m=1}^{3} \alpha^{im}_{n\sigma} v_{\gamma m}; \quad \Phi^-_{\gamma j} = \sum_{m=1}^{3} \beta^{jm}_{n\sigma} v_{\gamma m} \quad (25)$$

where $v_{\gamma m}$ is a velocity component and the subscripts $n$ and $\sigma$ are the band index and the spin direction, respectively. A function depending on the parameters $\alpha$ and $\beta$ follows from the functional. These parameters are determined by:

$$\frac{\partial F_{ij}[\Phi^-_j, \Phi^+_i]}{\partial \alpha^{im}_{n\sigma}} = 0; \quad \frac{\partial F_{ij}[\Phi^-_j, \Phi^+_i]}{\partial \beta^{jm}_{n\sigma}} = 0 \quad (26)$$

Under the assumption of cubic symmetry and two types of charge carriers (two-band model) and a field with an orientation $\vec{B} = {}^0\vec{e}_z B$, one obtains the following for the transverse resistivity:

$$\rho_\perp(B,T) = -\frac{\mathrm{Vol}(X_x)^2}{e^2} \times \left\{ \begin{array}{l} \bar{C}^{\mathrm{I}}_{xx}\bar{C}^{\mathrm{II}}_{xx}[(\bar{Z}^{\mathrm{I}}_{xx})^2(\bar{C}^{\mathrm{II}}_{xx}) + (\bar{Z}^{\mathrm{II}}_{xx})^2(\bar{C}^{\mathrm{I}}_{xx})] + \\ [(\bar{Z}^{\mathrm{I}}_{xx})^2(\bar{l}^{\mathrm{II}})^2(\bar{C}^{\mathrm{I}}_{xx}) + (\bar{Z}^{\mathrm{II}}_{xx})^2(\bar{l}^{\mathrm{I}})^2(\bar{C}^{\mathrm{II}}_{xx})]B^2 \end{array} \right\} \times \{[(\bar{Z}^{\mathrm{I}}_{xx})^2(\bar{C}^{\mathrm{II}}_{xx}) + (\bar{Z}^{\mathrm{II}}_{xx})^2(\bar{C}^{\mathrm{I}}_{xx})]^2 + [(\bar{Z}^{\mathrm{I}}_{xx})^2\bar{l}^{\mathrm{II}} + (\bar{Z}^{\mathrm{II}}_{xx})^2\bar{l}^{\mathrm{I}}]^2 B^2\}^{-1} \quad (27)$$

where the superscripts I and II denote the two bands for which the calculation must be performed.

The following abbreviations have been used:

$$\bar{C}^{n\sigma}_{ij} = \mathrm{Vol}\int_{BZ} \frac{\mathrm{d}^3k}{(2\pi)^3} v_{\gamma i} C v_{\gamma j} \quad (28)$$

$$\bar{Z}^{n\sigma}_{ij} = \mathrm{Vol}\int_{BZ} \frac{\mathrm{d}^3k}{(2\pi)^3} Z_{\gamma i} v_{\gamma j} \quad (29)$$

$$\bar{l}^{n\sigma} = \bar{l}^{n\sigma}_{xyxy} - \bar{l}^{n\sigma}_{xxyy} \quad (30)$$

$$\bar{l}^{n\sigma}_{irsj} = -\mathrm{Vol}\frac{e}{\hbar c}\int_{BZ} \mathrm{d}^3k \left(\frac{\partial f_0}{\partial \varepsilon_\gamma}\right) v_{\gamma i} v_{\gamma r} \frac{\partial}{\partial k_s} v_{\gamma j} \quad (31)$$

The resistivity without an external magnetic field ($B=0$) in a two-band model ($n=$I,II) is then given by:

$$\rho(B=0,T) = -\frac{\mathrm{Vol}(X_x)^2}{e^2} \times \frac{\bar{C}^{\mathrm{I}}_{xx}\bar{C}^{\mathrm{II}}_{xx}}{[(\bar{Z}^{\mathrm{I}}_{xx})^2(\bar{C}^{\mathrm{II}}_{xx}) + (\bar{Z}^{\mathrm{II}}_{xx})^2(\bar{C}^{\mathrm{I}}_{xx})]} \quad (32)$$

Accordingly, the resistivity for only one conduction band ($n=1$, $\bar{C}^{\mathrm{II}}_{xx} \to \infty$) is given by:

$$\rho(B=0,T) = -\frac{\mathrm{Vol}(X_x)^2}{e^2}\frac{\bar{C}^{\mathrm{I}}_{xx}}{(\bar{Z}^{\mathrm{I}}_{xx})^2} = -\frac{1}{e^2}\frac{\bar{C}_{xx}}{n\left[\frac{2}{(2\pi)^3}\int \mathrm{d}^3k \frac{\partial f_0}{\partial \varepsilon_\gamma} v^2_{\gamma x}\right]^2} \quad (33)$$

For the calculation of the transverse magnetoresistance defined by Eqn. (4), we combine Eqns. (27) and (32) and obtain (after extensive calculations, the details of which and a critical discussion of the underlying assumptions are given in Gratz *et al.* (2001)) the following simple relationship:

$$\frac{\Delta\rho_\perp}{\rho} = \frac{B^2}{a[\rho(B=0,T)]^2 + bB^2} \quad (34)$$

where $a$ and $b$ are field- and temperature-independent parameters, depending on the properties of the two different conduction bands.

### *2.3 Analysis of Magnetoresistance Data of Nonmagnetic Compounds*

From Eqn. (34) it follows that in order to calculate the temperature variation of the transverse classical magnetoresistance one simply needs to know the temperature dependence of the resistivity in zero magnetic field. In order to fit $\Delta\rho_\perp/\rho$ for $YAl_2$ (shown

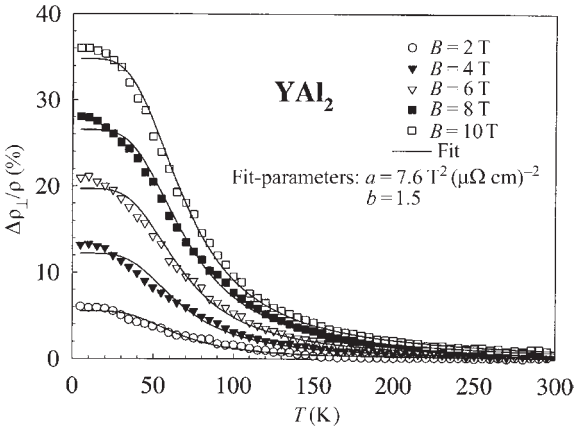

***Figure 3***
Solid lines are the result of fit procedures of Eqn. (34) ($a$ and $b$ are the fit parameters in Eqn. (34), see text) to the experimentally determined transverse magnetoresistance data of $YAl_2$ (symbols).

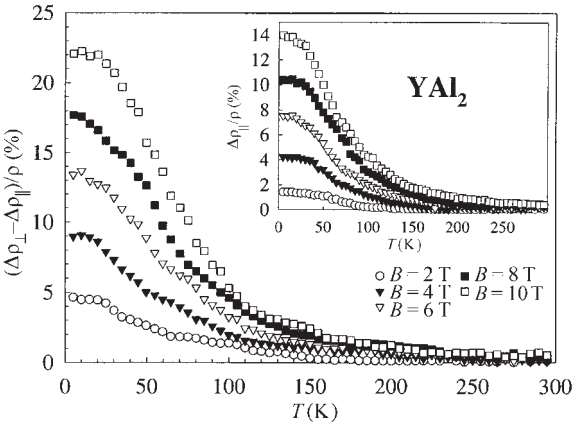

***Figure 4***
Anisotropy of the normal magnetoresistance $(\Delta\rho_\perp - \Delta\rho_\parallel)/\rho$. Inset shows the temperature variation of the longitudinal magnetoresistance of $YAl_2$ for various field strengths.

in Fig. 2) one can use the Bloch–Grüneisen relationship (Eqn. (9) of *Intermetallic Compounds: Electrical Resistivity*):

$$\rho(B=0,T) = \rho_0 + \rho_{\mathrm{ph}} = \rho_0 + 4R_\Theta \times \left(\frac{T}{\Theta}\right)^5 \int_0^{\Theta/T} \frac{x^5 \mathrm{d}x}{(\mathrm{e}^x - 1)(1 - \mathrm{e}^{-x})} \qquad (35)$$

The result of a fit of Eqn. (34) to the experimental data for $YAl_2$ is given in Fig. 3 by the solid lines. The residual resistivity of the $YAl_2$ sample is 4.4 μΩcm (see inset (a) of Fig. 1), and the two fit parameters in the Bloch–Grüneisen law are $R_\Theta = 35$ μΩcm (this value represents the resistivity at the Debye temperature) and $\Theta = 310$ K (the Debye temperature of $YAl_2$). The two fit parameters in Eqn. (34) are $a = 7.6\,\mathrm{T}^2$ $(\mu\Omega\mathrm{cm})^{-2}$ and $b = 1.5$.

*(a) Anisotropy of the normal magnetoresistance*

The above calculations concern the transverse magnetoresistance; however, in all of the compounds studied, there is always a smaller but nonvanishing longitudinal magnetoresistance observed. In the inset of Fig. 4 the longitudinal magnetoresistance $(\Delta\rho_\parallel/\rho)$ is shown. The anisotropy of the magnetoresistance, defined as $(\Delta\rho_\perp - \Delta\rho_\parallel)/\rho$, of the $YAl_2$ sample under consideration is shown in the main part of Fig. 4.

In the case of free electrons occupying a spherical Fermi surface, both the transverse and the longitudinal magnetoresistance vanish identically. For $\Delta\rho_\perp/\rho$ simple arguments can be given, the transverse electric Hall field is just sufficient to compensate for the deflection produced by the magnetic field. When there are two types of carrier, the resulting Hall field is an average of the two, and therefore cannot exactly compensate for the external magnetic field. For $\Delta\rho_\parallel/\rho$ it can be argued that the electrons travel down the magnetic lines of force, under the influence of the magnetic field, as if the magnetic field does not exist. It is clear from experiments that in order to account for the nonvanishing longitudinal magnetoresistance a more complicated theory must be developed than that provided by Eqn. (27).

## *3. Magnetoresistance in Ferromagnetic Rare-earth (RE) Compounds*

The situation is even more complex in compounds where the RE ions bear magnetic moments, since spin-dependent scattering processes are also involved, below as well as above the magnetic ordering temperature. The resistivity of $GdAl_2$ for various transverse magnetic fields is presented in Fig. 5. The change of the $\rho(T)$ curves with the magnetic field is typical of ferromagnetic compounds. In inset (a) of Fig. 5, the transverse magnetoresistance of $GdAl_2$ in the vicinity of the Curie temperature ($T_C = 168$ K) is shown.

One of the first studies of the magnetic contribution to the resistivity using a mean field theory was made by Kasuya (1968). A comprehensive theoretical treatment of the magnetoresistance in the ferromagnetic and antiferromagnetic state was carried out by Yamada and Takada (1973a, 1973b). In the following we provide a brief calculation of the magnetoresistance in a ferromagnet.

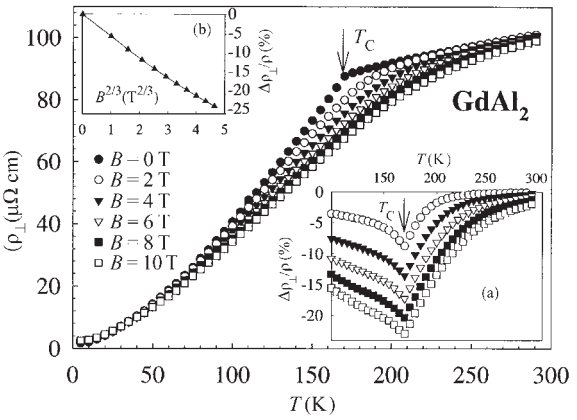

***Figure 5***
Temperature dependence of the resistivity of $GdAl_2$ from 4 K to 300 K in transverse magnetic fields of various strengths. Inset (a) shows details of the transverse magnetoresistance in the vicinity of the Curie temperature of $GdAl_2$ ($T_C = 168$ K). Inset (b) shows the $B^{2/3}$ dependence of the transverse magnetoresistance of $GdAl_2$ at the Curie temperature.

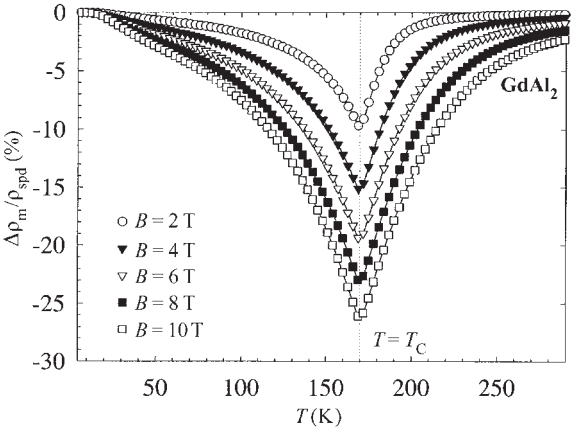

***Figure 6***
Calculated temperature dependence of the spin-dependent magnetoresistance ($\Delta\rho_m \equiv \rho_m(B,T) - \rho_m(0,T)$) for different field strengths of $GdAl_2$ plotted as $\Delta\rho_m/\rho_{spd}$ vs. $T$ ($\rho(GdAl_2)_{spd} = 72\ \mu\Omega$cm, $J = 7/2$).

### *3.1 Magnetic Scattering in the Molecular Field Approximation*

For this calculation we make use of the corresponding equations in *Boltzmann Equation and Scattering Mechanisms*. Combining Eqns. (81a), (84a), and (85a) in a molecular field approximation for a RE element with a total quantum number $J$, we obtain the following expression for the resistivity owing to spin-dependent scattering:

$$\rho_m(B,T) = C_m \frac{1}{J(J+1)} \left( \langle J_z^2 \rangle - \langle J_z \rangle^2 + \frac{\eta \langle J_z \rangle}{\sinh^2 \eta} \right) \tag{36}$$

where $\langle \ldots \rangle$ denotes the thermodynamical expectation value in the molecular field approximation. Here

$$\langle J_z^2 \rangle = J(J+1) - \langle J_z \rangle \coth \eta \tag{37}$$

and

$$\langle J_z \rangle = J B_J(2J\eta) \tag{38}$$

where $B_J(2J\eta)$ is the Brillouin function and $\eta$ is a function of the reduced temperature, $T/T_C$, given by:

$$\eta = \frac{T_C}{T} \left[ \frac{3}{2J(J+1)} \langle J_z \rangle + \frac{g\mu_B}{2k_B T_C} B \right] \tag{39}$$

Note that Eqn. (39) differs from Eqn. (83c) of *Boltzmann Equation and Scattering Mechanisms* since an external magnetic field, $B$, is now taken into consideration.

The prefactor in Eqn. (36) is given by:

$$C_m = \frac{\pi}{\hbar e^2} \frac{3N|\bar{G}|^2}{\mathrm{Vol} v^2(\varepsilon_F)} (g-1)^2 J(J+1) \tag{40}$$

In Fig. 7 of *Intermetallic Compounds: Electrical Resistivity* the experimentally determined spin disorder resistivity, $\rho_{spd}$ ($= C_m$, see Eqn. (82a) of *Boltzmann Equation and Scattering Mechanisms*), is shown for some $REAl_2$ and REPt compounds. As can be seen from this figure, $\rho_{spd}$ ($= \rho_m(T > T_C)$) is proportional to the deGennes factor, $(g-1)^2 J(J+1)$, which means that $|\bar{G}|^2$ and $v^2(\varepsilon_F)$ are approximately the same across these series.

By combining Eqns. (36)–(40), $\Delta\rho_m/\rho_{spd}$ can be calculated, which describes the difference in the magnetic (spin-dependent) resistivity with and without an external magnetic field, normalized to $\rho_{spd}$ ($= \rho_m$ ($T \to \infty$)). The formula obtained in this way covers the temperature range below and above $T_C$ and can be calculated for different external magnetic field strengths.

Calculated $\Delta\rho_m/\rho_{spd}$ vs. $T$ curves for $GdAl_2$ ($J = 7/2$, $\rho_{spd} = 72\ \mu\Omega$cm, $T_C = 168$ K) for various magnetic field strengths are shown in Fig. 6.

The problem with Eqn. (39) is that a value for $\eta$ is not easily obtained, since $\eta$ appears also in the argument of the Brillouin function (Eqn. (39) represents an implicit function for $\eta$). Furthermore, Eqns. (36) and (37) include $\eta$ as $\sinh \eta$ and $\coth \eta$, respectively.

For limited temperature regions below and above $T_C$ and at $T = T_C$, simple expressions can be obtained

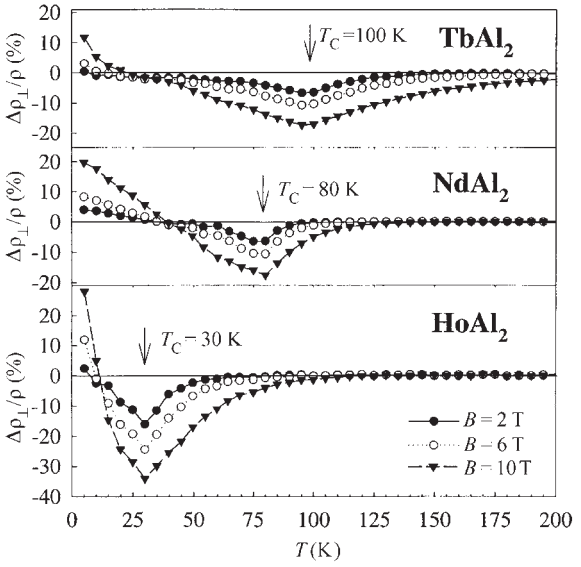

***Figure 7***
Temperature variation of the transverse magnetoresistance of $REAl_2$ compounds, with decreasing magnetic ordering temperatures and at various field strengths. The positive $\Delta\rho_\perp/\rho$ values towards the low-temperatures region are caused by the normal magnetoresistance, which is superimposed on the negative spin-dependent magnetoresistance.

for $\Delta\rho_m/\rho_{spd}$. There are three basic regions:

(i) Paramagnetic region for $T \gg T_C$:

$$\frac{\Delta\rho_m}{\rho_{spd}} = -C_1 \frac{h^2}{(T/T_C - 1)^2} \tag{41}$$

where

$$C_1 = \frac{4(J^2 + J + 1)}{9};\ h = \frac{g\mu_B}{2k_B T_C} B \tag{42}$$

and under the condition $(T/T_C - 1) \gg h$.

(ii) Magnetically ordered region for $T < T_C$:

$$\frac{\Delta\rho_m}{\rho_{spd}} = -C_1 h \left(\frac{C_2}{1 - T/T_C}\right)^{1/2} \tag{43}$$

where

$$C_2 = \frac{2(2J^2 + 2J + 1)}{15} \tag{44}$$

and under the condition $1 \gg [1-(T/T_C)]^3 \gg h^2$.

(iii) For the increase of the minimum at $T \cong T_C$, with increasing magnetic field:

$$\frac{\Delta\rho_m}{\rho_{spd}} = -C_1 \left(\frac{h}{C_2}\right)^{2/3} \tag{45}$$

under the condition $[(T/T_C) - 1]^2 \ll h^2$. From Eqn. (45) it follows that $|\Delta\rho_m/\rho_{spd}|$ at $T_C$ increases proportional to $B^{2/3}$.

### *3.2 Analysis of the Magnetoresistance in Ferromagnetic Compounds*

A confirmation of Eqn. (45) is shown in inset (b) of Fig. 5 for $GdAl_2$. It is found that a fit of Eqn. (36) to the experimental data for $GdAl_2$ gives good agreement in the paramagnetic temperature range and in fields up to about 6 T, and below $T_C$ (= 168 K) down to roughly 80 K. In order to subtract the normal magnetoresistance from the experimental data, the magnetoresistance of $YAl_2$ (see Fig. 2) is used, which is normalized to the residual resistivity of $GdAl_2$ at the corresponding field strength. (The normalization is necessary, since $GdAl_2$ and $YAl_2$ do not show the same residual resistivity.)

Not such a good agreement is found for other $REAl_2$ compounds, because of the following:

(i) For lower values of $T_C$ in $REAl_2$ compounds, the correction for the normal magnetoresistance becomes more important. In order to demonstrate that the normal magnetoresistance gives rise to positive $\Delta\rho/\rho$ values at low temperatures, data for other magnetic $REAl_2$ compounds (with R = Tb, Nd, or Ho) with decreasing $T_C$ values are presented in Fig. 7.

(ii) Equation (36) is based on the molecular field concept, which is not valid in the spin wave region at low temperatures.

(iii) An influence of the crystal electric field might also play a role in the temperature dependence of $\Delta\rho_m/\rho_{spd}$ and this is not accounted for in Eqn. (36).

A comprehensive discussion of the magnetoresistance in ferromagnetic iron, cobalt, and nickel compounds is given by Campbell and Fert (1982).

#### *(a) Anisotropy of the magnetoresistance in ferromagnetic compounds*

In all these compounds the anisotropy curves ($(\Delta\rho_\perp - \Delta\rho_\parallel)/\rho$ vs. $T$) show a sharp change at the onset of the ferromagnetic order. It is interesting to note that $(\Delta\rho_\perp - \Delta\rho_\parallel)/\rho$ for $T < T_C$ is positive for the light $REAl_2$ compounds and mainly negative for the heavy $REAl_2$ compounds (Gratz *et al.* 2001). The problem of the anisotropy of RE impurities in a noble metal matrix has been attributed to hybridization of the valence electron states of the RE impurities with conduction electron states (Lacueva *et al.* 1982).

## *4. Magnetoresistance in Antiferromagnetic RE Compounds*

It is obvious that the situation is more complex in the case of an "antiferromagnetic" spin arrangement, since there are a very large number of possible spin

configurations. The spin arrangements, which in addition depend on the strength (and direction; however, only in a single-crystal sample, see *Elemental Rare Earths: Magnetic Structure and Resistance, Correlation of* ) of the applied external field, are most important for the sign and the value of this spin-dependent magnetoresistance. Furthermore, there is an effect associated with the shape of the Fermi surface, which alters in an antiferromagnet, since the spin ordering has a periodicity different from that of the lattice and additional (magnetic) Brillouin zones appear below $T_N$. This effect is sometimes called the "superzone boundary effect" (Elliott and Wedgwood 1963).

In the paramagnetic state ($T > T_N$) there is, in principle, no difference to that which occurs in a ferromagnetic material with a negative magnetoresistance at a given temperature above $T_N$, $\Delta\rho_m/\rho_{spd} \propto - B^2$ (Eqn. (41)).

Yamada and Takada (1973a, 1973b) discussed the field and temperature dependence of $\Delta\rho_m/\rho_{spd}$ for two simple magnetic moment configurations in the antiferromagnetic ordered state. The assumption is made that there are two magnetic sublattices with opposite magnetic moments. These sublattices can have moments aligned either parallel or perpendicular to the external $B$-field. In the latter case there is no influence of $B$ on $\Delta\rho_m/\rho_{spd}$ if the moments in both sublattices are perpendicular to $B$ (e.g., see the transverse $c$-axis magnetoresistance in erbium for $T = 60$ K shown in Fig. 5 of *Elemental Rare Earths: Magnetic Structure and Resistance, Correlation of* ). In the former case there is an influence on $\Delta\rho_m/\rho_{spd}$, since the external field creates disorder in the sublattice with the opposite orientated spin arrangement (see the transverse $a$-axis magnetoresistance in erbium for $T = 64$ K in Fig. 4 of *Magnetic Structure and Resistance in Elemental Rare Earths, Correlation of* ). Thus, $\Delta\rho_m/\rho_{spd}$ is positive. If the $B$-field strength (necessary to induce a ferromagnetic spin arrangement) exceeds the critical field, $\Delta\rho_m/\rho_{spd}$ starts to decrease as in a ferromagnet. The corresponding formula derived by Yamada and Takada (1973a) for $T < T_N$ is

$$\frac{\Delta\rho_m}{\rho_{spd}} = \chi_2(T/T_N) \cdot h^2 \qquad (46)$$

where $h = (g\mu_B/2k_BT_N)B$. The function $\chi_2$ includes an important parameter $\alpha$ ($= V(0)/V(Q)$, where $Q$ is the wave vector of the antiferromagnetic spin arrangement and $V(0)/V(Q)$ describes the relative strength of the nearest-neighbor interaction in the magnetic lattice). The condition for antiferromagnetism is $V(Q) > V(0)$ ($\alpha < 1$) and for ferromagnetism $V(Q) < V(0)$ ($\alpha > 1$). The calculated temperature variation of the function $\chi_2(T/T_N)$ for different $\alpha$ values (according to Eqn. (3.16) in Yamada and Takada (1973a)) is shown in Fig. 8. It can be seen that the discontinuity at $T_N$ increases with increasing $\alpha$.

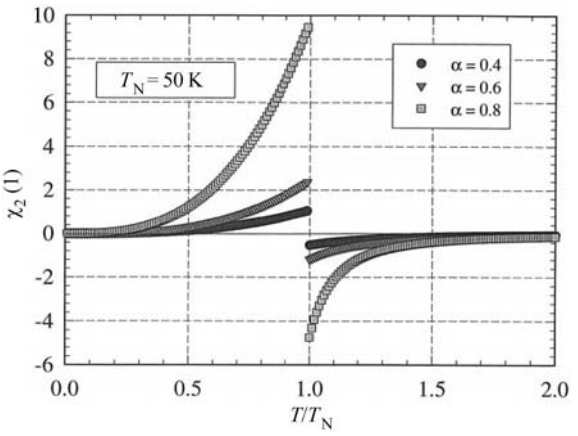

***Figure 8***
Temperature variation of the function $\chi_2(T/T_N)$ calculated for different $\alpha$ values and for a Neel temperature of 50 K (according to Eqn. (3.16) in Yamada and Takada (1973a)).

### *4.1 Analysis of the Magnetoresistance in Antiferromagnetic Compounds*

In order to give an example of the magnetoresistance of an antiferromagnetic moment configuration, DyAg ($T_N = 56$ K) will be considered. The REAg compounds crystallize in the cubic CsCl-type structure. Neutron diffraction studies show that DyAg has an antiferromagnetic spin arrangement of the $(\pi,\pi,0)$ type below $T_f = 46.5$ K. At temperatures $T_f < T < T_N$ a sinusoidally modulated spin wave propagation exists along the $\langle 110 \rangle$ direction, polarized in the $\langle 001 \rangle$ direction (Kaneko *et al.* 1987). Figure 9 shows $\Delta\rho_\perp/\rho$ vs. $T$ for DyAg, which is typical of many of these polycrystalline cubic REAg antiferromagnetic compounds. The analysis of these magnetoresistance data, using the above-outlined concept, is shown in the following. For the determination of the function $\chi_2(T/T_N)$ from the $\Delta\rho_\perp/\rho$ data, the magnetoresistance of LuAg is used to correct for the normal magnetoresistance. The function $\chi_2$ thus obtained (using Eqn. (46)) for DyAg is shown in the inset of Fig. 9. Except for the temperature region $T_f < T < T_N$, where there is a sinusoidally modulated spin configuration, the function $\chi_2(T/T_N)$ is basically independent of the magnetic field strength, as it should be. This result exemplifies the correspondence with the calculation shown in Fig. 8 (especially in the paramagnetic range).

For fields smaller than the critical field, in many antiferromagnetic compounds a step-like change of $\Delta\rho/\rho$ at $T_N$ has been observed. The experimental evidence of a discontinuity can serve as a first proof as to whether a noncollinear spin structure appears at the magnetic ordering temperature.

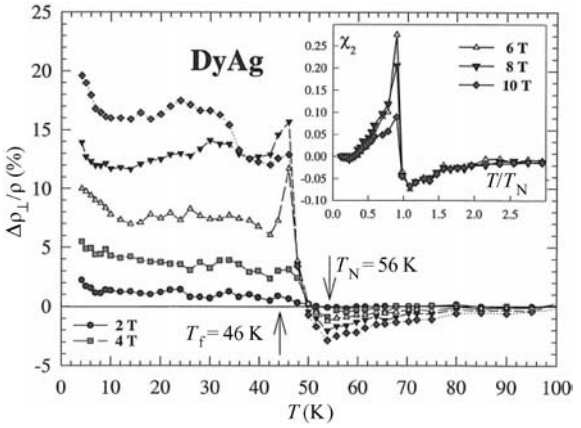

***Figure 9***
Temperature variation of the transverse magnetoresistance of the cubic antiferromagnetic DyAg compound. $\Delta\rho_\perp/\rho$ vs. $T$ shows the characteristic increase at the onset of the antiferromagnetic ordering. Inset shows the temperature variation of $\chi_2(T/T_N)$ determined from experiment for DyAg. It exemplifies the correspondence with the theoretical $\chi_2$ function shown in Fig. 8. The agreement is less good for the temperature region with the sinusoidally modulated spin configuration ($T_f < T < T_N$).

### 5. *Summary*

The influence of an external magnetic field on the resistivity is the subject of this article. The effect of a field on the electrical resistivity can be considered as consisting of two parts. The first originates from the influence of the magnetic field on the conduction electron trajectories owing to the Lorentz force, which deflects the electrons on their way through the specimen. This mechanism always increases the resistivity with increasing field. The other part is owing to the influence of the external magnetic field on the magnetic state and thus on the spin-dependent scattering mechanism. The effect is that in the paramagnetic and the ferromagnetic cases the resistivity decreases with increasing field, whereas in the antiferromagnetic state an increase of the magnetoresistance is in general expected.

## Magnetoresistive Heads: Physical Phenomena

Electrical resistivity is a powerful probe of the electronic and physical structure of a material. This sensitivity has resulted in electrical resistance commonly being used to sense indirectly other material properties such as temperature or defect concentration. Electrical resistance can also vary with the magnetic state of the material, magnetoresistance, stimulating the development of magnetoresistive magnetic field sensors that are not compromised by the inherent speed dependence of inductive field sensing. The anisotropic magnetoresistance (AMR) (McGuire and Potter 1975) of bulk ferromagnetic materials has,

until recently, provided the greatest potential for magnetic field sensors.

The development of the technology to create magnetic thin-film structures with layer thicknesses of the order of the electron mean free path led to the discovery of giant magnetoresistance (GMR) (Baibich *et al*. 1988) that promised an increase of one to two orders of magnitude in field sensitivity (see *Giant Magnetoresistance*). GMR sensors are now to be found as the field-sensing element in the read heads of commercial hard disks (Toigo 2000). The origins of GMR lie in the spin-dependent scattering experienced by an electron traveling through the material that results from the spin-polarized electronic band structure of a ferromagnetic material. Both intrinsic and extrinsic factors affect the magnitude and field sensitivity of the GMR.

## 1. AMR

AMR was first discovered by Lord Kelvin. Due to spin–orbit coupling, the orientation of the electron orbitals in a ferromagnetic material is determined by the direction of the magnetic field (see *Magnetoresistance, Anisotropic*). This results in a greater scattering cross-section for a transport electron when the direction of the current is parallel to the applied field (McGuire and Potter 1975) (see Fig. 1):

$$\rho = \rho_0 + \Delta\rho_{\mathrm{AMR}} \cos^2\theta \qquad (1)$$

where $\theta$ is the angle between the applied field and the current. This effect is greatest in materials with large spin–orbit coupling such as $Ni_{80}Fe_{20}$ where magnetoresistance values of 4% are possible.

## 2. Origin of Spin-dependent Transport

The band structure of the free electron like s electrons in ferromagnetic materials is not spin polarized; however, they have the highest mobility and would be expected to be responsible for carrying the majority of the current. However, the 3*d* electrons have the greatest density of states at the Fermi surface and

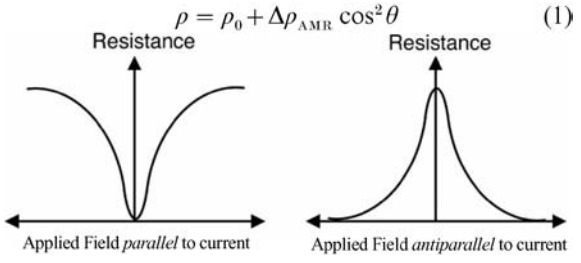

***Figure 1***
Orientation dependence of AMR.

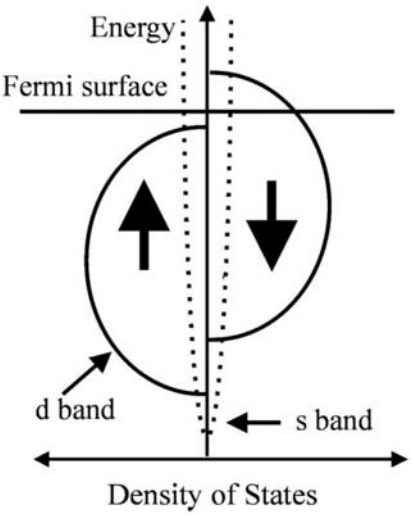

***Figure 2***
Schematic electronic band structure for a strong ferromagnet, e.g., cobalt.

their band structure is spin split. The probability of electron scattering is proportional to the density of states at the Fermi surface resulting in a probability of s electrons scattering into empty states in the spin split d band and hence spin-dependent scattering. The spin asymmetry parameter is often represented by

$$\alpha = R_{\uparrow}/R_{\downarrow} \qquad (2)$$

A schematic diagram of the spin split band structure of a strong ferromagnet such as cobalt and nickel is shown in Fig. 2. In the example shown, the higher density of states at the Fermi level for the spin down band results in a higher probability of scattering for this band and hence a value of $\alpha$ less than unity. Iron is only a weak ferromagnet; however, its band structure is readily modified by distortion of its local electronic environment, for example at a surface or interface. First principles band structure calculations are often necessary to determine the degree of spin-dependent scattering, especially for alloys such as $Ni_{80}Fe_{20}$.

## 3. GMR

Mott in 1936 determined that the spin quantum number is usually conserved during scattering processes allowing the transport of spin up and spin down electrons to be treated as two parallel spin currents. Taking into account the spin-dependent scattering described in Sect. 2, consider the schematic model shown in Fig. 3.

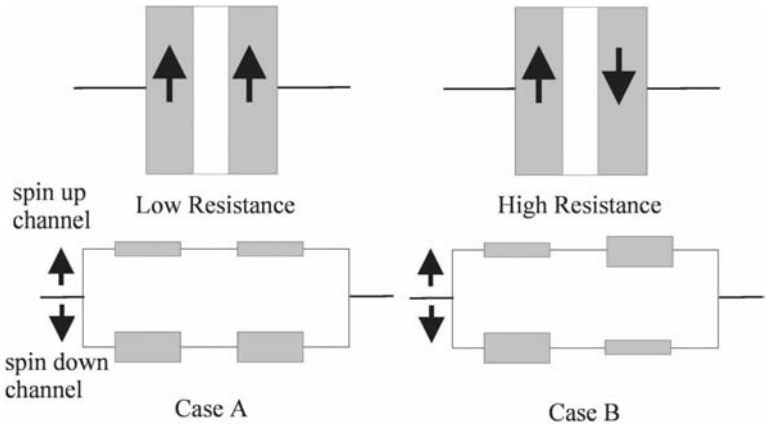

***Figure 3***
Spin-dependent scattering leading to GMR in a trilayer represented using the resistor model.

The magnetic elements represent regions of saturated magnetization whose relative orientation can be altered as indicated. The resistances of the spin up and spin down channels are modeled as resistors, a larger resistor representing a larger resistance, and are shown acting in parallel in accordance with the Mott two-current model. A current entering the device will contain both spin up and spin down electrons. In case (a) spin up electrons will remain majority electrons throughout their passage and will only be weakly scattered. Spin down electrons, however, will remain minority electrons throughout their passage and will be strongly scattered throughout. The overall resistance in case (a) will therefore be dominated by the low-resistance spin up channel and the current will be spin polarized in the up direction as it emerges.

By contrast, in case (b) where the magnetic regions are misaligned, both the spin up and spin down electrons will spend some time as both majority and minority electrons resulting in a high resistance in both channels. If the device can be switched between these two magnetic states a change in resistance will be observed. The magnetoresistance due to this mechanism can be represented by

$$\frac{R_{\uparrow\downarrow} - R_{\uparrow\uparrow}}{R_{\uparrow\uparrow}} = \frac{(1-\alpha)^2}{4\alpha} \tag{3}$$

where $R_{\uparrow\downarrow}$ ($R_{\uparrow\uparrow}$) is the resistance in the antiparallel (parallel) configuration, and is called GMR. The name refers to the mechanism responsible for the resistance change rather than to the size of the effect itself.

Bulk magnetic material is normally divided up into regions of saturated magnetization called magnetic domains; however, within the domain wall separating domains of different magnetization direction, the local direction of the magnetic moment rotates. As the spin-polarized electrical current travels through the domain wall its spin may be able to rotate about the local direction of magnetization thus quenching any GMR effect (Gregg *et al*. 1996). The thinner the domain wall, the more rapid the rotation of the local moment will be and the lower the probability that the electron spin will be able to precess with the local moment. Therefore, to increase the GMR effect the domain wall should be made as thin as possible. By separating adjacent magnetic domains by a nonmagnetic material the domain wall is effectively removed. This is best achieved in a magnetic multilayer in which the layer thicknesses can be reduced to a few atomic layers.

This was first achieved by Baibich *et al*. (1998) and Binasch *et al*. (1989) in Fe/Cr multilayers; the original data showing GMR for the first time is reproduced in Fig. 4.

Since this initial discovery the subsequent understanding of the underlying mechanisms has enabled GMR of 220% to be achieved at 4.2 K in Fe/Cr multilayers (Schad *et al*. 1994), and at room temperature values of 65% have been realized for Co/Cu multilayers (Parkin *et al*. 1991).

Given that multilayering magnetic and nonmagnetic materials creates a good system for spin-dependent scattering, the choice of materials and the microstructure of the multilayer will determine the maximum value of GMR. However, for effective application as a magnetic field sensor this magnetoresistance must also occur for small changes in applied field. The mechanism by which the multilayer switches between the two magnetic states of parallel and antiparallel alignment of adjacent magnetic layers is therefore crucial in GMR design. Despite their lower magnetoresistance, AMR devices do in fact have quite a good field sensitivity, as a thin film of $Ni_{80}Fe_{20}$, for example, can be switched in fields of only a few tenths of a millitesla.

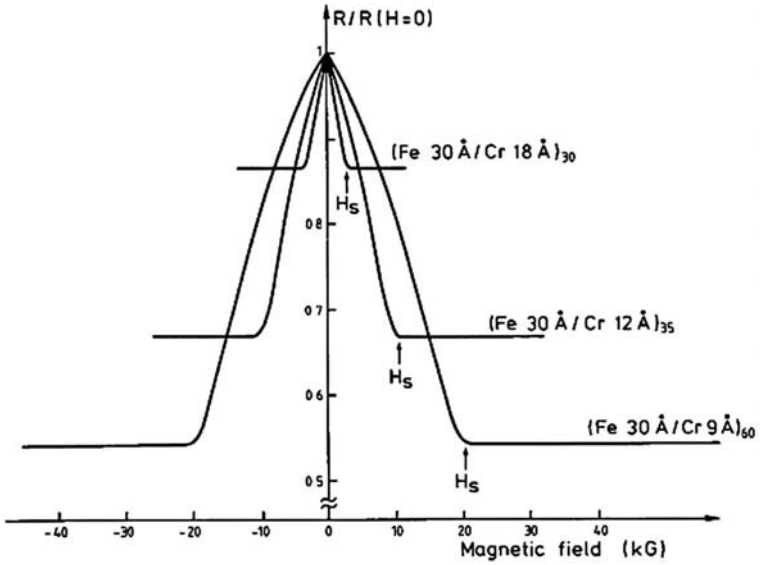

***Figure 4***
GMR in Fe/Cr multilayers (after Baibich *et al.* 1988).

In the schematic diagram in Fig. 2 the current is shown traveling perpendicular to the layers in the current perpendicular to the plane (CPP) geometry. In this case the resistances of subsequent layers can be added in series and this is the most straightforward type of structure to model theoretically. However, owing to the large cross-sectional area to length aspect ratio, the CPP resistance is extremely small making practical realization more difficult. Superconducting contact pads are often used (Pratt *et al.* 1991) or pillars are formed by etching (Gijs *et al.* 1993) or electrodeposition (Piraux *et al.* 1994) to reduce the cross-section and thereby increase the measurement resistance.

As the electron mean free path in a typical metal multilayer is typically much longer that the thicknesses of the individual layers, it is possible to measure GMR with the current in the plane (CIP) geometry in which the current travels parallel to the layers. In this case the resistances of the layers are added in parallel for each spin current channel. CIP magnetoresistance is practically much easier to measure, as the resistance values are typically a few ohms.

There are now many designs of nanostructures that enable the relative alignment of the magnetic components to be controlled by the application of a magnetic field—some of which are described below. They enable the variation of magnetic field to be controlled according to the following angular-dependent equation:

$$R(\theta) = R(\theta = 0) + \Delta R_{\mathrm{GMR}} \frac{1 - \cos\theta}{2} \qquad (4)$$

where $\theta$ is the angle between the magnetization directions of adjacent layers.

### *3.1 Exchange Coupled Multilayers*

GMR was discovered in an Fe/Cr magnetic multilayer whose antiparallel alignment of magnetic layers was the result of interlayer exchange coupling. This coupling is due to spin-dependent reflection coefficients at interfaces setting up a spin density wave in the interlayer. The thickness of the interlayer determines at which point of the spin density wave the next magnetic layer is situated resulting in either antiferromagnetic (antiparallel) alignment or ferromagnetic (parallel alignment) coupling between the magnetic layers (Grünberg *et al.* 1986). This coupling is much stronger than that arising from dipolar interactions. The application of a magnetic field to an antiferromagnetically coupled multilayer will eventually overcome the coupling energy and align the magnetic layers in the direction of the magnetic field.

The relative alignment of the magnetic layers in the multilayer can therefore be altered by the application of a magnetic field resulting in GMR. The disadvantage of an exchange coupled multilayer is that for strong coupling a large field is often required to overcome the exchange coupling resulting in poor field sensitivity of the GMR. In addition, the magnitude and sign of the exchange coupling is very sensitive to interlayer thickness; the coupling typically cycles between ferromagnetic and antiferromagnetic with a period of only 1.1–1.2 nm. This makes

the reproducible manufacture of such systems very demanding and the problem of interdiffusion at the magnetic/nonmagnetic interface very significant (see *Multilayers: Interlayer Coupling*).

### 3.2 Spin Valves

In a spin valve (Dieny *et al*. 1991a), the exchange coupling between the magnetic layers is suppressed by separating them with a thick nonmagnetic interlayer. One of the magnetic layers is then pinned by, for example, exchange biasing with an antiferromagnet, e.g., FeMn. The other magnetic layer is left free to magnetically switch in a small magnetic field. The most sensitive GMR materials have been made in this way producing values in the region of 18% $kAm^{-1}$ (see *Magnetic Recording Systems: Spin Valves*). Exchange biased multilayers suffer from the relatively low Curie temperature of the antiferromagnet. This limitation has been overcome by replacing the pinning antiferromagnet by an antiferromagnetically coupled multilayer such as Co/Ru (van den Berg *et al*. 1996).

### 3.3 Heterogeneous Alloys

Layering of the materials is not a requirement for GMR, but the dimensions of the magnetic and nonmagnetic regimes must be on the nanoscale. For example, granular materials will also exhibit GMR (Berkowitz *et al*. 1992, Xiao *et al*. 1992). Such systems are most easily realized using immiscible magnetic and nonmagnetic materials such as CoAg and can readily be prepared by coevaporation, cosputtering, or even mechanical alloying to produce a bulk material with a nanoscale microstructure. The highest resistance is observed when there is the most magnetic disorder at the coercive field. In general, the field sensitivity is not high owing to the relatively high fields often needed to rotate the magnetic moment of small magnetic particles. As the GMR is very sensitive to the moment–moment correlation of neighboring particles, it can be used to probe the magnetic state of the sample (Gregg *et al*. 1996).

### 3.4 Tunneling Magnetoresistance

If the nonmagnetic layer is replaced by a thin insulator such as $Al_2O_3$, the quantum mechanical tunneling probability through the insulator will also be spin dependent owing to the number of available states to tunnel into leading to a tunnel magnetoresistance (TMR) (Juliere 1975).

## 4. Critical Length Scales

The two critical length scales in giant magnetoresistive structures are the electron mean free path and the spin diffusion length. The spin diffusion length is the length over which the polarization of the electron current is destroyed owing to spin flip scattering. It is related to the momentum mean free path by the following:

$$l_{sd} = \sqrt{v_F \lambda \tau_{\uparrow\downarrow}} \qquad (5)$$

where $v_F$ is the Fermi velocity, $\lambda$ the momentum mean free path, and $\tau_{\uparrow\downarrow}$ the spin flip time.

Typical values for a GMR multilayer are 10 nm for the mean free path and 100–1000 nm for the spin diffusion length in the nonmagnetic material. For a CIP structure, the mean free path is usually the critical parameter as it will control the number of layers an electron will typically encounter in its journey through the multilayer. In a CPP structure, the electron will always sample all the layers in the structure and it is therefore the spin diffusion length that is usually the critical length scale as it determines the degree of polarization of the current as each new interface is reached. In addition, the spin diffusion length in the magnetic layer will affect the degree of polarization of the electron current. Heterogeneous alloys exhibit both CIP and CPP character with the resistances of the magnetic particles adding in both series and parallel. Both length scales are therefore important in these materials.

## 5. Sources of Electron Scattering

All scattering will reduce the mean free path of the material. All spin-independent scattering, such as scattering in the nonmagnetic layer, will therefore reduce the GMR. This scattering may be the result of the microstructure such as vacancies, defects, interdiffusion, and roughness at the surface or interface or stress and can often be improved by the careful choice of underlayer materials. In a thin film there will also be scattering from the interface with the substrate and the capping layer. Scattering in the ferromagnetic layer or at the interface may be spin dependent and may therefore make a positive contribution to the GMR.

The potential of the scattering process to be spin dependent is interdependent on intrinsic properties such as the band structure, the composition of the multilayer, and its microstructure. Scattering can be spin dependent if there is a matching of the atomic potentials for one spin direction and not in the other; for example, in the Fe/Cr system there is good band matching for the spin down band, but poor matching for the spin up band leading to spin-dependent scattering and GMR. The reverse situation is true for nickel or cobalt at an interface with copper where the spin up band of the ferromagnet is full. Poor structural matching between materials at an interface results in a high dislocation density with high consequent scattering. Note that the highest values

of GMR at room temperature are obtained for the Co/Cu system for which there is good matching of both the electronic and lattice structure.

Additional complications arise for atomic mixing at the interface where the magnetic moment of the alloy thus produced is different to the bulk material, e.g., Ni/Cu (Nicholson *et al.* 1994). This has additional consequences for exchange coupled material where the interdiffusion will also affect the exchange coupling and hence the degree of misalignment of the adjacent magnetic layers. An effective way to benefit from, say, the soft magnetic properties of $Ni_{80}Fe_{20}$, avoid the problems of interdiffusion at the $Ni_{80}Fe_{20}$/Cu interface, and exploit the effective spin-dependent scattering at the well-matched Co/Cu interface is to dust the $Ni_{80}Fe_{20}$/Cu interface with a thin layer of cobalt (Parkin 1993). In general, the band structure at the interface is likely to differ from the bulk making it difficult to predict the performance of a particular interface (Coehoorn 1993, Itoh *et al.* 1993, Nicholson *et al.* 1994).

## 6. *Effect of the Layer Thicknesses*

The function of the nonmagnetic layer is to separate the magnetic layers sufficiently to allow independent switching in a spin valve material and in an exchange coupled material to control the interlayer coupling and thereby the degree of magnetic layer misalignment. Increasing the thickness of the nonmagnetic layer beyond what is required to achieve these functions will result in a degradation of the GMR. Typically the nonmagnetic layer has a higher conductivity than the ferromagnet, so in a CIP structure it acts as an effective electrical shunt. Some materials commonly used as nonmagnetic layers such as gold also have a high degree of spin flip scattering resulting from large spin–orbit coupling. This will reduce the spin diffusion length and hence be particularly degrading to the GMR in CPP structures. There is, however, a risk for both CIP and CPP structures in making the nonmagnetic layer too thin owing to the potential for the formation of structural pinholes that will result in direct magnetic coupling between the magnetic layers destroying the magnetic misalignment and with it the GMR (Dieny *et al.* 1991b).

The magnetic layer must be thick enough to effectively spin polarize the current; if it is too thin there will be a high degree of diffuse scattering at the interfaces reducing the mean free path considerably. The GMR will increase with the number of layers until in a CIP structure the mean free path is exceeded; there is therefore also an electrical shunting effect associated with the magnetic layer (Dieny *et al.* 1992).

## 7. *Temperature Dependence*

The temperature dependence of the GMR is necessarily connected to the Curie temperature of the magnetic material, and the formation of magnons increases the amount of spin flip scattering as the temperature is increased. The temperature at which the GMR is reduced to zero is lower than the Curie temperature, but related to it. The increased conductivity of the whole magnetic structure at low temperatures results in a reduction of spin-independent scattering, and an increase in the electron mean free path and consequently in an increase in the GMR ratio. For spin valves it is found that the GMR decreases linearly with increased temperature (Dieny *et al.* 1992).

## 8. *Theories of GMR*

A model of GMR needs to include spin-dependent scattering probabilities in the bulk, the outer boundaries, and at the interfaces within the structure. As the origin of the spin-dependent scattering derives from the spin splitting of the d band, a truly classical model is incapable of describing the GMR. However, a great deal of physical insight can be gained by incorporating a quantum mechanically derived spin dependence into the scattering parameters of classical theories to form semiclassical models.

The first semiclassical model was that of Camley and Barnas (1989) who used the Boltzmann transport equation. The Fuchs and Sondheimer formulation can be used to take into account the effect of the finite thickness of the thin film. The spin-dependant probability of specular reflection at the outer boundary must be considered and at the interface: transmission, specular reflection, and diffuse scattering must all be taken into account in deriving spin-dependent transmission coefficients. These models lead to the conclusion that in $Ni_{80}Fe_{20}$-based materials spin-dependent scattering within the ferromagnetic layer is dominant, in contrast to cobalt-based multilayers in which the interface is found to dominate. In both cases the detailed microstructure plays a significant role and can be the dominant factor.

Valet and Fert (1993) describe spin-dependent transport using the idea of spin accumulation at the internal interfaces and use a semiclassical formalism of the Boltzmann equation with the addition of spin-dependent electrochemical potentials. These models work well in CPP structures when the spin diffusion lengths in both the ferromagnetic and nonmagnetic layers are much greater than the thicknesses of the individual layers. Pratt *et al.* (1997) have incorporated the spin diffusion length of the ferromagnetic material into a similar model.

Quantum mechanical theories take into account finite size effects on the electronic structure and the transport owing to the presence of a potential barrier, but have been less successful in predicting realistic values of the GMR. Realistic band structures have been successfully incorporated into these models,

most notably by Tsymbal and Pettifor (1996), who considered hybridization of the *sp* and *d* electrons. They considered scattering from spin-independent disorder introduced using the Anderson model, using the Kubo formula. The degree of disorder can be altered as a parameter to obtain typical resistivities for thin-film structures and, for the first time, realistic values obtained for the GMR.

## 9. Summary and Future Developments

Although the underlying mechanisms of GMR are now understood, accurate predictions are still difficult owing to the significant effect minor changes in electronic band structure and microstructure can have on the spin-dependent scattering. GMR sensors have successfully found a major market for applications most notably as read heads in the data storage industry (Toigo 2000) (see *Magnetic Recording Devices: Inductive Heads, Properties*) and increasingly in a wider range of applications. The latest developments are in magnetic random access memory (MRAM) (Pohm *et al*. 1994) (see *Random Access Memories: Magnetic*) and hybrid spin electronic devices (Gregg *et al*. 1997, Hammar *et al*. 1999) (see *Magnetic Recording Systems: Spin Electronics*). More detailed reviews of GMR can be found in the literature (e.g., Dieny 1994, Gijs and Bauer 1997).

# Magnetostrictive Materials

Magnetostriction is the term given to the mechanical deformation induced in a solid substance by the modification of its magnetic state. Inverse magnetostriction refers to the modification of the magnetic state by an applied stress.

These phenomena are significant only in substances which are magnetically ordered or at least close to the onset of a magnetic order, and have practical importance only in those materials which exhibit a spontaneous magnetization, i.e., ferro- or ferrimagnetic materials. Only the latter will be considered in this article.

## 1. Spontaneous Magnetostriction

Generally speaking, spontaneous magnetostriction is defined as that part of strain which is due to the onset of a magnetic order in a material (du Tremolet de Lacheisserie 1993).

A phenomenological approach consists of treating the onset of spontaneous magnetization as a small perturbation of a hypothetical nonmagnetic state. At a given temperature, the perturbation is entirely defined by the magnetization direction cosines $\alpha_1,\alpha_2,\alpha_3$. The spontaneous magnetostriction tensor $\mathbf{S}$ is then expanded as a function of this perturbation. In a convenient frame (Nye 1957), allowing for time reversal invariance, and using the usual Einstein convention on repeated indices, this gives:

$$S_{ij} = Q_{ijkl}\alpha_k\alpha_l + \text{even higher order terms}(i,j = 1,2,3) \tag{1}$$

The tensor $\mathbf{Q}$ and the higher-order tensors are expected to be temperature-dependent. Consideration of the first term only is sufficient to account for the properties of most materials, so that only the form of $\mathbf{Q}$ will be considered in the following. Since $\mathbf{Q}$ is a polar tensor of order 4, it follows the same symmetry rules as the elastic tensors (Nye 1957). Two cases are worth considering: cubic crystals and isotropic materials. In the following, emphasis will be placed on cubic symmetry since it contains the isotropic situation as a special case.

In cubic crystals, the convenient reference frame is obviously the one that coincides with crystallographic axes.

There are only 15 nonzero components of $\mathbf{Q}$ out of which only three are independent, namely

$$\begin{aligned} &Q_{1111} = Q_{2222} = Q_{3333} = Q_{11} \\ &Q_{1122} = Q_{2211} = Q_{1133} = Q_{3311} = Q_{2233} = Q_{3322} = Q_{12} \\ &Q_{2323} = Q_{3232} = Q_{1313} = Q_{3131} = Q_{1212} = Q_{2121} = Q_{44} \end{aligned} \tag{2}$$

so that the components of spontaneous magnetostriction can now be written as:

$$\begin{aligned} S_{11} &= (Q_{11} - Q_{12})\alpha_1^2 + Q_{12}; \\ S_{22} &= (Q_{11} - Q_{12})\alpha_2^2 + Q_{12}; \\ S_{33} &= (Q_{11} - Q_{12})\alpha_3^2 + Q_{12} \\ S_{23} &= S_{32} = Q_{44}\alpha_2\alpha_3; \quad S_{13} = S_{31} = Q_{44}\alpha_1\alpha_3; \\ S_{12} &= S_{21} = Q_{44}\alpha_1\alpha_2 \end{aligned} \tag{3}$$

In isotropic material the reference frame can be chosen arbitrarily. The relevant $\mathbf{Q}$ components and the spontaneous magnetostriction are immediately derived from Eqns. (2) and (3), respectively, by expressing the isotropy relation, $Q_{44} = Q_{11} - Q_{12}$.

## 2. Volume Magnetostriction

The relative volume expansion of a fully saturated sample with respect to the nonmagnetic reference state is $\Delta V/V = S_{11} + S_{22} + S_{33}$, which, from Eqn. (3), turns out to be equal to $Q_{11} + 2Q_{12}$ whatever the orientation $\alpha_1,\alpha_2,\alpha_3$. It can be concluded that in cubic crystals (and therefore in isotropic materials) volume magnetostriction is actually independent of the technical magnetization state and equal to $Q_{11} + 2Q_{12}$.

## 3. Joule Magnetostriction

Joule magnetostriction is by definition the deformation of a magnetic material which is induced at a fixed temperature by those technical magnetization processes that involve a rotation of the spontaneous magnetization.

It is interesting from an experimental viewpoint to redefine the zero deformation reference state as the isotropic demagnetized state instead of the hypothetical nonmagnetic state. By this, it is meant a multidomain state with an isotropic distribution of

the magnetization orientation and, of course, vanishing average (or technical) magnetization. The strain components as measured with respect to this new reference state (called for convenience spontaneous Joule deformations) are then:

$$\begin{aligned}
&S_{11} = (Q_{11} - Q_{12})(\alpha_1^2 - 1/3);\\
&S_{22} = (Q_{11} - Q_{12})(\alpha_2^2 - 1/3);\\
&S_{33} = (Q_{11} - Q_{12})(\alpha_3^2 - 1/3)\\
&S_{23} = S_{32} = Q_{44}\alpha_2\alpha_3; \quad S_{13} = S_{31} = Q_{44}\alpha_1\alpha_3;\\
&S_{12} = S_{21} = Q_{44}\alpha_1\alpha_2
\end{aligned} \tag{4}$$

Joule magnetostriction in a cubic crystal may thus be characterized by only two parameters, namely $(Q_{11}-Q_{12})$ and $Q_{44}$. They can be determined, at least in principle, by measuring the relative elongation $\lambda(\alpha_1,\alpha_2,\alpha_3)$ along various magnetization directions when the sample is brought from the isotropic demagnetized state to the saturated state. Two particular orientations are worth considering, $\langle 100 \rangle$ and $\langle 111 \rangle$: a simple calculation gives

$$\lambda_{100} = 2/3(Q_{11} - Q_{12}); \quad \lambda_{111} = 2/3Q_{44}$$

so that the expression of the spontaneous Joule deformations can be rewritten as:

$$\begin{aligned}
&S_1^0 = 3/2\lambda_{100}(\alpha_1^2 - 1/3); \quad S_2^0 = 3/2\lambda_{100}(\alpha_2^2 - 1/3);\\
&S_3^0 = 3/2\lambda_{100}(\alpha_3^2 - 1/3); \quad S_4^0 = 3\lambda_{111}\alpha_2\alpha_3;\\
&S_5^0 = 3\lambda_{111}\alpha_1\alpha_3; \quad S_6^0 = 3\lambda_{111}\alpha_1\alpha_3
\end{aligned} \tag{5}$$

Here we have used the contracted technical notation for strains (Nye 1957): $S_{11} = S_1$, $S_{22} = S_2$, $S_{33} = S_3$, $S_{23} + S_{32} = S_4$, $S_{13} + S_{31} = S_5$, $S_{12} + S_{21} = S_6$. In practice, due to the difficulty of actual realization of an isotropic demagnetized state, the preferred method of measurement relies on the strain variations caused by controlled modifications of the orientation of fully saturated states (du Tremolet de Lacheisserie 1993).

In isotropic materials, Joule magnetostriction is characterized by only one parameter since $\lambda_{100} = \lambda_{111} = \lambda_s$ where $\lambda_s$ is called the saturation magnetostriction.

## 4. *Free Energy Density and Other Magnetostrictive Effects*

The knowledge of equations of state is essential to most applications of a material. This is related to the knowledge of its free energy density function $F$. The free energy density function of a single domain cubic magnetostrictive crystal at a given temperature can be easily calculated for a given elastic and saturated magnetic state specified by stress components $T_{11} = T_1$, $T_{22} = T_2$, $T_{33} = T_3$, $T_{23} = T_{32} = T_4$, $T_{13} = T_{31} = T_5$, $T_{12} = T_{21} = T_6$ and magnetization direction cosines $\alpha_1$, $\alpha_2$, $\alpha_3$. Calculation can be made in two different ways. First the crystal is saturated in the specified directions $\alpha_1$, $\alpha_2$, $\alpha_3$ allowing it to deform freely (zero applied stress), so that it takes the spontaneous Joule deformations (Eqn. (5)). Then suitable increasing stresses are applied to the sample in order to bring it reversibly into its specified elastic state while blocking the magnetization. The result is:

$$\begin{aligned}
F = {} & K_0^T(\alpha_1, \alpha_2, \alpha_3) + 1/2s_{11}[T_1^2 + T_2^2 + T_3^2]\\
& + s_{12}[T_2T_3 + T_1T_3 + T_1T_2] + 1/2s_{44}\\
& \times [T_4^2 + T_5^2 + T_6^2]
\end{aligned} \tag{6}$$

where $K_0^T(\alpha_1, \alpha_2, \alpha_3)$ is the zero stress anisotropy energy of the crystal (defined to within a constant) and the $s_{ij}$ are the elastic compliances at blocked magnetization.

Alternatively, the stress **T** can be applied in the demagnetized state, and then the magnetization is brought to state $\alpha_1,\alpha_2,\alpha_3$ which still produces the spontaneous deformation (Eqn. (5)). Therefore, the total work supplied to the material is:

$$\begin{aligned}
F = {} & 1/2s_{11}[T_1^2 + T_2^2 + T_3^2] + s_{12}[T_2T_3 + T_1T_3 + T_1T_2]\\
& + 1/2s_{44}[T_4^2 + T_5^2 + T_6^2] + K_T^T(\alpha_1, \alpha_2, \alpha_3)\\
& + 3/2\lambda_{100}[T_1(\alpha_1^2 - 1/3)\\
& + T_2(\alpha_2^2 - 1/3) + T_3(\alpha_3^2 - 1/3)]\\
& + 3\lambda_{111}[T_4\alpha_2\alpha_3 + T_5\alpha_1\alpha_3 + T_6\alpha_1\alpha_2]
\end{aligned} \tag{7}$$

A comparison of Eqns. (6) and (7) shows that the anisotropy energy density under stress **T** is given by

$$\begin{aligned}
K_T^T(\alpha_1, \alpha_2, \alpha_3) = {} & \mathbf{K}_0^T(\alpha_1, \alpha_2, \alpha_3) + 3/2\lambda_{100}[T_1(\alpha_1^2 - 1/3)\\
& + T_2(\alpha_2^2 - 1/3) + T_3(\alpha_3^2 - 1/3)]\\
& - 3\lambda_{111}[T_4\alpha_2\alpha_3 + T_5\alpha_1\alpha_3 + T_6\alpha_1\alpha_2]
\end{aligned} \tag{8}$$

Finally, noticing that $T_i = c_{ij}(Sj - Sj^0)$ where $i,j = 1-6$, and putting $-3/2\ (c_{11}-c_{12})\lambda_{100} = B_1$ and $-3c_{44}\lambda_{111} = B_2$, it is easy to obtain from Eqns. (5) and (6):

$$\begin{aligned}
F = {} & K_0^S(\alpha_1, \alpha_2, \alpha_3) + 1/2C_{11}[S_1^2 + S_2^2 + S_3^2]\\
& + c_{12}[S_2S_3 + S_1S_3 + S_1S_2]\\
& + 1/2c_{44}[S_4^2 + S_5^2 + S_6^2] + B_1[S_1(\alpha_1^2 - 1/3)\\
& + S_2(\alpha_2^2 - 1/3)\\
& + S_3(\alpha_3^2 - 1/3)] + B_2[S_4\alpha_2\alpha_3 + S_5\alpha_1\alpha_3 + S_6\alpha_1\alpha_2]
\end{aligned} \tag{9}$$

where the $c_{ij}$ are the elastic stiffnesses, and $K_0^S(\alpha_1, \alpha_2, \alpha_3)$ is the anisotropy energy at zero strain which, for

symmetry reasons, has the same form as $K_0^T$. $B_1$ and $B_2$ are called magnetoelastic coupling coefficients.

For an isotropic material, since $\lambda_{100} = \lambda_{111} = \lambda_s$ and $c_{11} - c_{12} = 2c_{44}$, Eqn. (9) reduces to

$$\begin{aligned} F = {} & K_0^S(\alpha_1, \alpha_2, \alpha_3) + 1/2c_{11}[S_1^2 + S_2^2 + S_3^2] \\ & + c_{12}[S_2S_3 + S_1S_3 + S_1S_2] + 1/2c_{44}[S_4^2 + S_5^2 + S_6^2] \\ & + B[S_1(\alpha_1^2 - 1/3) + S_2(\alpha_2^2 - 1/3) + S_3(\alpha_3^2 - 1/3) \\ & + S_4\alpha_2\alpha_3 + S_5\alpha_1\alpha_3 + S_6\alpha_1\alpha_2] \end{aligned} \tag{10}$$

where $B = -3\lambda_s c_{44}$ is the unique magnetoelastic coupling coefficient.

### *4.1 Inverse Magnetostrictive Effect*

Equation (8) shows that the application of a stress on a magnetostrictive sample induces an additional anisotropy. This is the actual mechanism of the inverse effect since in general this added anisotropy will produce a reorientation of the magnetization.

### *4.2 ΔE Effect*

The effective elastic constants of a magnetostrictive material are generally modified by the application of a static magnetic field (ΔE effect). The reason is that the effective elastic constants are different depending on whether the magnetization is free to rotate (at zero d.c. field) or bound to a given direction (at high d.c. field). Calculation of the ΔE effect is easy only in simple domain configurations. A particularly simple example is that of a single domain cubic crystal bearing an anisotropy of the usual form $K_0^S(\alpha_1,\alpha_2,\alpha_3) = -K_1[\alpha_2^2\alpha_3^2 + \alpha_1^2\alpha_3^2 + \alpha_1^2\alpha_2^2]$ with $K_1 > 0$, magnetized along 100 by a static field $H$. Starting from Eqn. (9), the differential shear stiffness can be given by

$$\partial T_4/\partial S_4 = \partial T_5/\partial S_5 = c_{44} - B_2^2/(K_1 + 1/2\ \mu_0 M_s H)$$

As expected, it tends to the blocked magnetization value at high field and decreases when the applied field is reduced. A measure of the ΔE effect is the relative variation controlled by the applied field, i.e., $B_2^2/(K_1c_{44}) = k_{15}$ (Nye 1957). The interest in this parameter and the reason for this notation will be made clear in the next section.

### *4.3 Nonlinear elasticity*

In correlation with the ΔE effect, strong nonlinear elastic effects are also observed in high coupling factor materials. The source of this elastic nonlinearity lies in the nonlinearity of the magnetic response itself. Some calculations can be made for simple single-domain configurations but they will not be developed here.

## *5. Magnetostriction of Unsaturated States: Piezomagnetic Formulation*

Below saturation, the magnetostrictive response of polycrystalline and amorphous materials involves domain processes which can be quite complicated. The usual method, at least for application purposes, is to characterize the material properties only around the relevant bias point as far as possible by phenomenological linear and reversible equations of states.

In general, both a bias field and a bias uniaxial stress are applied to the material along the same direction. The material has then uniaxial symmetry around the bias direction which is taken as axis three of a rectangular frame. In this frame the linearized properties are therefore described by matrix relations that are analogous to those of piezoelectric ceramics (Nye 1957). Taking, for example, differential field **h**, and differential stress **T** as independent variables, the equations of state are written as

$$S = s\mathbf{T} + \mathbf{d} * \mathbf{h}; \quad b = \mathbf{d}\mathbf{T} + g\mathbf{h} \tag{12}$$

Here, taking advantage of the contracted notation, **T** and the differential strain **S** are six-component vectors whereas **b**, the differential induction, and **h** are three-component vectors. **d** is thus a three line, six columns rectangular matrix. **d*** is actually the transposition of **d**, a consequence of the reversibility assumption.

The form of the piezomagnetic matrix **d** is the same as its piezoelectric analogue, i.e., there are only five nonzero components out of which only three are independent, namely $d_{31} = d_{32}$, $d_{24} = d_{15}$, and $d_{33}$.

In general in transducer configurations, stress and strain are collinear single-component vectors, as are the field and induction. Vector Eqn. (12) then reduces to a system of two scalar linear equations (no summation on repeated subscripts!):

$$\mathbf{S}_i = \mathbf{s}_{ii}\mathbf{T}_i + \mathbf{d}_{il}\mathbf{h}_l; \quad \mathbf{b}_l = \mathbf{d}_{il}\mathbf{T}_i + \mu_{11}\mathbf{h}_l$$

It is convenient to define a dimensionless coefficient $k_{il} = (d_{il}^2/s_{ii}\ \mu_{11})^{1/2}$ called the magnetomechanical coupling factor. The reason is that its square actually measures the ratio of output to input energy in a static reversible conversion process. By a conversion process, it can define a transformation of magnetic energy into mechanical energy or vice versa. Three useful magnetomechanical coupling factors may be defined in uniaxial magnetostrictors, namely:

$$\begin{aligned} k_{33} &= (d_{33}^2/\mu_{33}s_{33})^{1/2}; \\ k_{31} &= k_{32} = (d_{31}^2/\mu_{33}s_{11})^{1/2}, \quad \text{and} \\ k_{15} &= k_{24} = (d_{15}^2 s_{44})^{1/2} \end{aligned}$$

## 6. Microscopic Origin of Magnetostriction

Within the model of localized electron ferromagnetism, two microscopic mechanisms are the origin of magnetostriction: exchange interaction between spins, and interaction of a given spin with its local electric field via the spin–orbit coupling. Although it may provide some good clues even in the case of transition metals and alloys, the localized electron model is inadequate for these materials and must be replaced by the band magnetism model. In this model magnetostriction appears as an interaction between the strain and the spin-dependent band structure (du Tremolet de Lacheisserie 1993).

### 6.1 Spin–Spin Interaction

The dependence of the isotropic Heisenberg exchange on distance between neighboring spins leads to a volume magnetostriction which is generally negative and therefore leads to an enhancement of the lattice thermal expansion. This is the "normal" situation, observed, for example, in pure nickel. The strong positive volume magnetostriction observed in the so-called INVAR alloys is a band magnetism effect and will not be discussed here (see *Invar Materials: Phenomena*).

In addition to the isotropic Heisenberg contribution, the exchange interaction also includes, in general, anisotropic terms of increasing order which depend both on the distance between interacting spins and on the orientation of the bond with respect to spin direction. The orientation dependence is the origin of the magnetic anisotropy energy. Both the distance dependence and the orientation dependence are the origin of Joule magnetostriction.

### 6.2 Crystal Field Interaction

Ions with a nonspherical electron distribution interact with the nonuniform electric field produced by their neighbors—the so-called crystal field. This interaction can be expanded in terms of orbital multipolar moments and associated field spatial derivatives. For example, the lowest moment is quadrupolar and it is coupled to the first field derivatives (the field gradient tensor). In any case this electrostatic energy depends on the orientation of the electron orbitals with respect to the crystal field and hence the crystal axes (see *Localized 4f and 5f Moments: Magnetism*). In magnetic ions the magnetic moment is either tied to the orbitals or coupled to them by spin–orbit interaction. The final result is that there is a contribution to the free energy of the crystal that depends on the orientation of the spontaneous magnetization with respect to the crystal axes, i.e., an anisotropy energy. The dependence of this anisotropy energy on (anisotropic) strain leads to the Joule magnetostriction. It must be emphasized here that high magnetostriction does not necessarily imply large anisotropy since a function may be zero at a given value of the variable while its derivative is not.

## 7. Practical Magnetostrictive Materials and their Applications

From a practical point of view it is worth distinguishing four main families of magnetostrictive materials: (i) the so-called INVAR alloys; (ii) the high coupling factor alloys; (iii) the high-saturation magnetostriction alloys; and, finally (iv) the ferrite crystals or ceramics which, in contrast to the previous metallic materials, are almost perfect insulators.

### 7.1 INVAR Alloys

It was discovered by Guillaume in 1896 that in some alloys of nickel and iron the volume magnetostriction is positive and its temperature dependence just compensates for the normal thermal expansion of the alloy. The result is a metallic alloy bearing a very weak thermal expansion coefficient over a wide temperature range. The applications of these INVAR alloys include very large structures such as methane tankers as well as the most tiny parts of metrology, together with very specific electronic components, such as the masks for high-resolution color TV (du Tremolet de Lacheisserie 1993). A drawback of these materials is that they exhibit a very large forced volume magnetostriction, $\delta V/V\delta H \cong 10^{-10}\,\mathrm{m\ A^{-1}}$, preventing their use in a high magnetic field environment.

### 7.2 High Coupling Factor Alloys

This category includes magnetically soft polycrystalline and amorphous alloys based on iron, nickel, and cobalt. Their saturation magnetostriction is rather low ($\lambda_s < 50 \times 10^{-6}$) and their high coupling factor is rather a consequence of their very low anisotropy.

The most remarkable and useful example of this category of materials is an amorphous alloy known as Metglass 2605 SC with the composition $Fe_{81}B_{13.5}Si_{3.5}C_2$. Due to its fabrication technique (Kavesh 1977), this alloy is available only in the form of a thin ribbon (around 25 μm thick). Table 1 lists some of its relevant characteristics. The last four parameters may be considered as "soft" since they depend strongly on postdeposition treatments which modify all the properties that are related to anisotropy. It is well known that intrinsic anisotropy in amorphous materials is actually a random function of the spatial position with a correlation length typically less than 1 μm. Extrinsic large-scale anisotropy can, however, be induced by appropriate treatments.

Typically, annealing at 642 K for 10 min under a saturating magnetic field parallel to the ribbon plane

***Table 1***
Some relevant characteristics of Metglass 2605SC.

| | |
|---|---|
| Young's modulus at blocked magnetization $Y_{33}^{M}$ (GPa) | 200 |
| Curie temperature (K) | 643 |
| Spontaneous induction at 300 K (T) | 1.61 |
| Saturation magnetostriction at 300 K, $10^{-6}$ | 30 |
| Relative permeability, $\mu_{33}$ | 20000 |
| Relative permeability $\mu_{33}$ under stress bias ($T_{33} = 1$ MPa) | 80000 |
| Static magnetostrictivity $d_{33}$ (nm $A^{-1}$) | 1000 |
| Magnetomechanical coupling factor $k_{33}$ (under 50A $m^{-1}$ bias field) | 0.97 |
| Young's modulus at free magnetization $Y_{33}^{H}$ (GPa) | 25 |

induces a uniaxial anisotropy with an easy axis parallel to the applied field. The value of the induced anisotropy field is in the order of 50A $m^{-1}$. Such a field-annealed Metglass ribbon has uniaxial symmetry and, as explained in Sect. 5, it may be characterized by differential piezomagnetic parameters around a given bias point. It is usual to take the easy axis as the $z$ or "3" axis. Table 1 refers to a field-annealed Metglass alloy in the demagnetized state under zero field and zero stress, unless otherwise specified.

Remarkable points in Table 1 are: (i) an extremely high coupling factor, (ii) a giant $\Delta E$ effect (from 25 GPa at zero field up to 200 GPa at high bias field, i.e., at blocked magnetization); and (iii) an extreme sensitivity of permeability to applied stress. However, this is associated with a rather low saturation magnetostriction. All these characteristics make the Metglass alloy a very good candidate for low-power transducer applications (du Tremolet de Lacheisserie 1993, du Tremolet de Lacheisserie *et al.* 1998).

Force transducers make use of the stress dependence of permeability, and more generally of the modification of magnetic response by stress. A significant advantage of these transducers is that since magnetic measurements do not require physical contact with the material, it is quite easy to sense forces acting on moving parts. As an example, consider the noncontact measurements of the torque transmitted by a rotating shaft. A Metglass ribbon is wrapped around the shaft and is submitted to the shearing forces associated with the torque. The ribbon permeability is measured by a fixed coil arrangement placed close to the moving ribbon surface. Permeability must be measured along one of the principal stress directions, in this case at 45° off the shaft axis.

### *7.3 High-saturation Magnetostriction Alloys*

Giant magnetostrictive effects were discovered in 1975 in the intermetallic cubic compound $TbFe_2$, known as Terfenol (Clark 1980). This alloy exhibits magnetostrictive deformations which are 50 to 100 times larger than the high coupling factor materials. Such a giant magnetostrictive effect can be clearly explained by the localized electron model as a crystal field effect on the rare-earth site. Unfortunately this is obtained at the price of a relatively large anisotropy. Therefore, high driving fields are necessary to generate the magnetostrictive deformation.

The improved alloy $Tb_{0.3}Dy_{0.7}Fe_2$, known as Terfenol D, still has a very large magnetostriction but a much lower anisotropy. This is because the main contributions to anisotropy, due to terbium and dysprosium, have opposite signs and nearly compensate for each other at this composition, whereas the respective contributions to magnetostriction do not. Table 2 lists some useful room-temperature characteristics of Terfenol and Terfenol D. Even the improved material remains relatively hard and despite the very large saturation magnetostriction, the magnetomechanical coupling factors are definitely lower than those of low-saturation magnetostriction but very soft alloys.

Progress in giant magnetostriction materials has been directed towards the fabrication of highly textured materials and even single crystals (Clark 1986). Potential applications of giant magnetostriction alloys include large displacement transducers and high-power ultrasonic generation. However for static displacement generation, piezoelectric transducers based on PZT ceramics are still the best choice mainly because they do not require a permanent excitation power.

In contrast, Terfenol D is a better candidate than PZT for high-power ultrasonic generation (Claeyssen *et al.* 1988) because it is not brittle and it generates a higher deformation and higher power density. A noticeable disadvantage of these alloys is their metallic electrical conductivity which, due to the so-called skin effect, prevents their use at high frequency.

Giant magnetostriction alloys were also prepared as thin films, with the idea that new specific routes to a vanishing anisotropy could be followed in view of applications to low driving field microactuators (du Tremolet de Lacheisserie *et al.* 1998). Thin films of amorphous $Tb_{1-x}Dy_x(Co_{0.55}Fe_{0.45})_y$ were deposited by Duc *et al.* (1996) using d.c. sputtering. Due to their amorphous structure these films are expected to have a vanishing large-scale magnetic anisotropy together with an isotropic, and still giant, magnetostriction. In practice they always bear some induced anisotropy of various origins. It is preferable in most cases intentionally to induce a homogeneous in-plane uniaxial anisotropy rather than to rely on uncontrolled (and often spatially inhomogeneous) parasitic effects.

This is done both by controlling the sputtering conditions (Quandt *et al.* 1994) and by applying a bias field, either during the deposition itself or during a postdeposition treatment (typically 10 min to 1

***Table 2***
Main characteristics of Terfenol ($TbFe_2$) and Terfenol D ($Tb_{0.3}Dy_{0.7}Fe_2$). Curie temperature $T_c$, spontaneous induction $\mu_0 M_s$, saturation magnetostriction $\lambda_s$, magnetomechanical coupling factor $k_{33}$, and static magnetostrictivity $d_{33}$.

| Material | $T_c$ (K) | $\mu_0 M_s$ (T) | $10^6\ \lambda_s$ | $k_{33}$ max | $d_{33}$ max(nm $A^{-1}$) |
|---|---|---|---|---|---|
| $TbFe_2$ | 698 | 1.1 | 1750 | 0.35 | |
| $Tb_{0.3}Dy_{0.7}Fe_2$ | 653 | 1.0 | 1100 | 0.6 | 57 |

hour at 150–300 °C under a 10000 A $m^{-1}$ field). Films are deposited on substrate plates (silicon or pyrex) of known elastic properties thereby constituting a magnetoelastic bimorph (Klokholm 1976). If the magnetostrictive layer is much thinner than the substrate plate, the magnetostrictive stress at zero deformation, rather than the magnetostrictive deformation at zero stress, can be directly determined (du Tremolet de Lacheisserie and Peuzin 1994). This is done by measuring the curvature and torsion of the magnetoelastic bimorph induced by a known applied field. Magnetostrictive deformation at zero stress can then be calculated by making reasonable estimations of the layer elastic modulus.

For example, in $Tb_{0.32}(Fe_{0.45}Co_{0.55})_{0.68}$, a fairly well-defined easy axis can be induced by an annealing at 250 °C. The elongation, $\lambda(H)$, produced along the in-plane hard direction is then determined as a function of the field $H$ applied along the same direction. Giant magnetostriction is observed with $\lambda(H) = 0.8 \times 10^{-3}$ at $\mu_0 H = 0.3$ T and still $\lambda(H) = 0.3 \times 10^{-3}$ at $\mu_0 H = 0.1$ T. However, these driving fields are still high for microsystem applications. This is due in part to the ferrimagnetic character of these alloys which leads to a rather low spontaneous magnetization ($\mu_0 M_s \cong 0.3$ T) and therefore to a high anisotropy field.

In order to improve further the low field magnetostrictive response, a periodic laminar nanocomposite was fabricated by repeated stacking of a weakly magnetostrictive, but high magnetization, layer of polycrystalline FeCo and a highly magnetostrictive amorphous TbCo layer (Betz 1997). Typical layer thicknesses were about 6 nm and up to hundreds of layers could be stacked by using sequential sputter deposition. As a consequence of the strong exchange coupling between the FeCo and TbCo layers the obtained films behaved as a homogeneous ferromagnetic alloy combining relatively high magnetization and giant magnetostriction. Deformation of up to $0.4 \times 10^{-3}$ was obtained in a field of only 20 mT. These thin films of giant magnetostriction alloys have given rise to the development of various types of micromechanical devices (du Tremolet de Lacheisserie *et al.* 1998) among which are a micropump (Quandt 1997), a torsional microactuator which is claimed to be free of thermal drift (Betz *et al.* 1996) and a two-dimensional optical microscanner (Garnier *et al.* 1999). These devices are, however, still at the laboratory level.

### *7.4 Magnetostrictive Insulators: Ferrites*

Two families of magnetoelastic ferrites are worth mentioning from the practical point of view: the spinel ferrites of general formula $MFe_2O_4$ where M is a metal of the first transition series; and the garnets of general formula $R_3Fe_5O_{12}$ where R is a rare-earth metal or yttrium.

Magnetoelastic spinel ferrites such as $NiFe_2O_4$ and $Ni_{0.98}Co_{0.02}Fe_2O_4$ have a resistivity in excess of $10^4\ \Omega$.m, a spontaneous induction of 0.33 T, and a Curie temperature of 863 K. Their spontaneous magnetostriction is comparable with that of high coupling factor materials but since they are somewhat less soft, their magnetomechanical coupling factors are modest (0.2–0.38). These materials face a difficult competition with piezoelectric ceramics.

The garnets, especially $Y_3Fe_5O_{12}$ (YIG), have found many applications in general microwave devices, mostly because they are almost perfect insulators and bear remarkable magnetodynamic properties (von Aulock 1965). Because of their excellent acoustic properties, and despite their rather weak magnetostriction ($\lambda_{100}$ and $\lambda_{111}$ are in the order of $10^{-6}$), YIG single crystals have been exploited, at least at the laboratory level, in magnetoelastic signal processing devices taking advantage of such effects as magnetic field control of acoustic propagation and coupling between magnetostatic waves and acoustic waves (Auld 1968, 1971).

## Magnets, Soft and Hard: Magnetic Domains

Below the Curie temperature, the elementary magnetic moments of ferro- and ferrimagnetic materials are spontaneously ordered (see *Magnetism in Solids: General Introduction*). On a mesoscopic scale in the nanometer range, many of these elementary dipoles can be collected in an average value called magnetization, which is represented by a classical vector $\mathbf{M}(\mathbf{r})$ of unit A/m ($\mathbf{r}$ is the position vector). The absolute value of the magnetization vector, given by the saturation magnetization $M_s$, is a function of temperature alone for all regular magnetic materials, it is constant throughout a (chemically uniform) sample and is largely independent of applied magnetic fields. We can therefore write $\mathbf{M}(\mathbf{r}) = M_s\mathbf{m}(\mathbf{r})$ with $\mathbf{m}^2 = 1$, where $\mathbf{m}(\mathbf{r})$ is the unit vector field of magnetization.

For samples of finite dimensions, this vector field is usually subdivided into magnetic domains, i.e., volumes that are themselves uniformly magnetized to a value equal to $M_s$ along different directions. They are separated by domain walls, in which the magnetization vector continuously rotates on the 10–1000 nm scale to accommodate the change in magnetization orientation between adjacent domains. Domain formation is driven by energy minimization, with the reduction of the stray field energy being responsible for their development above all. The character of a domain pattern depends on the strength and orientation of "easy axes of magnetization" (anisotropy, see also *Magnetic Anisotropy*) relative to the main surfaces of the magnet, but also its shape, dimensions, and physical microstructure are important.

The *magnetic microstructure*, i.e., the arrangement of domains and walls, together with their reaction in external magnetic fields (magnetization processes) determine the macroscopic properties of magnetic materials. Due to the presence of domains, a magnet can accommodate a continuous range of magnetic states that reach from complete demagnetization (if the moments of all domains cancel each other) to saturation in external fields. In *soft magnetic materials*, the magnetic microstructure can easily be modified in small fields either by wall motion or magnetization rotation.

For instance, a high permeability in the core of inductive devices is provided by easily displaceable domain walls leading to a steep magnetization curve, whereas a linear curve for sensor applications requires rotation processes mainly. If major and irreversible rearrangements of domains occur during magnetization, they are responsible for losses and noise in devices, and pinning of domain walls by material imperfections results in hysteresis with coercivity and remanence (see *Magnetic Hysteresis*). Strong pinning or the prevention of domain nucleation causes a high coercivity and leads to *hard magnetic materials* (see *Hard Magnetic Materials, Basic Principles of* ).

In Sects. 2 and 3 of this contribution, the basic domain structures in both material classes will be reviewed based on Kerr-microscopical domain studies (see *Kerr Microscopy*), following some introductory remarks on the fundamentals of domains in Sect. 1. Reviews on magnetic materials with emphasis on magnetic microstructure can be found in Cullity (1972), Chikazumi (1997), and O'Handley (2000). A comprehensive review on domains together with an extended bibliography is given in Hubert and Schäfer (1998).

## 1. Fundamentals of Magnetic Domains

### 1.1 Energetics of a Ferromagnet

Domain formation is driven by minimization of the total free energy. The relevant magnetic energies are introduced here by showing their effect on the magnetization vector field of (soft) magnetic films (Fig. 1).

*(a) Exchange energy*

A ferromagnet prefers a parallel alignment of magnetization vectors (Fig. 1(a)). Deviations from this condition invoke an energy penalty, the exchange energy that can be described by a stiffness expression $E_{ex} = A\int(\text{grad}\ \mathbf{m})^2 \mathrm{d}V$ ($A$ is the exchange constant).

*(b) Stray field energy*

A saturated state as assumed in Fig. 1(a) would cause a magnetic stray field for a finite sample. This can be derived from the material law $\mathbf{B} = \mu_o(\mathbf{H} + \mathbf{M})$ and Maxwell's equation div $\mathbf{B} = 0$ ($\mathbf{B}$ is the magnetic flux density in teslas and $\mathbf{H}$ the magnetic field in amperes per meter), leading to div $\mathbf{H} = -$div $\mathbf{M}$. The sinks and sources of magnetization (div $\boldsymbol{M}$) may be interpreted as *magnetic charges* (note that magnetic charges never appear isolated but are always balanced by opposite charges, different to electric charges). A field arises from these charges that acts as stray field outside the sample and as demagnetization field in the interior. Volume, interface, and surface charges may be distinguished (Fig. 1(b)), the latter occurring if the magnetization vector is not parallel to a surface or edge. The energy connected to the stray field is $E_{stray} = -0.5\,\mu_o \int \mathbf{H}_{stray} \cdot \mathbf{M}\mathrm{d}V$. It scales with the factor $K_d = M_s^2 \mu_o/2$ (stray field energy coefficient, units J m$^{-3}$), which is a measure of the maximum stray field energy density of a material.

If the stray field energy dominates, flux-closed magnetization configurations will develop that tend to avoid stray fields. For the disk in Fig. 1(a), a concentric pattern would be completely charge-free, at the expense of some exchange energy though. Such a continuously flowing, isotropic configuration is in fact observed in anisotropy-free NiFe (Permalloy) disks (Fig. 1(c)).

The existence of ''real'' domains is, in a conventional picture, connected with the presence of anisotropy, which would favor homogeneously magnetized volumes along ''easy directions.'' However, in thin film elements, domains can also be present in the absence of anisotropy, just induced by the shape as shown in Fig. 1(d) for rectangular and elliptical elements. This follows from the requirement of pole avoidance (Van den Berg 1986): To be completely stray-field-free, the vector field $\mathbf{m}$ must be divergence-free within the element (div $\mathbf{m} = 0$), it must be parallel to the edges and to the film plane, and it must have a constant length ($|\mathbf{m}| = 1$). These

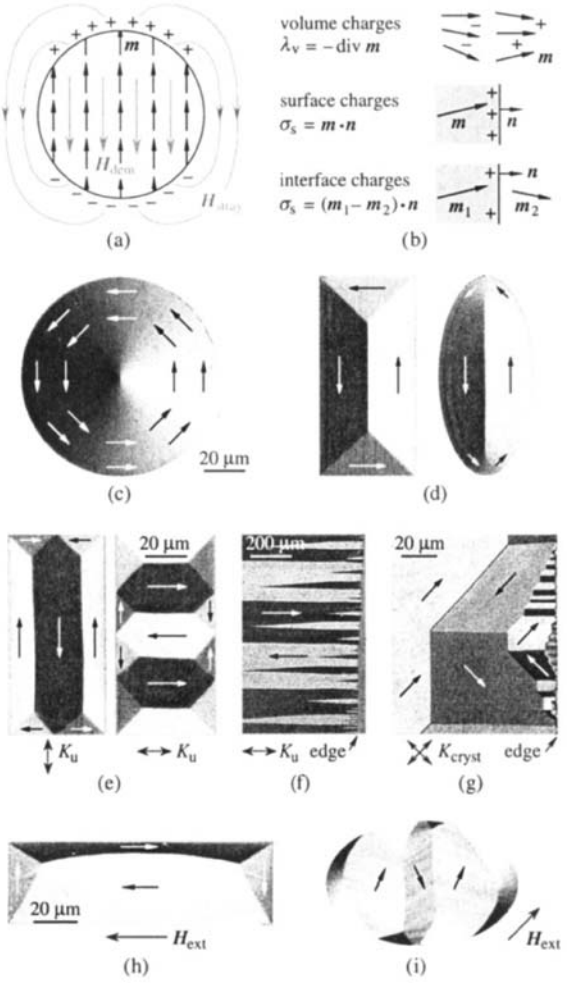

***Figure 1***

The effect of magnetic energies on domain formation, demonstrated for magnetic films. The magnetic charges (b) of the hypothetical, saturated state in (a) can be avoided by a flux-closed configuration as observed by Kerr microscopy on a $Fe_{81}Ni_{19}$ (Permalloy) film disk of 240 nm thickness (c). The shape-induced domains of the anisotropy-free Permalloy elements in (d) are modified by magnetization-induced anisotropies of the order of 100 J/m$^3$ in (e). The stress-induced anisotropy of the extended amorphous CoFeSiMo-film (f) (thickness 800 nm) is an order of magnitude higher than that of Permalloy, leading to a spike-like closure structure at the film edge. In the (100)-oriented, single-crystalline iron film of 100 nm thickness (g), four domain ''phases'' are found according to crystal anisotropy. External magnetic fields can cause wall motion and magnetization rotation as shown for 240 nm-thick NiFe elements in (h) and (i), respectively.

requirements can only be met simultaneously if the magnetization stays parallel to the edges on every point along an edge normal, as long as no other edge interferes. Consequently, uniformly magnetized *domain*s result in a certain neighborhood of straight edges. Similar considerations also apply to bulk specimens. However, in most magnetic specimens (especially in bulk magnets) the occurrence of ''regular'' domains and their arrangement is, in fact, strongly connected with the presence of anisotropy.

*(c) Anisotropy energy*

In most magnetic materials, easy axes do exist that are preferably occupied by the magnetization vector. Deviations cause an anisotropy energy $E_{\text{anis}} = K_u \sin^2\theta$ (for a uniaxial anisotropy, where $\theta$ is the angle between easy axis and magnetization, and $K_u$ is the anisotropy constant in J m$^{-3}$) (see also *Magnetic Anisotropy*).

Anisotropy may have different origins. In the case of Permalloy films, for example, a uniaxial anisotropy may be caused by preferred pair ordering of the atomic nickel and iron components along the local magnetization direction present during film deposition or at annealing (magnetization-induced anisotropy). Well-defined easy axes can be induced by annealing in magnetic fields, leading to oriented basic domains and closure domains at the sample edges to avoid magnetic charges (Fig. 1(e)). The anisotropy energy of the hard-axis closure domains could be reduced by decreasing their volume. This, however, necessarily would decrease the basic domain width at the expense of *domain wall energy*. The wall energy is proportional to $\sqrt{(AK)}$ because in a wall, the magnetization deviates from the anisotropy axes and from parallel arrangement. So the domain structures in the case of Fig. 1(e) are determined by the minimization of anisotropy and wall energy under the constraint of zero stray field energy.

Mechanical stress may induce or modify anisotropies as well, if the magnetostriction constant is different from zero. The stress-induced anisotropy in the amorphous film of Fig. 1(f) is an order of magnitude larger than the magnetization-induced anisotropy of the Permalloy elements in Fig. 1(e). Towards the film edge, the stray field energy is reduced by domain refinement in a spike-like way rather than by closure domains, which would involve considerable anisotropy energy. This mechanism of magnetostatic energy reduction by subdivision of the pole distribution towards an edge or surface is generally found in high-anisotropy, uniaxial materials.

In crystalline materials, the magnetocrystalline anisotropy—the preference of the magnetization vector to align with so-called easy crystal axes—is usually dominating. In the example of Fig. 1(g), two of the $\langle 100 \rangle$ easy axes in a single crystalline iron film are occupied, leading to a four-phase domain pattern with charge-free 180° and 90° domain walls.

Another important phenomenon can be seen in Fig. 1(g): the edge of the extended film is misoriented, i.e., it does not contain an easy axis. Here the two requirements of using only easy directions and avoiding stray fields are incompatible. A compromise is found by *domain branching*: towards the film edge, the pattern is refined in several generations of easy-axis-domains, so that the hard-axis closure domains (necessary to completely avoid stray fields) are getting as small as possible. They are restricted to the outermost edge and are not resolved in the image. Far away from the edge, the domains stay wide to save wall energy. The branching process connects the wide and narrow domains in a way that depends on the number of easy directions. In Fig. 1(f), for instance, only two-phase branching is possible due to the uniaxial anisotropy. In the case of a very weak uniaxial anisotropy (Fig. 1(e)), regular closure domains rather than branching may be preferred on misoriented edges. Domain branching also plays a major role in bulk materials if the easy directions are incompatible with the *surface* orientation. For strongly misoriented surfaces, a low energy is achieved by simple domains in the volume and a finely divided surface pattern.

*(d) Magnetostrictive energy*

A magnetic material with a nonvanishing magnetostriction constant is elongated along the magnetization direction. If the spontaneous deformations of the various parts of a domain pattern do not fit together elastically, a magnetostrictive self-energy arises that can modify the domain arrangement, especially in bulk materials.

*(e) Zeeman energy*

Applying an external field also adds energy. Domains with magnetization components along the field direction are favored and grow by wall displacement (Fig. 1(h)). In stronger fields, magnetization rotation occurs (Fig. 1(i)).

### *1.2 Classification of Materials and Domains*

The character of a domain pattern is determined by the relative size of anisotropy and stray field energy, defined by the dimensionless material parameter $Q = K/K_d$ (where $K_d = M_s^2\mu_o/2$ is the stray field energy coefficient, and $K$ is the effective anisotropy constant). If the stray field energy dominates ($Q \ll 1$), then flux-closed domain patterns develop that avoid stray fields, eventually at the expense of anisotropy energy in closure domains at surfaces if they do not contain an easy axis. A dominating anisotropy energy ($Q \gg 1$) forces the magnetization along easy axes, allowing for magnetic charges.

The ratio $Q$ determines the applicability of a material. A soft magnetic material should have a small value $Q \ll 1$, and strong permanent magnets are often based on materials with $Q \gg 1$. Note, however, that the properties of high and low relative anisotropy are not directly related to magnetic hardness, i.e., to high and low coercivity. Coercivity, as an extrinsic property, depends on additional structural features such as defects, grain boundaries, sample or particle size, and surface irregularities in conjunction with the magnetic microstructure. The intrinsic $Q$-parameter determines the potential to achieve a desired magnetic hardness (or softness).

### *1.3 Domain Walls*

The characteristic feature of *thin* soft magnetic films (thinner than 30 nm for Permalloy) is the symmetric Néel wall with an in-plane magnetization rotation (Fig. 2(a)). This is a magnetically charged wall, where most of the charges are concentrated in a wall core which scales with the exchange length of the stray-field energy $\sqrt{(A/K_d)}$ ($= 5$ nm for Permalloy). In thick films (thicker than 100 nm for Permalloy), the charged walls are replaced by completely stray-field-free, two-dimensional vortex walls (Fig. 2(b)). The width of the vortex scales with the film thickness.

Above a thickness of the order of $5\sqrt{(A/K)}$ (where $K$ is crystal or an induced anisotropy), a wall structure develops, which is still related to the asymmetric Bloch wall of thick films. Instead of a single vortex in the middle, two vortices are formed in the neighborhood of the surfaces that close most of the magnetic flux arising from the polar magnetization components in the wall interior (Fig. 2(d)). In the volume, this stray-field-free wall assumes a one-dimensional character with a rotation parallel to the wall plane as in a classical Bloch wall (see Fig. 2(c)), and at the surfaces, the magnetization rotates in-plane. Whereas the surface wall width steadily increases with thickness, the interior wall width approaches the classical value of $\pi\sqrt{(A/K)}$. Note that even in low-$Q$ materials the wall width stays finite, because a real soft magnetic material is never completely anisotropy-free, even if it has extremely high permeability. In high-$Q$ materials, the surface vortices are more or less suppressed and the wall approaches the classical Bloch wall structure (c) all through, allowing for magnetic charges at the surfaces.

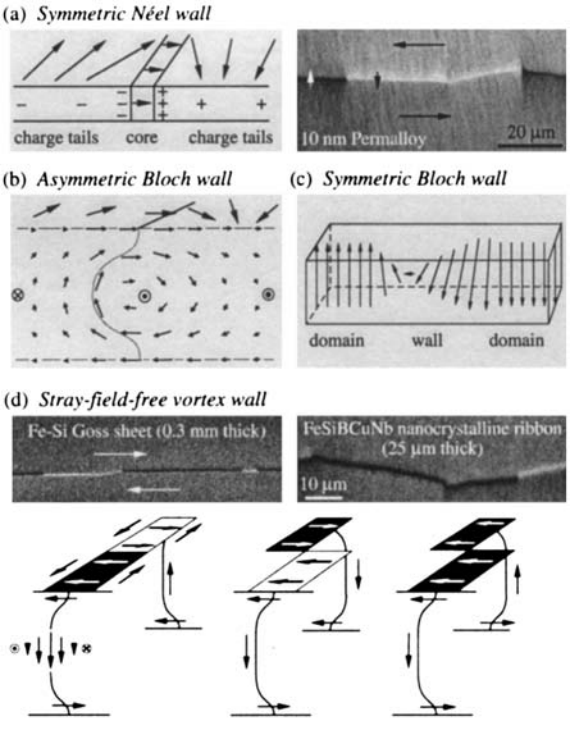

***Figure 2***
The fundamental types of domain walls in *soft* magnetic materials. In a, b, and d, the surface magnetization and the projection on the cross-section plane is schematically shown together with observations by Kerr microscopy. The black-and-white wall segments are due to different chiralities of the surface magnetization. The magnetic charges of the Néel wall (a) are distributed between a sharply localized core and extremely wide tails, which take over a good part of the rotation. The asymmetric Bloch wall (b) and its derivative for high sample thickness (d) are free of magnetic charges. The slight tilting of some wall segments in (d) is a consequence of the vertical flux, indicating segments of opposite chirality. Those transitions not connected with a kink represent mere "cap switches"—a change in the orientation of the surface vortex without a change in the basic wall chirality. The classical (symmetric) Bloch wall, which is approached in high-$Q$ materials, is sketched in (c) for comparison. Here, the magnetization rotates parallel to the wall plane across the whole sample thickness.

## *2. Domains in Soft Magnetic Materials*

Soft magnetic materials play a major role as core material in inductive devices. Such devices rely on the high permeability of their cores that reaches values up to one million times the air value. Domain wall displacement is the primary origin of this extraordinary quality of soft magnetic materials. But also, magnetization rotation can lead to high permeability if anisotropies are uniform and small. Depending on applications, magnetization processes have to be carefully controlled by selecting proper materials with suitable domain patterns. In high-frequency applications, for instance, wall displacement processes are generally less favorable than rotation

because of the "anomalous" eddy current losses connected with wall motion (see *Magnetic Losses*).

The avoidance of wall motion requires that all 180° walls are oriented perpendicular to the field direction. This can be achieved in ring cores of low-anisotropy materials with a transverse easy axis, showing a linear response with low remanence and coercivity. Irregularities connected with domain wall pinning and domain annihilation or creation processes cause losses in electrical machines and noise in communication and sensor devices. A general rule is: if the character of the magnetic microstructure can be improved in the sense of a more regular domain structure leading to more reversible magnetization processes, a better performance of inductive devices can be achieved.

In this section, the magnetic microstructure of selected soft materials is reviewed. Emphasis will be on equilibrium domains in the field-free state, largely neglecting the rich variety of patterns that occur on application of magnetic fields. The domains in all soft magnetic materials follow the principle of flux closure ($Q \ll 1$), but anisotropy together with the surface orientation has a decisive influence on domain arrangement.

### 2.1 *Grain-oriented Electrical Steel*

Grain-oriented transformer material consists of large grains of Fe 3 wt.% Si. They are oriented within a few degrees deviation of the [001] easy direction from the preferred axis of the material. The surfaces of all grains are (110)-related within the same accuracy in misorientation (forming altogether a [001](110) texture, the Goss texture). The sheets are insulated by thin ceramic layers to avoid eddy currents between the sheets and to provide favorable mechanical stress (see also *Steels, Silicon Iron-based: Magnetic Properties*).

The basic domain structure of well-oriented Goss grains consists of wide domains magnetized parallel and antiparallel to the easy [001] direction (grain A in Fig. 3(a)). If the [001] direction is slightly misoriented out of plane (grains B, C), the basic domains are supplemented to reduce the stray field energy: shallow surface domains (lancets) collect the perpendicular flux, which would otherwise emerge from the surface due to the misorientation, and feed it into internal transverse easy-axis domains where it is transported to the other surface of opposite charge polarity or to the neighboring basic domain to be distributed again (Fig. 3(d)). In a variant, the lancets join into combs (grain C) by using a common internal transverse domain that is properly oriented to avoid magnetostrictive energy. Therefore, the combs are aligned along a $\langle 111 \rangle$-axis at the surface.

The magnetization process along the preferred axis occurs by motion of the basic 180° walls. However, during a magnetization cycle, the system of

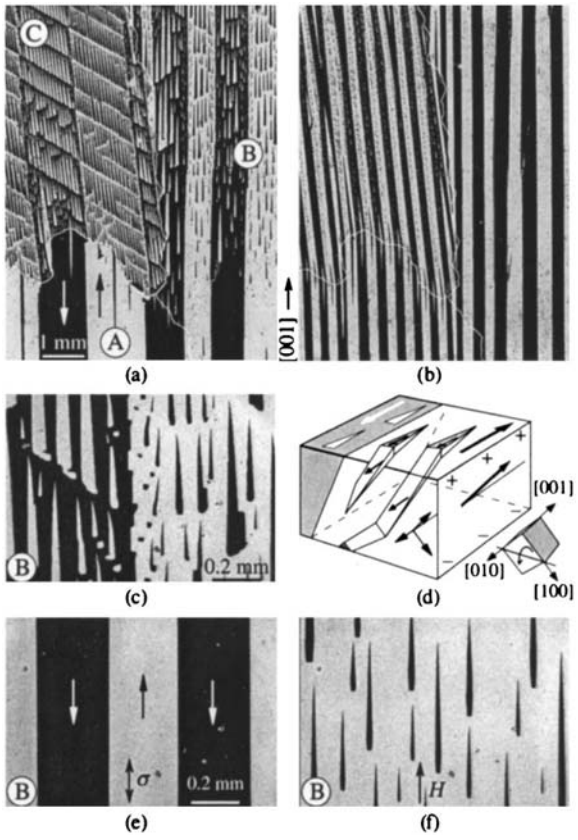

***Figure 3***
(a) In Goss-textured transformer steel, simple (grain A) or supplemented-bar domains (grains B, C) are observed, depending on the misalignment of the [001] easy axis relative to the surface (that is 0°, 1°, and 2° in grains A, B, C, respectively). Details of grain B are shown at higher magnification in (c) together with a three-dimensional model of a supplementary pattern in (d). A uniaxial tensile stress along the preferred axis (b) largely suppresses the supplementary domains and causes domain refinement in misoriented grains, which also extends to well-oriented grains to maintain flux continuity. The tensile stress of 2 kg mm$^{-2}$ in (b) was applied externally to simulate the stress-effective insulation coating that was removed here to allow for Kerr microscopy. If the basic domains (e) of a stressed grain are wiped out during the magnetization cycle, the supplementary domains return (f). Images (e) and (f) are from the same location, but a field is applied in (f) leading to a relative magnetization of $M/M_s = 0.9$.

supplementary domains is destroyed and rebuilt. The energy bound in the supplementary domains is lost in every cycle, thus forming an important part of hysteresis loss in transformer sheets. Since several nonplanar easy axes are always engaged in

supplementary domain patterns, their generation and annihilation is also connected with magnetostrictive, acoustic noise (note that the magnetostrictive elongation would not change by the motion of a 180° wall).

Two possibilities do exist to avoid the unfavorable supplementary domains. They can be largely suppressed by mechanical tensile stress along the preferred axis (Fig. 3(b)). It magnetostrictively favors the basic domains and wipes out the transversely magnetized domains. The basic domain spacing is then decreased because otherwise the overall stray field energy would rise in the absence of the supplementary domains. The reduced domain width also reduces anomalous eddy current losses, which become important if the basic domain width is larger than the sheet thickness. Fortunately, the planar stress exerted by the stress-effective insulating coating is for the Goss texture equivalent to a uniaxial stress along the preferred axis and will thus suppress supplementary domains. Note, however, that for magnetostatic reasons, the lancet structure reappears when the basic domains are wiped out during the magnetization cycle as is demonstrated in the sequence in Fig. 3(e) and 3(f). This causes extra losses.

It is also possible to avoid supplementary domains completely if a misorientation of better than one degree is achieved. But such a quasi-single-crystalline material would tend to develop very wide basic domains (Fig. 4(a)) with correspondingly large anomalous eddy current losses. The basic domain width can be artificially reduced by scratching or by laser scribing (Fig. 4(b)). The stress introduced locally in this way interrupts the basic domains, acting like an artificial grain boundary (see also *Steels, Silicon Iron-based: Magnetic Properties*).

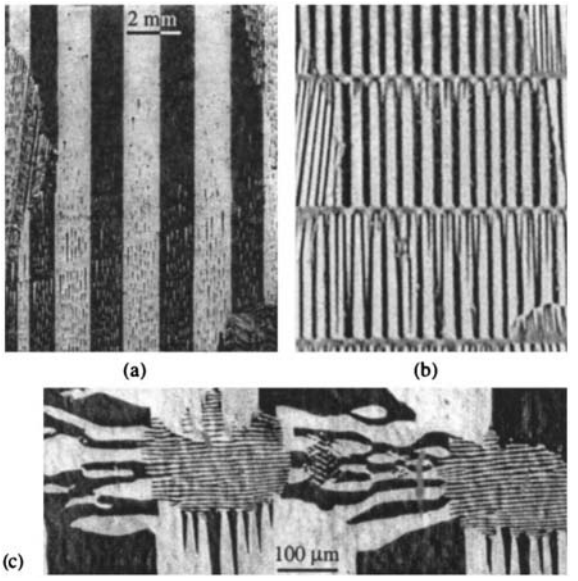

***Figure 4***
Domain spacing in well-oriented grains (a) can be reduced by laser scribing (b). The stress between the laser spots causes unfavorably oriented domains that interrupt the basic domains (c). Image (b) was obtained by applying a powder emulsion to a laser-treated surface with insulating coating, whereas the Kerr image (a) is from the same location after removing the coating and relieving stress by annealing. Kerr image (c) was obtained before annealing at higher magnification.

### *2.2 Nonoriented Electrical Steel*

Figure 5 gives an impression of the huge variety of domains on the surface of nonoriented silicon–iron material commonly used in rotating electrical machines (see also *Steels, Silicon Iron-based: Magnetic Properties*). Domain complexity depends on crystal orientation. Domains in ideal Goss-grains (grain A) or slightly misoriented Goss-grains (grain B) are readily identified by comparison with Fig. 3. In the (100)-oriented grain (C), a simple four-phase surface pattern is found as in the corresponding thin film case (Fig. 1(g)). Note, however, that for a thick sheet also the easy axis perpendicular to the surface will be occupied by internal domains. A slightly misoriented (100) surface (grain D) shows fir-tree domains—a supplementary pattern that distributes the perpendicular flux between neighboring basic domains by shallow surface domains.

With stronger misorientation, the supplementary domain system becomes increasingly complicated (grain E in Fig. 5), and above a critical misorientation, *branched* domain patterns take over (grains F and G in Fig. 5). Branching (see Sect. 1) at the surface of a bulk cubic material occurs in a similar way as shown in Fig. 1(g) for a two-dimensional case, but further possibilities will be added by allowing the third dimension to be used both by the magnetization direction and by the spatial domain structure. The fractal nature of branched patterns with up to four generations of domains is also revealed in the surface pattern of the extremely misoriented grain G (for this (111)-surface the easy axes are aligned at the maximum angle of 54° relative to the surface). Note that in a fine-grained material, not only the orientation of the free surface is important. Even if there might be grains for which this surface is well oriented, there can be inner grain boundaries that are strongly misoriented, consequently dominating the domain pattern in the whole grain.

The bottom images in Fig. 5 give an impression of the complicated domain reorganization processes in misoriented grains when a magnetic field is applied. Only the fact that the branched surface structures are confined to a limited near-surface zone (of about

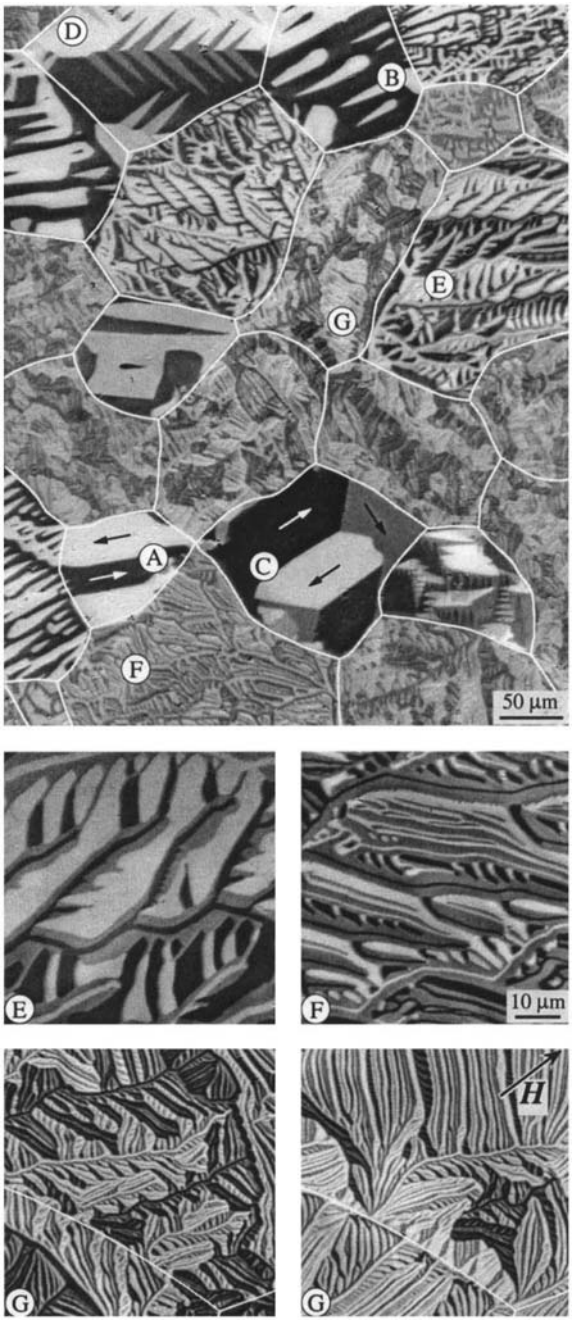

***Figure 5***
The domains on the surface of nonoriented electrical steel (thickness 0.5 mm) depend on the orientation of the crystallites. Patterns of selected grains are enlarged below. The images in the bottom row show the same location in a (111)-oriented grain, with a magnetic field applied on the right.

50 μm depth) makes a reasonable permeability in nonoriented material conceivable, which will rely on the underlying (wide) basic domains. The rearrangement of the branched closure pattern causes a kind of friction for the displacement of the basic domain walls and leads to unavoidable hysteresis losses.

### *2.3 Crystalline High-permeability Materials*

Much smaller anisotropies than in silicon–iron material and thus higher permeabilities of more than 100 000 can be reached in NiFe alloys near the 80:20 composition, known as Permalloy or Mumetall. These high-permeability materials are adjusted in composition and heat treatment to reach zeros of first-order anisotropy constant and in the mean magnetostriction constant. Nevertheless, regular domains with clearly delineated domain walls are usually observed within the crystallites of coarse-grained Permalloy (Fig. 6(a)). They scale with the grain size and change from grain to grain, demonstrating the influence of residual crystal anisotropy.

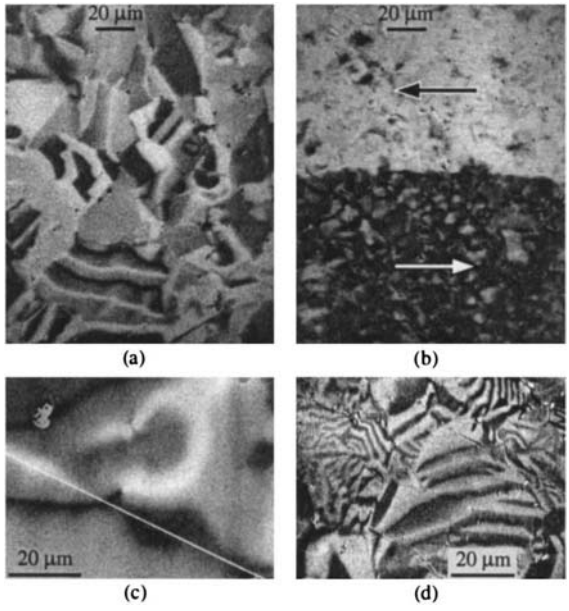

***Figure 6***
In coarse-grained Permalloy sheets [(a), grain size around 30 μm, thickness 20 μm], regular domains do exist that are correlated over the grain boundaries. Occasionally, domain walls may become dissolved in a continuously rotating magnetization (c), if anisotropy becomes negligibly small. In the fine-grained material [(b), grain size around 13 μm], macroscopic domains extend over many grains and are modulated by the local anisotropies in the grains. A coarse-grained manganese–zinc ferrite is shown in (d).

Absent are the complex branched surface domains that typically occur in misoriented grains of iron-based material. Only occasionally regular domains may be replaced by a smoothly varying magnetization configuration as actually expected for zero anisotropy (Fig. 6(c)). In fine-grained Permalloy material (Fig. 6(b)), the domain structure resembles that of Permalloy thin films in which the domains extend over the grains (see Fig. 1, and the interpretation in Sect. 2.5). Uniformly magnetized grains are also found in coarse-grained NiFe materials after annealing in magnetic fields. Such regular magnetic microstructures cause reversible magnetization processes and thus low noise in sensor applications.

Similar domains as in coarse-grained Permalloy ribbons are observed in soft magnetic spinel ferrites with a sufficiently large grain size (Fig. 6(d)). Ferrites are prepared by sintering and they are used in high-frequency applications due to their insulating properties (see *Ferrites*). Domain wall processes are important in the whole application range of ferrites up to GHz frequencies.

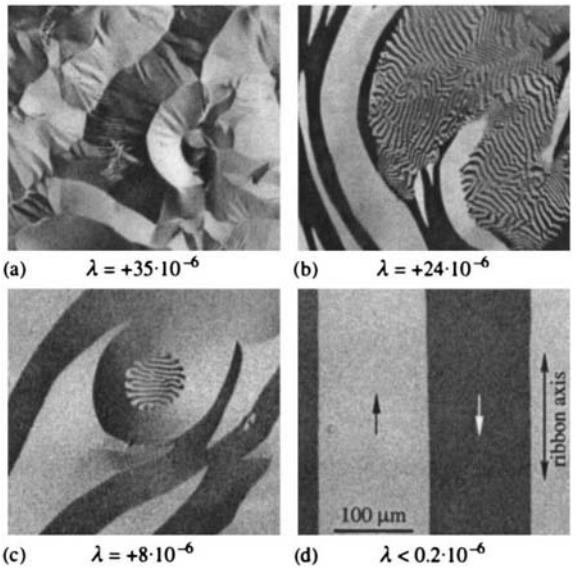

***Figure 7***
Typical zero-field domain patterns in 20 μm-thick amorphous ribbons of different magnetostriction constant $\lambda$.

### 2.4 *Amorphous Ribbons*

Amorphous magnetic ribbons are alloys with typically 80% iron, cobalt, or nickel, and 20% "metalloids" like silicon or boron. They are quenched from the melt with a thickness around 20 μm (see *Amorphous and Nanocrystalline Materials*). In application, they compete with high-permeability NiFe alloys. While crystal anisotropy is small in NiFe materials, it cannot exist in metallic glasses by definition. Nevertheless, "regular" domains do exist in such ribbons, again caused by residual anisotropies.

The main source of anisotropy is internal stress, frozen in by the rapid quenching process. The magnetization is coupled to the stress by the magnetostriction constant, so that the domain complexity in as-quenched ribbons depends on magnetostriction as shown in Fig. 7. Two types of domains are typical: wide curved domains that follow a varying in-plane easy axis (caused by dominating tensile stress for positive magnetostriction constant), and narrow fingerprint domains. The fingerprints are closure domains of underlying perpendicular domains, caused by planar compressive stress which induces an easy axis perpendicular to the surface. Internal stress can not only vary laterally, but also in depth. This leads to layered domain structures as demonstrated in Fig. 8. A layered in-plane anisotropy with twisted easy directions is visible in Fig. 7(a).

Even magnetostriction-free metallic glasses show regular (but wide) domains in the as-quenched state (Fig. 7(d)). They are often aligned along the ribbon axis, caused by magnetization-induced anisotropy (see Sect. 1). The easy axis follows the magnetization direction present during quenching, which is frozen in

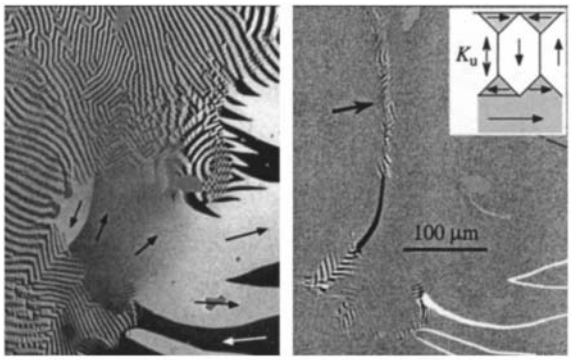

***Figure 8***
Demagnetized state (a) of a magnetostrictive amorphous ribbon, and the image difference (b) between image (a) and a state where a small magnetic field was applied, showing domain changes. The 180°-wall displacement continues in the area of the fingerprint structure (see arrow in (b)), proving that the fingerprint pattern must be restricted to the surface zone as sketched. Obviously there is a layered stress distribution: compressive stress near the surface and dominating tensile stress underneath.

while cooling through the Curie point and which is along the ribbon axis for magnetostatic reasons. Such induced anisotropies are also present in magnetostrictive materials where it is difficult to separate them

from stress-induced contributions. Residual anisotropies may also be caused by the flow pattern during quenching, by the surface structure of the ribbons (due, for example, to "air bubbles" on the wheel side), and by mechanical creep due to different quenching speed at different ribbon locations.

Controlling anisotropy in metallic glasses is possible. Frozen-in stress can be relaxed by more than 95% by carefully annealing below the crystallization temperature. In addition, annealing can be performed in uniform magnetic fields below the Curie temperature or under external mechanical load. This leads to well-defined anisotropies by the same mechanisms as discussed before. A variety of ordered domain-states is possible in this way (Fig. 9), allowing tailoring of magnetization curves for specific applications. For instance, transverse and perpendicular domains shown in (a) and (e), respectively, are essentially magnetized by rotation in fields along the (vertical) ribbon axis, causing a linear hysteresis curve with only minor domain rearrangement processes. Losses are correspondingly low.

### 2.5 *Nanocrystalline Ribbons*

Modern nanocrystalline ribbons with grain sizes in the 10 nm range compete in high-permeability applications with classical Permalloy and amorphous ribbons (see *Amorphous and Nanocrystalline Materials*). The best-known alloy is the FeSiBNbCu system, which consists of nanocrystalline SiFe grains embedded in an amorphous magnetic matrix. Because of the small grain size, the exchange interaction averages over anisotropic properties of the individual grains, so that anisotropy is smoothed out and the material is effectively anisotropy-free (the same mechanism applies to the Permalloy films discussed in Sect. 1 and the fine-grained Permalloy sheets of Sect. 2.3). Together with a very small magnetostriction, excellent soft magnetic properties can be achieved.

Well-defined domains and walls are found in these materials (Fig. 10), which cannot be distinguished at optical resolution from those in metallic glasses. Another class of nanocrystalline materials contains some zirconium and has a higher iron content to obtain a higher saturation magnetization. The patchy modulation of magnetization (Fig. 10(b)) seems to be caused by the effects of the irregular polycrystalline nature of this material. Hard and immobile patch domains are observed when the crystallites are getting too big or if the coupling between the crystal grains is too weak.

## 3. *Domains in Hard Magnetic Materials*

The magnetic microstructure of hard magnets is trivial in the permanent magnetic state: the elementary carriers of the magnetic moment, the more-or-less independent grains or particles in these materials,

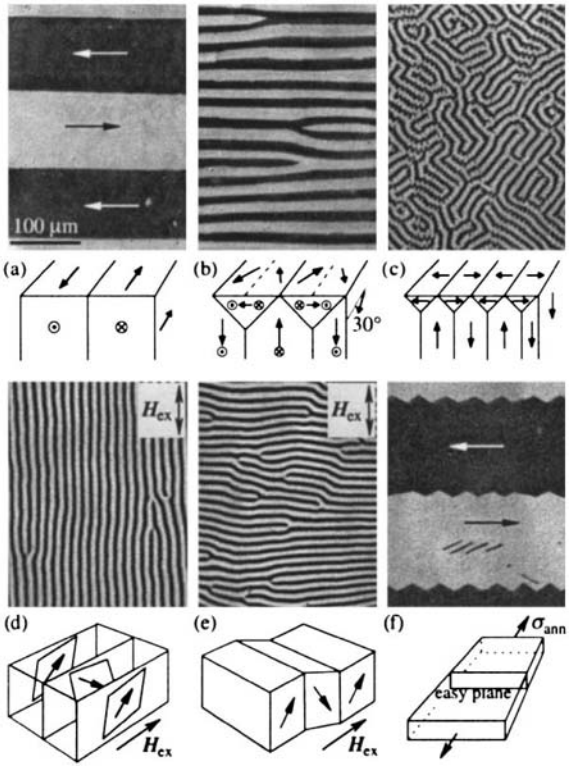

***Figure 9***
Ordered domain states in metallic glasses after different annealing treatments. The ribbon axis is along the *vertical* direction in all images. Annealing in a field *transverse* to the strip axis results in wide transverse domains (a). A strongly reduced domain width is obtained after annealing in fields perpendicular to the ribbon surface, resulting in an *oblique* (b) or *perpendicular* anisotropy (c) in dependence of the annealing field strength. The orientation of the narrow stripe domains in the case of a perpendicular anisotropy depends on the magnetostriction constant. If the ribbon is demagnetized in an alternating field along its axis, the stripes are oriented parallel to the field axis for a low-magnetostriction material (d) and perpendicular in a high-magnetostriction material (e). This can be explained by the compatibility of magnetostrictive deformations: a positive magnetostriction favors stripe nucleation perpendicular to the field (sketch e) as opposed to parallel stripes (sketch d) in which the deformations are incompatible. The latter is only possible in low-magnetostriction materials and is preferred there because a parallel stripe pattern saves wall energy. The transverse pattern in (f) is obtained by a "creep" annealing treatment under mechanical load. At zero field, the magnetization is forced in the transverse in-plane direction to reduce magnetostatic energy.

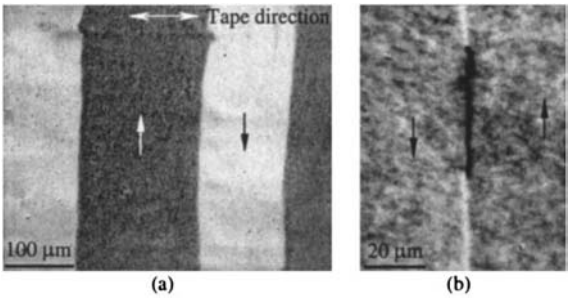

***Figure 10***
(a) Ordered domain structure on a nanocrystalline FeSiBNbCu-based soft magnetic ring core annealed in a field perpendicular to the tape direction. (b) High-resolution observation on a zirconium-containing nanocrystalline ribbon, showing wall and modulated domain contrast.

keep saturated along a preferred direction in remanence. Domains are not connected to the permanent magnet function and should be completely eliminated to obtain a high coercivity and remanence. They only play a role during switching. Two main classes of permanent magnets must be distinguished: Small-particle magnets and anisotropy-based coarse-grained magnets (see *Hard Magnetic Materials, Basic Principles of*). Most hard magnetic materials rely on a strong uniaxial anisotropy with $Q \gg 1$, as opposed to soft magnetic materials, which typically have a manifold of easy directions.

### *3.1 Coarse-grained Magnets*

In large-grained sintered magnets, two classes can be separated: nucleation- and pinning-type magnets. The difference becomes evident in the initial magnetization curves. Starting from the thermally demagnetized state, every grain in a nucleation-type material contains many domain walls that can be displaced easily (see Fig. 11(a), (b)), leading to a large initial permeability. The permanent magnet properties appear only when the initial domain walls are driven out in a large field (Fig. 11(c)) so that also residual domains, which are a natural consequence of particle shape and localized stray field concentration, are completely annihilated. This requires magnetic fields that may well exceed the saturation field $M_s$ along the preferred axis, in particular for isotropic samples or for misoriented grains in textured material. The magnet can be demagnetized after this step only if new domain walls are nucleated. In contrast, in a pinning-type magnet, the domain walls are effectively pinned by precipitates, leading to a low initial permeability.

Examples of nucleation-type magnets are hexaferrite magnets (see *Alnicos and Hexaferrites*) and

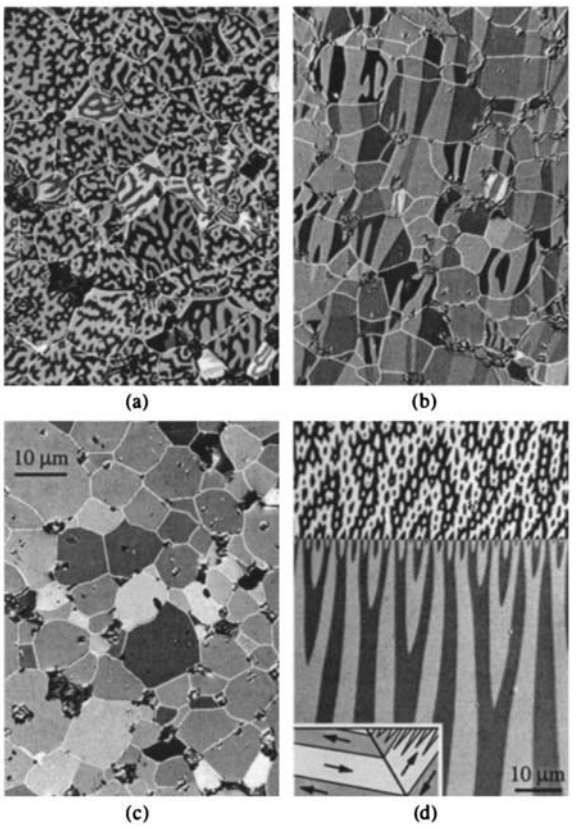

***Figure 11***
Domains on a sintered NdFeB magnet. (a) The thermally demagnetized state on the basal plane, with the axis of the textured magnet perpendicular to the viewing surface. (b) The same state viewed parallel to the axis reveals the high degree of texture in this material. The grains are magnetostatically coupled as exchange interaction is prevented by a nonmagnetic grain boundary phase. (c) Domain-free, remanent state after applying a saturation pulse [same location as (a)]. The character of the branched domains visible in (a) is displayed in (d) for a large-grained precursor material. The twin grain boundary acts like a mirror for the domains, so that ''surface'' domains (upper part) and ''volume'' domains (lower part) show up at the same time (compare Fig. 1(f)).

high-quality rare-earth magnets of the $SmCo_5$ and the $Nd_2Fe_{14}B$ types (see *Magnets: Sintered*). They consist of highly anisotropic grains in a textured, polycrystalline compound, which is prepared in such a way that switching of one grain has little influence on its neighbors. Coercivity is thus primarily given by some mean switching thresholds of the individual grains. Both the initial and the final states of the switching process are essentially saturated in

high-coercivity materials, but the switching process itself traverses a multidomain state (note that the grain size is in the 10 μm range, which is much larger than the single-domain size of about 100 nm).

If the domain walls are narrow due to high crystalline anisotropy, the walls may be effectively pinned by a finely dispersed nonmagnetic phase. The alloy $Sm_2(CoFe)_{17}$ containing copper-rich $Co_5Sm$ precipitates is an example for a high-quality permanent magnet based on this principle. The precipitation phase has a reduced magnetization and exchange constant, so that the domain walls prefer to travel along the platelet-shaped precipitates. The elimination of residual domains plays no role because these domains are pinned (like all others) and the coercivity is determined by the interaction between domain walls and microstructure.

Note that both nucleation and pinning type magnets rely on the high energy and narrow width of their domain walls. A high wall energy makes nucleation of new domains difficult, a narrow wall width favors an effective pinning of walls. The finely divided domains in Fig. 11(a), which are of the two-phase branched type discussed in Sect. 1, can be applied to measure the wall energy. It was shown that the surface domain width of such a pattern stays constant, independent of crystal thickness, whereas the internal domain width increases with thickness. This is determined by an equilibrium between stray field energy and wall energy. From the measurement of the surface domain width, the domain wall energy can conveniently be determined.

### *3.2 Small-particle and Fine-crystalline Magnets*

If a magnetic body becomes very small, it will not contain domain walls and the particle becomes *single-domain*. This occurs when the expense of wall energy becomes greater than the gain of stray field energy. The critical single domain size depends on the $Q$-parameter and the particle shape. The single domain limit rises with increasing elongation of the particle.

Permanent magnets can also be prepared from such single-domain particles. If the individual particles consist of a low-anisotropy material, they must have an elongated shape to remain single-domain. For such large particles, the danger of thermally activated spontaneous switching (superparamagnetism) is absent. Elongated single-domain particles are therefore thermally stable even if they are completely isolated. Classical examples of this permanent magnet class are the *Alnico* alloys, consisting of fine filaments of a high-saturation FeCo alloy that are embedded into a nonmagnetic NiAl matrix (see *Alnicos and Hexaferrites*).

Modern small-particle magnets are based on high-anisotropy materials that consist of single-domain *grains*. A number of techniques can be used to prepare

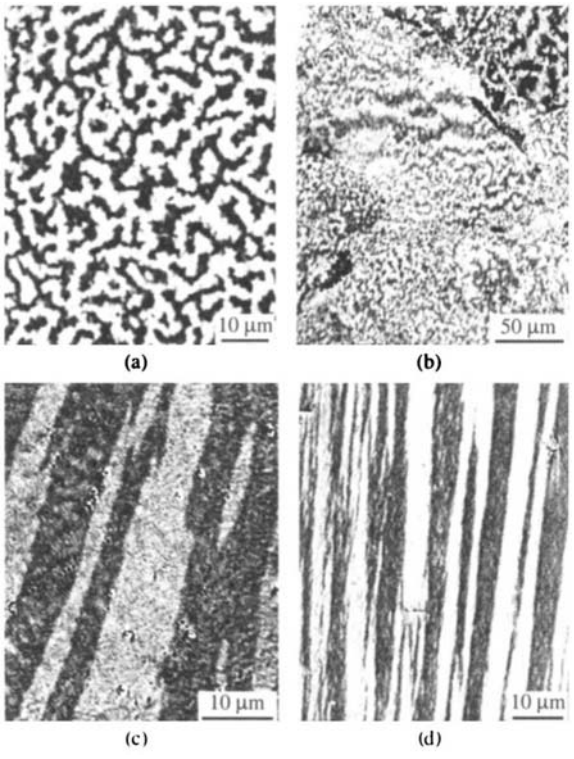

***Figure 12***
(a) Interaction domains observed on a surface perpendicular to the preferred axis of textured, fine-grained NdFeB material prepared by melt spinning and hot deformation. In the HDDR-processed material (b), the interaction domain width depends on the degree of texture. In (c), the interaction domains are observed parallel to the texture axis in the same material as in (b). (d) Interaction domains on the side face of an oriented Alnico crystal.

fine-crystalline magnets out of precursors such as $Nd_2Fe_{14}B$: rapid quenching and subsequent crystallization, mechanical alloying (see *Magnets: Mechanically Alloyed*), and the HDDR process (see *Magnets: HDDR Processed*). All these methods generate a fine powder with a particle size around 100 μm, which then has to be compacted into solid magnets. Oriented magnets can be produced by "die-upsetting" (see *Textured Magnets: Deformation-induced*). Also by the HDDR process, an anisotropic powder can be produced which can be oriented in a magnetic field.

But even nonoriented fine-crystalline materials remain interesting as a relatively weak exchange interaction between very small grains can lead to an enhanced remanence without a significant loss in coercivity (exchange-enhanced fine-crystalline magnets). The coupling enhances the remanence above the average $M_r = 0.5\ M_s$ of independently oriented

uniaxial grains. A further possibility for achieving high remanence in nonoriented small-grain materials consists of adding a high-saturation soft magnetic phase, which is strongly exchange-coupled to the basic hard magnetic phase if the extension of the soft phase is sufficiently small (see *Magnets: Remanence-enhanced*). The coercivity in these two-phase fine-crystalline magnets is dominated by the hard phase, whereas the high remanence is primarily a consequence of the soft phase.

The magnetization of the grains in fine-grained permanent magnets is strongly correlated. An irregular magnetic microstructure is displayed in the demagnetized state as shown in Fig. 12(a)–(c). The black-and-white contrasts correspond to grain neighborhoods that are magnetized along a certain net magnetization direction. These patterns are predominantly determined by dipolar interactions between the fine grains—an assumption which is justified by the fact that this kind of domains is also observed in small-particle magnets like Alnico (Fig. 12(d)) for which the presence of exchange interaction between the needles can be excluded. To indicate their special nature, they were called "magnetostatic interaction domains." A characteristic feature of interaction domains is their elongated shape extending along the preferred axis of the material as is visible in Fig. 12(c). The "domain boundaries" of the interaction domains can move laterally to some extent by the successive switching of neighboring grains (or particles in case of Alnico), thus providing a certain permeability for the demagnetized state.

### *3.3 Conclusions*

The domain patterns in a variety of soft and hard magnetic (mainly bulk) materials have been reviewed. In both material classes, magnetic domains are formed to reduce the magnetostatic energy of finite samples. The interactions between physical microstructure, easy axes, applied fields, surface orientations, and mechanical stress leads to an enormous variety of domain patterns, only a small fraction of which could be presented by focusing on selected, undisturbed samples.

Although in *soft magnetic materials* the avoidance of magnetic charges is the dominating principle, the domain arrangement is strongly influenced by anisotropy. The orientation of the main surfaces with respect to the easy directions is decisive. If a surface contains easy directions, it is no problem to reconcile pole avoidance with avoiding anisotropy energy by employing the surface-parallel easy directions only. Grain-oriented transformer steel belongs to this class. Here the degrees of freedom for domain formation are strongly reduced and the basic domain patterns are related to those of ideally oriented grains even in the case of small misorientation.

Due to the near-single-crystal nature of this material, its magnetic microstructure is conveniently observable and well understood, so that the losses of transformer steel are steadily reduced by studying and controlling the domain structure. Domain control is also possible in amorphous and nanocrystalline ribbons if the influence of mechanical stress can be avoided. For most other bulk soft magnetic materials—the nonoriented polycrystalline SiFe, NiFe, and ferrite materials—similar possibilities are not available. Observing the complex, often heavily branched domains at the surface of such materials offers only a glimpse at the magnetization processes in the volume.

Domains in hard magnetic materials are only important during switching. In coarse-grained material they are determined by a strong uniaxial anisotropy, and in fine-grained magnets the magnetostatic interaction between small grains results in an inhomogeneous magnetic microstructure called interaction domains.

## Magnets: Biomedical Applications

This article deals with magnetic substances used inside living beings, particularly humans. The application of magnets in medicine has been known for more than 2500 years. Probably the earliest document dates from about 600 BC and concerns the extraction of an iron arrow tip by means of an extracorporally applied loadstone (Hirschberg 1899). Several publications of pre-Christian centuries described the application of magnetic material as a remedy for a variety of diseases (Häfeli 1998). Nevertheless, it was not before the middle of the twentieth century that the number of different magnetic materials for biomedical applications considerably increased.

## 1. Natural Magnetic Substances in Humans

The existence of magnetic material, mainly magnetite ($Fe_3O_4$), in living beings was found for the first time in 1962 (Lowenstam 1962) and later recognized as being responsible for the orientation capabilities of a number of animals. The discovery of small particles consisting of magnetite and maghemite ($\gamma$-$Fe_2O_3$) in human tissue was reported for the first time by Kirschvink *et al.* (1992). There is evidence for some influence of this material with reference to magnetic resonance imaging (MRI), where it may be responsible for contrast alterations. Human tissue is almost completely diamagnetic. There are, however, some paramagnetic substances with high values of susceptibility: hemosiderin and ferritin. These substances are responsible for storage and transport of iron in organisms and can be used for the noninvasive examination of the iron content in the liver (Nielsen *et al.* 1998). Finally, it is worth noting that the magnetic susceptibility of hemoglobin, an important part of red blood cells, changes depending on its oxygenation state. This behavior is used for the so-called blood oxygenation level dependent (BOLD) contrast in functional MRI (Schreiber *et al.* 1998).

## 2. Bulk Magnets

Important properties of bulk magnets positioned inside a living being concern the force or the torque exerted in magnetic fields on appropriately designed pieces of the material, the magnetic stray field that may be used for monitoring the position of the magnet, and the magnetic losses arising in alternating magnetic fields. All the substances have to be nontoxic. This can be achieved either by the choice of nonpoisonous magnetic materials, as is the case with magnetite, or by covering the magnet with suitable coatings (plastic, gold film, etc.).

### 2.1 Bulk Magnets for Force or Torque Applications

A magnetic field may be generated by permanent magnets inside the body. Another way is to use fields generated outside the body by coils or permanent magnets. An example of permanent magnets used inside the body is the application in veterinary medicine (Fahlenbrach and Fahlenbrach 1970) where cows are forced to swallow rods of Alnico, a permanent magnetic material, covered with plastic to prevent both the magnet from corrosion and tissues from toxic effects. The magnet remains in one of the stomachs and attracts steel parts often swallowed by the animals together with green fodder or hay. In this way the stomach and intestines are protected against being damaged. The same principle is sometimes also used in human medicine to remove pins, nails, and other steel parts that have been swallowed (Häfeli 1998). Another example concerns the fixation of temporary pacemaker electrodes by hand-held permanent magnets in emergency cases (Paliege *et al.* 1979). Pieces of gold-plated iron wires have been used as tips of flow-in stimulation catheters for this end. Interesting experiments have been performed with certain kinds of catheters that are able to move through blood vessels driven by a combination of a d.c. magnetic field and an a.c. field. These parts consist of a small permanent magnet (barium–ferrite cylinders of a few cubic millimeters) and a flexible plastic tail (Frei *et al.* 1966).

In spite of this fascinating idea these catheters could obviously not be introduced into general medical practice. Guidance of small magnetic probes is being investigated in terms of the so-called magnetic stereotaxis, i.e., the minimally invasive manipulation of a permanent magnet inside the human brain along a path of minimum damage to a position where it can be used to heat a well-defined small region of tissue (e.g., a brain tumor) or to act as a catheter for other purposes. *In vivo* experiments have been successfully performed with animals (Grady *et al.* 1990) and application in humans, e.g., using multiple superconducting coils, looks promising (Meeker *et al.* 1996). Equipment for generating fields outside the body is generally less complicated. However, it was not until the mid-1990s that a piece of permanent magnetic material (Nd–Fe–B disk of 5 mm diameter and 2 mm thickness) was positioned in the stomach and kept there for several hours simply by the force exerted by an external fixed permanent magnet (Gröning *et al.* 1996). The magnetic disk covered by a layer of carnauba wax was part of a tablet designed for osmotically controlled drug release. An interesting application is the magnetic stoma seal for colostomy. It consists of an implanted permanent magnetic ring (Sm–Co covered with titanium) and a suitably formed lid. At first glance this system seems to be very attractive. A critical review of about five years' practice, however, showed a relatively high percentage of incontinence (Schwemmle 1982). Therefore, the conventional technique is still widely used.

### 2.2 Bulk Magnets for Monitoring

For many years there have been attempts to investigate the motility of the gastrointestinal tract by magnetic monitoring (Forsman 1998) with the aim of avoiding exposure to x rays or other ionizing radiation. However, it was not before 1997 that satisfying results were presented. Weitschies *et al.* (1997) published reliable images of magnetic marker monitoring with a spatial resolution in the millimeter range and a temporal resolution down to 4 ms. The technique uses markers consisting of sucrose pellets coated with a mixture of magnetite and polymethyl methacrylate and enclosed in silicone rubber. After ingestion of

these markers the magnetic stray field outside the body is measured by means of a superconducting quantum interference device (SQUID) and can be used to calculate the actual position of the marker.

However, the technique is a rather expensive one (SQUID array cooled by liquid helium, sophisticated electronics, and a shielded room to reduce background fields by several orders of magnitude). A simpler novel technique is where an extracorporally applied pulsed magnetic field is used to repeatedly align the marker with its magnetic axis. The stray field is measured during the impulse pauses after successively alternating pulses. In this way two essential advantages result: the use of much cheaper conventional field sensors and working without any magnetic shielding, i.e., in a normal environment (Andrä *et al.* 2000). It is worth noting that the same principle can be used to monitor other objects, e.g., the tip of a heart catheter.

### *2.3 Bulk Magnets for Tissue Heating*

One kind of tumor therapy already introduced in clinical practice is the combined treatment by radiation and heat. Here, heating can be realized by eddy currents induced in metallic pieces, so-called thermoseeds, implanted in the tumor region as an array of appropriately positioned needles. Magnetic metals offer the possibility of using magnetic losses with the important advantage of having a mechanism for self-regulation of the maximum temperature by means of the appropriately chosen Curie temperature (Burton *et al.* 1971). In contrast to most other medical applications of magnets, the materials of thermally self-regulating implants are specially designed and consist of nickel alloys with copper, silicon, and palladium, or alloys of Fe–Pt and Pd–Co. A novel principle (Cetas *et al.* 1998) makes use of the field concentration due to the high permeability of a specially composed ferrite material (e.g., containing manganese, zinc, and copper) with a Curie temperature in the range 45–60 °C. The rod-shaped ferrite core is surrounded by a nonmagnetic electrically conductive sheath (e.g., stainless steel), which simultaneously provides biocompatibility.

## *3. Magnetic Particles*

The biomagnetic application of magnetic particles has been known since the late 1950s (Gilchrist *et al.* 1957) but there is now renewed interest. The fields of interest concern contrast media, vascular occlusion, localized heating, targeting of drugs and radiation sources, and cell separation. Most of the modern literature can be found under the keyword "magnetic carriers."

### *3.1 Magnetic Contrast Agents*

An early attempt to use magnetic powders as contrast agents for x-ray investigations was made by Frei *et al.* (1968). Satisfactory visualization was achieved of the gastrointestinal tract by means of commercially available powders (e.g., consisting of magnesium ferrite) even with human volunteers. These investigations were not continued in spite of an advantage over conventional contrast agents, namely the possibility of manipulating the material by external fields during the x-ray investigation. Other studies were concerned with MRI of the abdomen using orally administered superparamagnetic particles consisting of polymer spheres surrounded by iron oxide crystals, each crystal measuring less than 50 nm (Boudghène *et al.* 1993). Dextran-coated superparamagnetic iron oxide particles (presumably magnetite) can be used for cell labeling (Yeh *et al.* 1993), particularly after coupling to special monoclonal antibodies. Other magnetite nanoparticles have already been approved for imaging of liver metastases.

### *3.2 Vascular Occlusion*

Several investigations have been performed with respect to vascular occlusion by means of magnetic particles. One of the first publications deals with the occlusion of intracranial aneurisms (Roth 1969). Iron particles were used and a clinical experiment was performed generating a magnetic thrombus with injected particles exposed to a localized magnetic field of implanted magnets. Vascular occlusion with magnetic particles has also been investigated as a technique for selective infarction of tumors and organs. Mosso and Rand (1973) injected mixtures of carbonyl–iron microspheres with liquid silicone into the renal arteries of dogs. After a certain time, during which the material was held in place by an extracorporally applied magnetic field, vulcanization occurred. Other authors have reported experiments performed without silicone and also found agglomeration by means of the magnetic field.

### *3.3 Localized Heating*

Many attempts have been made to use the heating of magnetic particles in high-frequency magnetic fields for selective treatments of cancer cells within unaffected normal tissue. Gilchrist *et al.* (1957) described this idea and reported on promising experimental results obtained with $\gamma$-$Fe_2O_3$ particles (20–100 nm diameter) administered by injection into different kinds of tissue of dogs from where the particles were carried into the lymph nodes. The hope was to heat the nodes and in this way to destroy lymphatic metastases.

Similarly, the treatment of other tumors seemed to be possible either by direct injection or by transport via blood vessels, particularly the vessels formed by neo-vascularization near growing tumors. A great number of both *in vitro* and *in vivo* experiments has

been carried out since the pioneering work. Magnetic particles of different size (diameters ranging from the so-called multidomain state down to the superparamagnetic region) and different material (magnetite, maghemite, magnetic glass-ceramic, Ba–Co–ferrite, etc.) have been tested. The particles are covered or composed with different organic material or used in the bare state. Reviews of the results (Jordan *et al*. 1993, 1999, Hergt *et al*. 1998, Andrä 1998) show that clinical application cannot yet be applied and several essential problems are still to be solved.

### 3.4 Magnetic Targeting of Drugs and Radiation Sources

Magnetic drug targeting, i.e., guidance and retention of drug-carrying magnetic particles by means of externally applied magnetic fields, has been investigated since the 1970s. The first clinical experiences with human patients were reported by Kuznetsov *et al*. (1997) who used Fe–C particles combined with anticancer drugs. Lübbe and Bergemann (1997) used magnetic carriers of multidomain particles of $Fe_3O_4$ coated with starch derivatives and loaded with epirubicin. A concentration of the particles was achieved by means of suitably arranged permanent magnets outside the body of the patient. Magnetic drug targeting may also be used for the localized treatment of thrombosis, as demonstrated by Inada *et al*. (1987) who performed *in vitro* experiments with magnetic enzyme particles consisting of magnetite and polyethylene glucol coupled to urokinase. A further kind of magnetic targeting is the application of particles for the transport of radioisotopes, e.g., $^{90}Y$, to the region where the radiation is to be applied. This novel technique was tested in animal experiments by Häfeli *et al*. (1997) who used microspheres (10–30 μm in diameter) consisting of a mixture of polylactic acid and magnetite.

### 3.5 Magnetic Cell Separation

An already commercially introduced technology is the selective cell separation by means of polymer spheres containing small magnetic particles, so-called magnetic beads. The surface of the beads is coated with different kinds of monoclonal antibodies designed for special selective binding with appropriately prepared biological objects. In this way blood cells, bacteria, or even specific nucleic acid sequences can be isolated and manipulated in special magnetic separation equipment. The magnetic component of the beads in most cases is magnetite. A review of this field can be found in Ugelstad *et al*. (1997).

# Magnets: Bonded Permanent Magnets

Bonded magnets are generally prepared by blending coercive powder with a binder followed by compacting or molding the material to the final shape. Because of the presence of the binder the energy product of bonded magnets is always lower than that of their sintered counterparts. However, two great advantages of bonded magnets are their superior mechanical properties and the fact that the magnets can be prepared under net shape conditions. Bonded and sintered magnets of ferrites have been known for many decades. Both types of magnets have very low energy products when compared to sintered rare earth-based magnets. The excellent properties of rare earth-based magnets are, however, accompanied by a high price.

The last decade of the twentieth century saw an increased use of actuators and small electromotors not only of low weight but also of low energy consumption, as in battery-driven motors in particular. There has also been an increased use of electronically controlled, electrically actuated systems in automobiles, especially for critical vehicle control functions. All this and the increased use of electromagnetic devices in the electronic and electric industry has led to an enhanced pressure to find improved or alternative permanent magnet materials lying between the low-cost low-performance ferrite magnets and the high-cost high-performance sintered NdFeB magnets. Bonded NdFeB magnets meet most of the criteria mentioned and their use is growing steadily. For this reason bonded types of rare earth permanent magnets will be discussed below in somewhat more detail.

## *1. Bonding Technologies*

Bonded magnets are generally prepared by blending coercive powder with a binder or by encapsulating coercive powder in a binder, followed by compacting or molding the material to the final shape. The powder of the magnetic materials used in bonded magnets may be ferrites, alnico, samarium cobalt or neodymium–iron–boron. In some cases also hybrid powders are used.

Depending on the binder, the magnets produced may be flexible or rigid. Nitrile rubber or vinyl are commonly used for the former type whereas for the latter type nylon, teflon, polyester, or thermoset epoxies are employed.

There are four main manufacturing routes for bonded magnets: calendering, injection molding, extrusion, and compression bonding.

(i) Calendering involves processing the material between rollers and leads to continuous strips of adjustable thickness and length. This process is schematically shown in Fig. 1. The material used for calendering is usually a mixture of the magnetic powder and a thermoplastic binder. This mixture is processed between rollers forming a continuous strip that may be up to 100 m in length. Magnetic loading can be up to 70% by volume.

(ii) The injection molding process is schematically represented in Fig. 2. This process involves forcing the heated mixture of magnetic powder and thermoplastic binder via tubes into a mold where it is allowed to cool and harden. In this case too, magnetic loading can reach 70%, especially when using powder of spherical shape (Ma *et al.* 2002).

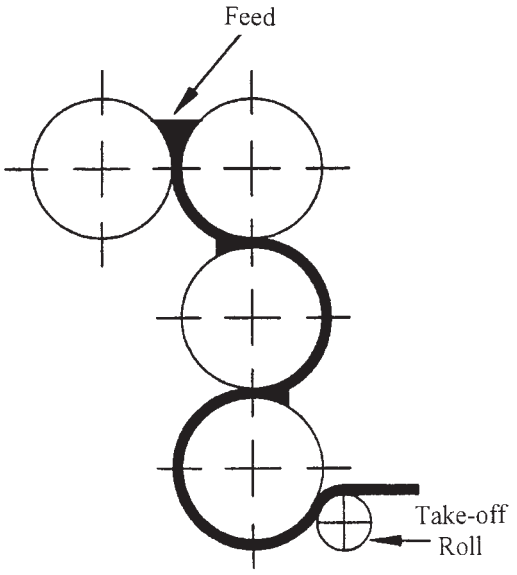

***Figure 1***
Schematic diagram showing the manufacturing of magnetic strips by calendering (after Ormerod and Constantinides 1997).

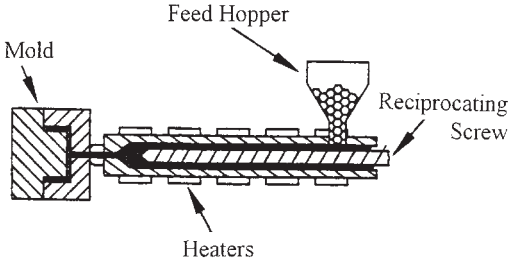

***Figure 2***
Schematic representation of the injection molding process. This process involves forcing the heated mixture of magnetic powder and thermoplastic binder via tubes into a mold where it is allowed to cool and harden (after Ormerod and Constantinides 1997).

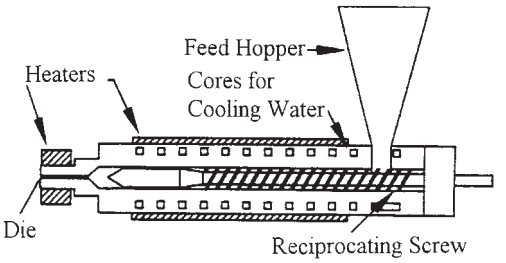

***Figure 3***
Schematic representation of the extrusion process. The compounded magnetic material is squeezed through an orifice. During the extrusion process the orifice is heated and the profile is controlled as the compounded material cools (after Ormerod and Constantinides 1997).

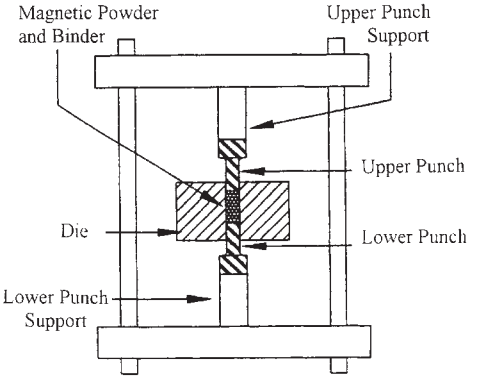

***Figure 4***
Diagram showing the compression bonding process. The magnetic powder is blended with an epoxy that has been dissolved in an organic solvent. The latter is evaporated during the blending process, leaving the magnetic particles in an epoxy-encapsulated state. The coated powder is flowed into a conventional powder press and compacted into the desired shape. The compacted magnet is finally cured in an oven (after Ormerod and Constantinides 1997).

(iii) Extrusion makes use of an orifice through which the compounded material is squeezed, as illustrated in Fig. 3. During the extrusion process the orifice is heated and the profile is controlled as the compounded material cools. Depending on the binder, the cooled product can be firm, as for flexible end products, or rigid if a nonflexible end product is desired. The loading can reach slightly higher values (up to 75% by volume) than in the two previous cases.

(iv) Compression bonding uses magnetic powder blended with an epoxy that has been liquefied by dissolution in an organic solvent. The latter is evaporated during the blending process, leaving the magnetic particles in an epoxy-encapsulated state. After drying, the coated powder is flowed into a conventional powder press (Fig. 4) and compacted into the desired shape. Finally, the compacted magnet is cured in an oven at temperatures of around 150–175 °C. This process can reach magnetic loadings up to 80%.

Because of the presence of the binder, the magnetic remanence is always lower than that of the fully dense magnetic material, as obtained, for instance, by sintering. The situation is even less favorable for the energy product, being roughly proportional to the remanence squared. There are, however, obvious advantages. The major advantage is that bonded magnets can be

produced in net shape or near-net shape. Even fairly complicated shapes may be involved, as in injection molding. Another advantage is their superior mechanical properties. Bonded magnets are mainly manufactured from ferrite powder or coercive NdFeB-based powders. Bonded magnets based on NdFeB, owing to their superior intrinsic magnetic properties, offer substantial advantages in terms of size, weight, and performance over bonded ferrite magnets and even over sintered ferrite magnets.

## 2. The Permanent Magnet Materials

The most common types of magnets used at present are hard ferrite magnets, rare earth-based magnets such as SmCo or NdFeB, and alnico-type magnets. Of these the alnico magnets have only a modest coercivity which leads to nonlinear demagnetization characteristics. For this reason their applicability is very limited compared with the other two types. The hard ferrites have higher coercivities than the alnico magnets and their demagnetizing characteristics are linear. However, the remanence and the concomitant maximum energy product are already low and are further decreased by bonding. Because of their low cost, ferrite magnets are still widely applied, although most of the corresponding magnetic devices are rather bulky and often give far from optimal performance. Ferrite permanent magnets currently dominate automotive and many other applications due to their low cost and proven long-term stability (see *Alnicos and Hexaferrites*).

The rare earth based magnets have high values of coercivity which gives them linear demagnetization characteristics (see *Rare Earth Magnets: Materials*). They have high remanences and typical values of the energy products reached in sintered magnets are 150 kJ $m^{-3}$ for $SmCo_5$, and 300 kJ $m^{-3}$ for $Nd_2Fe_{14}B$. The first types of magnets are frequently used in high-temperature applications, which possibility is lost in bonded magnets (see *Magnets: High-temperature*). $SmCo_5$ type magnets are expensive owing to the high price of both samarium and cobalt. The situation is more favorable for NdFeB magnets because neodymium is cheaper than samarium and iron is much cheaper than cobalt, the powder metallurgical processing arts being comparable with those of $SmCo_5$. Hence the performance/price ratio for $Nd_2Fe_{14}B$ is better than for $SmCo_5$. For this reason the market for sintered $Nd_2Fe_{14}B$ magnets has flourished and is still growing (see *Magnets: Sintered*).

Although bonded magnets can be manufactured from all of the materials mentioned above, only bonded ferrite magnets and bonded $Nd_2Fe_{14}B$ magnets have penetrated into the market to an appreciable extent. The ferrites can be easily obtained in powder form (see *Alnicos and Hexaferrites*). A somewhat special processing of the ferrite powders leads to hexagonal platelets that can be easily aligned mechanically during the formation process of flexible bonded magnets. The situation is more difficult in the case of $Nd_2Fe_{14}B$, because a simple powder metallurgical route from cast or annealed $Nd_2Fe_{14}B$ ingots does not generally lead to powders of sufficiently high coercivity for use in bonded magnets. Coercive NdFeB powders can be obtained though by melt spinning. In this technique a fine stream of molten alloy is sprayed onto the outer surface of a rapidly spinning wheel, leading to thin rapidly quenched ribbons or flakes. During the melt spinning the material is protected from oxidation by performing this process in a protective atmosphere or in vacuum. The quenching rate is of the order of $10^5$ K $s^{-1}$ and can be varied by changing the rotational speed of the spinning wheel. Different quenching rates lead to different microstructures which in turn determine the magnetic properties of the melt spun material. Optimum melt spinning conditions lead to a nanocrystalline alloy consisting of fine grains (typically 30 nm) of the compound $Nd_2Fe_{14}B$, surrounded by a thin layer of a neodymium-rich eutectic phase. In practice, more reliable and reproducible results can be obtained by using a slightly higher quenching rate and subsequently annealing the melt spun material under carefully controlled conditions. The melt spun material is fairly brittle and can be ground to a fine powder suitable for manufacturing bonded magnets. Because the $Nd_2Fe_{14}B$ grains have a random orientation, these bonded magnets are isotropic. Powder particles of spherical shape flow better in the injection molding process, which allows a higher loading factor. Such powder can be prepared by an inert gas atomization process with typical values for the mean particle diameter of 45 mm. An additional advantage of the atomization process is the high production rate and low processing costs of the powders (Ma *et al.* 2002).

A different route leading to coercive NdFeB powders consists of the so-called HDDR process (see *Magnets: HDDR Processed*). This process involves essentially four steps: **h**ydrogenation of $Nd_2Fe_{14}B$ at low temperatures, **d**ecomposition of $Nd_2Fe_{14}BH_x$ into $NdH_{2.7} + Fe + Fe_2B$, **d**esorption of $H_2$ gas from $NdH_{2.7}$, and **r**ecombination of $Nd + Fe + Fe_2B$ into $Nd_2Fe_{14}B$. This process profits from the fact that the formation of $Nd_2Fe_{14}B$ grains in the last step is a solid-state reaction and hence proceeds at a rate considerably lower than during solidification from the melt during a normal casting process. The average $Nd_2Fe_{14}B$ grain size remains in the nanometer range and gives rise to sufficiently large coercivities.

A further advantage is the fact that the HDDR process can successfully be used to obtain anisotropic particles. Takeshita and Nakayama (1992) discovered that additives of zirconium, hafnium, and gallium, in particular, are very effective in producing anisotropic HDDR powder. The amount of additive required is

surprisingly small (for instance, $Nd_{12.5}Fe_{69.9}Co_{11.5}B_6Zr_{0.1}$). Microscopic investigations described by Harris (1992) revealed that large facetted HDDR grains had formed within the original as-cast grain of the alloy. These facetted grains have a common orientation, which is probably the same as that of the original grain. The anisotropic nature of HDDR powders of alloys like $Nd_{12.5}Fe_{75.9}Co_{11.5}B_8Zr_{0.1}$ can thus be visualized by assuming that the HDDR grains have nucleated and grown within an original as-cast grain region from submicron grains, the latter having a common orientation (Harris 1992).

Evidently the effect of the additive is to bring about nucleation centers for nucleation and growth of the HDDR grains, the latter grains having kept the orientation of the original cast grain.

Tomida *et al*. (1996) have used x-ray diffraction to establish a correlation between the anisotropic nature of the ultimate HDDR powder and the amount of $Nd_2Fe_{14}B$ phase remaining unreacted in the hydrogenation process. TEM studies made by Tomida *et al*. on powder hydrogenated under optimum energy product conditions showed that after hydrogenation the powder consists mainly of coarse-grained $\alpha$-Fe and $Fe_2B$, with nanocrystalline particles embedded in between. These particles were identified by electron diffraction as $NdH_2$ particles. However, many of the particles were identified as $Nd_2Fe_{14}B$ particles having a crystallographical orientation almost the same as that of the original cast $Nd_2Fe_{14}B$ grains. Energy-dispersive spectra furthermore showed that these particles are of higher cobalt and gallium concentration than corresponding to the average concentration of the starting alloy. These results have led Tomida *et al*. to propose that this type of nanocrystalline $Nd_2Fe_{14}B$ particles serve as initiation centers in the recombination process and are the origin of the orientational memory effect in HDDR powders.

A different category of materials that appears to be promising is nanocrystalline rare earth-based composite magnets. Under special circumstances, two-phase composite materials can demonstrate a most interesting coercivity behavior. Such a behavior has been described by Kneller and Hawig (1991), who investigated the combined effect of two finely dispersed and mutually exchange-coupled magnetic phases. One of these phases has a large uniaxial anisotropy constant and is able to generate a high coercivity. By contrast, the second phase is magnetically soft. It has a larger magnetic ordering temperature and concomitantly a larger average exchange energy than the hard phase. It is the comparatively high saturation magnetization of the soft phase that, when the latter is exchange coupled to the hard phase, provides a high remanence to the composite magnet. The possibility to prepare magnets showing remanence enhancement has triggered extensive research in this area (see *Magnets: Remanence-enhanced*).

In most of the systems for which remanence enhancement has been reported, the magnetically soft phase is $\alpha$-Fe or an iron-rich or cobalt-rich alloy. Examples of magnetically hard phases are $Nd_2Fe_{14}B$, $Sm_2Fe_{17}N_3$, $Sm_2Co_{17}$, and $Nd(Fe,Mo)_{12}N_x$. The microstructures of all these composite magnets have in common that they consist of a very fine distribution of the magnetic particles, falling into the nanometer range. In order to reach this fine distribution various techniques are employed, including melt spinning and mechanical alloying (see *Magnets: Mechanically Alloyed*). This group of materials is referred to as lean rare earth permanent magnets. Their advantages compared with the standard alloys are their excellent corrosion resistance and the fact that they reach saturation in a comparatively low applied field. A disadvantage is their relatively low coercivity. The possibility of using these materials in resin-bonded magnets has been described by Croat (1997).

Another interesting group of materials are interstitially modified $R_2Fe_{17}$ compounds. Although the low Curie temperatures and comparatively low magnetocrystalline anisotropies make the $R_2Fe_{17}$ compounds less attractive for applications as permanent magnet materials, considerable improvements with respect to Curie temperature anisotropy and coercivity have been reached by forming interstitial solid solutions obtained by combining these materials with carbon or nitrogen. The composition of the corresponding ternary nitrides and carbides $R_2Fe_{17}C_x$ and $R_2Fe_{17}N_x$ is generally believed to be restricted to the range $0 \leqslant x \leqslant 3$. More details about the formation ranges and location of the interstitial atoms the lattice are described in the review of Fujii and Sun (1995).

Resin-bonded magnets from nitrogenated $Sm_2Fe_{17}$ powders have been prepared with $BH_{max} = 136\,kJm^{-3}$, $B_r = 9.0T$, and $\mu_{oB}H_c = 6.5T$. In order to explore the favorably low temperature coefficient of the coercivity in magnet bodies suitable for high-temperature applications Rodewald *et al*. (1993) and Kuhrt *et al*. (1993) have investigated tin- and zinc-bonded magnets. In these cases, however, the obtained remanences were fairly low ($B_r < 0.7$ T).

## 3. *Applications of Bonded Magnets*

Bonded ferrite magnets are commercially available in isotropopic and anisotropic grades (see Table 1). The calendered material is commonly called sheet. Sheet magnets are mainly used by screenprinters for advertising specialties, novelties, and picture frames. Sign manufacturers use it for vehicle signs, but there are also medical applications such as needle counters. Extruded profile flexible magnets are called strip. They are used for a variety of gasket applications such as for refrigerator doors, shower doors, and removable storm windows. Other applications are in small

***Table 1***
Maximum energy products (kJ $m^{-3}$) of commercially available bonded magnets (from Ormerod and Constantinides 1997).

| Magnet powder | Manufacturing route | Magnetic isotropic | Magnetic anisotropic |
|---|---|---|---|
| Ferrite | Calendered | 4.0–5.0 | 11.2–12.8 |
| | Extruded | 3.2–4.8 | 9.6–12.0 |
| | Injection molded | 4.0–6.4 | 12.0–13.6 |
| SmCo | Injection molded | | 68–76 |
| | Compression | | 104–136 |
| NdFeB | Calendered | 39–41 | |
| | Injection molded | 40–42 | 76–88 |
| | Compression | 64–88 | 112–128 |

motors and stereo speakers. Injection-molded ferrite magnets are mainly used in automotive applications, office automation, and in small motors. A great advantage of the ferrite magnets is that they are inexpensive and the raw materials are readily available.

Bonded SmCo-type magnets are used in applications where the temperature coefficients of remanence and coercivity have to be low and where a high corrosion resistance is required. Compared to bonded ferrite and NdFeB magnets their market share is low because of the high price of the raw materials.

The majority of bonded NdFeB magnets are used in personal computers but they are also used in a fairly wide range of automotive, consumer, and office products including VCRs, camcorders, and printers, and in smaller appliances such as watches, clocks, timer switches, and cameras. Most of the bonded NdFeB magnets go into various types of electric motors. The most prominent types of electric motors are spindle motors and stepper motors. Stepper motors have fairly small sizes and are characterized by their ability for precise incremental position or speed adjustment with electric pulses from digital controllers. In modern stepper motors, the stators consist of the coils system and the rotors are made of rare earth permanent magnets. The advantage of using rare earth permanent magnets is their high coercivity, which makes it possible to axially magnetize the rotor through the thickness with a large number of poles on the circumference. This allows fairly low step angles. The number of spindle motors produced is lower than the number of stepper motors. Spindle motors are much larger than stepper motors. This is the reason why they still consume a relatively large percentage of bonded NdFeB magnets. The largest application of electric motors is in computer peripherals, where they serve, for instance, as hard disk drive spindle motors, CD-ROM pick-up motors, CD-ROM spindle motors, floppy disk drive spindle motors, and floppy disk head actuators.

For a more detailed discussion of bonded magnet manufacturing, their performance, and their applications the reader is referred to the review articles of Croat (1997), Ormerod and Constantinides (1997), and Ma *et al.* (2002).

## Magnets: HDDR Processed

The HDDR (hydrogenation–disproportionation–desorption–recombination) process is a method for producing magnetically highly coercive rare-earth (RE) transition-metal (TM) materials by applying a reversible chemical reaction with hydrogen gas (Takeshita and Nakayama 1989, McGuiness *et al.* 1990). In magnets made from rapidly quenched or mechanically alloyed magnets, the high coercivity is achieved by reducing the average grain size of the anisotropic ferromagnetic phase (see *Magnets: Mechanically Alloyed*). The average grain size for the HDDR material is around 0.3 μm which is approximately an order of magnitude greater than those of rapidly quenched or mechanically alloyed material. The crucial difference, however, between the HDDR and melt-spun or mechanically alloyed materials is that in the former case it is possible to produce anisotropic powders without applying mechanical deformation.

This article starts with a general description of the HDDR process including the thermodynamic and kinetic aspects. Emphasis will be given in the discussion of possible origins for the anisotropic character of HDDR-treated Nd–Fe–B-based powders, and to technical and economical aspects of preparing magnets from HDDR powders. Finally, an outlook on further prospects of HDDR magnets will be given.

### 1. General Description of the HDDR Process

Hydrogen is already used very successfully for the hydrogen decrepitation process, which is most effective in terms of producing powders, e.g., for sintered

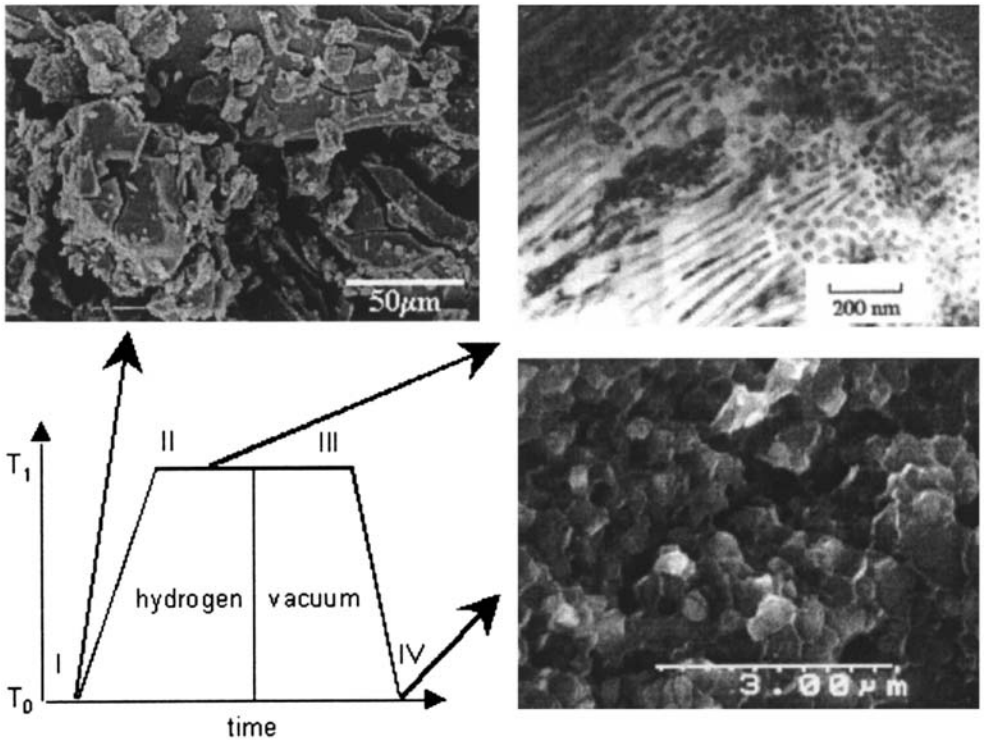

*Figure 1*
Schematic representation of the HDDR process. Microstructural changes are illustrated by SEM and TEM images of Nd–Fe–B material (I: starting powder after hydrogen decrepitation; II: disproportionated material (TEM); IV: particle fracture surface after HDDR).

magnets (see *Magnets: Sintered*). Another potential application of hydrogen is in the HDDR process. A general schematic representation of this process is given in Fig. 1. In the first step, an $AB_n$ compound (where A is a hydride former, e.g., a RE element) is heated in hydrogen. In many cases, an interstitial hydrogen absorption takes place at lower temperatures, which results in the hydrogen decrepitation of the ingot material and this is predominantly an intergranular fracture process. This decrepitation can be avoided by heating under vacuum and introducing the hydrogen at a temperature where the disproportionation takes place spontaneously. This "solid"-HDDR process is a useful tool for investigations which demand compact samples such as for TEM observations and electric resistivity measurements (Gutfleisch *et al.* 1994). The simplest representation of the exothermic disproportionation reaction is given by:

$$AB_n + (1 \pm \tfrac{1}{2}x)H_2 \rightarrow AH_{2\pm x} + nB + \Delta H \qquad (1)$$

where $\Delta H$ is the enthalpy, $+\Delta H$ being an exothermic reaction and $-\Delta H$ an endothermic reaction.

The value of $x$ depends on the precise processing conditions. The second step of the HDDR process is the recombination reaction under vacuum or low hydrogen pressure. The hydrogen is desorbed during stage III and the remaining A-rich regions act as nuclei for the recombination of the original $AB_n$ phase:

$$AH_{2\pm x} + nB \rightarrow AB_n + (1 \pm \tfrac{1}{2}x)H_2 - \Delta H \qquad (2)$$

By carefully controlling the process parameters of the recombination reaction, grain sizes of a few hundred nanometers can be obtained. This is of the same order of magnitude as the single domain particle size of magnetically highly anisotropic RE–TM compounds such as $Nd_2Fe_{14}B$ and $SmCo_5$.

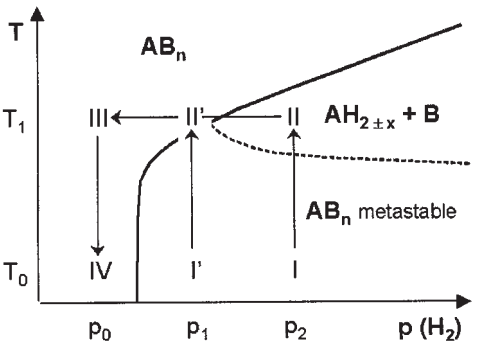

***Figure 2***
Phase diagram of the hydrogen–$AB_n$ system. The disproportionation reaction is given by I→II, the recombination by II→III. No disproportionation will take place for an insufficient hydrogen pressure $p_1$ (I′→II′).

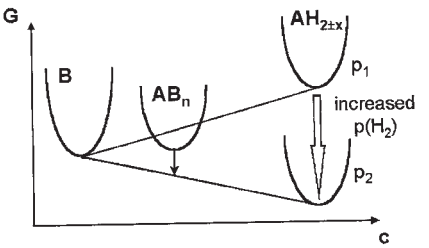

***Figure 3***
Schematic free enthalpy diagram for the hydrogen–$AB_n$ system at $T = T_1$ according to Fig. 2. A disproportionation of the $AB_n$ compound into $AH_{2\pm x}$ and B is only possible for an increased hydrogen pressure $p_2 > p_1$.

## 2. *Thermodynamics and Kinetics*

In principle, the HDDR process is applicable to a large number of $AB_n$-type compounds, e.g., with a RE element as a very strong hydride former A, and a TM and/or another element as nonhydride former B. This is especially true for those compounds with a high RE content and with a relatively low thermodynamic stability.

Figure 2 shows a phase diagram of the hydrogen–$AB_n$ system. It can be seen that, at a sufficient hydrogen pressure $p(H_2)$, the $AB_n$ phase is in a metastable state at room temperature ($T = T_0$). The disproportionated state is the thermodynamically stable state, but the reaction does not take place because of insufficient diffusion of the large A and B atoms. Only when the temperature is raised will the kinetic barrier (dashed line in Fig. 1) be passed and disproportionation into $AH_{2\pm x}$ and B take place. The kinetic barrier can be lowered by increasing the surface-to-volume ratio of the $AB_n$ material (smaller particles/grains) or by mechanical activation (e.g., reactive milling in hydrogen). A more stable $AB_n$ compound will lead to a narrowed processing window. A higher hydrogen pressure leads to an increased stability of the $AH_{2\pm x}$ hydride and hence the disproportionation of more stable compounds becomes possible (see Fig. 3). The recombination reaction will be initiated by lowering $p(H_2)$ which makes the $AB_n$ phase the preferred thermodynamic choice.

For the RE–TM phases with attractive intrinsic magnetic properties, the phases $Nd_2Fe_{14}B$ and $Sm_2Fe_{17}N_x$ have a relatively low thermal stability and the HDDR process can be applied easily. The

most important example is the HDDR process of $Nd_2Fe_{14}B$:

$$Nd_2Fe_{14}B + (2 \pm x)H_2 \rightarrow 2NdH_{2\pm x} + 12\alpha\text{-Fe} + Fe_2B + \Delta H \quad (1)'$$

$$2NdH_{2\pm x} + 12\alpha\text{-Fe} + Fe_2B \rightarrow Nd_2Fe_{14}B + (2 \pm x)H_2 - \Delta H \quad (2)'$$

Typical conditions for the disproportionation reaction (Eqn. (1)′) are $T \approx 800\,^{\circ}C$ and $p \approx 100\,kPa$. The recombination is normally carried out at comparable temperatures under continuous pumping.

The HDDR process is also applicable to the relatively low stability $RE(Fe, X)_{12}$ and $RE_3(Fe, X)_{29}$ materials (e.g., RE = Nd, Sm; X = Ti, V). However, in these cases the formation of other phases during recombination is a serious problem. It has been shown that the HDDR process can also be applied to more stable compounds such as $SmCo_5$ and $Sm_2Co_{17}$ when high hydrogen pressure or reactive milling is applied (Kubis *et al.* 1998).

## 3. Anisotropic Character of HDDR-treated Nd–Fe–B-based Powders

An apparently unique feature of $Nd_2Fe_{14}B$ is the preservation of the anisotropic character of the powder after the HDDR process. A "memory-cell" model suggests nanoscale 2:14:1 phase regions rich in additives such as Co, Ga, or Zr which stabilize the phase. Therefore these regions remain unaffected during the disproportionation reaction and can act as nucleation sites for the recombination reaction. This model is supported by thermodynamic arguments as well as by extensive microstructural investigations. However, there is some evidence that this model is not sufficient: (i) it has, so far, not been possible to maintain the anisotropic character of $Sm_2Fe_{17}$-type powders after the HDDR process by using additions that stabilize the 2:17 phase in the same manner as the 2:14:1 phase; and (ii) it is possible to obtain anisotropic HDDR powders from ternary Nd–Fe–B materials without the presence of stabilizing additions by applying "solid" disproportionation and recombination in a low hydrogen pressure ("slow" recombination).

As neodymium hydride and α-iron have a cubic crystal structure and do not exhibit preferred crystallographic axes, only the grains of the noncubic iron boride phase remain as possible "memory cells." The absence of the boride phase in the disproportionated state of $Sm_2Fe_{17}$ supports this assumption. A "one-to-one" crystallographic relation between a metastable tetragonal $Fe_3B$ phase and the original 2:14:1 matrix phase has been found in an alloy containing cobalt, gallium, and zirconium (Tomida *et al.* 1999). This $Fe_3B$ phase can also be found in solid-disproportionated ternary Nd–Fe–B materials. The elemental additions appear to stabilize the $Fe_3B$ phase and also to depress excessive grain growth during recombination. Anisotropic powders are harder to obtain from ternary materials probably because the $Fe_3B$ phase is only an intermediate phase in the disproportionation reaction and the subsequent $Fe_3B \rightarrow Fe_2B + Fe$ reaction is not slowed down by the presence of alloying additions. The "slow" recombination at low hydrogen pressures, e.g., 10 kPa at 900 °C, enables a better control of grain growth, which is essential for obtaining a high coercivity in ternary Nd–Fe–B materials together with a high degree of texture.

## 4. Technical and Economical Aspects

The HDDR process is an environmentally friendly and simple method of powder preparation. The combination of hydrogen decrepitation and the HDDR process makes it possible to produce highly coercive Nd–Fe–B-type powders from the ingot starting material in "one run." Additionally, the amount of free α-Fe in cast Nd–Fe–B materials, which has a significant detrimental effect on the magnetic properties, is reduced by the HDDR treatment.

The most sensitive part of the HDDR process is the recombination stage. A scaling up to larger batch sizes leads to the formation of an inhomogeneous microstructure after both processing steps, because of large temperature gradients caused by the strongly exothermic/endothermic character of the disproportionation/recombination reactions. The inhomogeneous microstructure of disproportionated material does not appear to have a great effect on the magnetic properties of isotropic HDDR powders and hence batch sizes of 15 kg are applicable. On the other hand, the batch size for the recombination step has to be limited to about 2 kg in order to avoid large variations in grain size which lead to poor magnetic properties. The application of the slow recombination method could make a significant contribution to solving this technological problem.

The possibility of producing highly coercive powders consisting of nanoscaled grains with a preferred crystallographic orientation is a special feature of the HDDR process that makes it extremely interesting for the cost-effective production of anisotropic hard magnetic powders. However, the degree of texture of HDDR materials is limited as there is always a certain loss of anisotropy after the HDDR treatment of an anisotropic powder. The best properties of HDDR magnets are remanences of about 1.2 T combined with coercivities of $\mu_0 H_C > 1\,T$, leading to $(BH)_{max}$ values of about $250\,kJm^{-3}$.

There is a large variety of processing routes for isotropic and anisotropic HDDR magnets (for more

details see Gutfleisch and Harris 1998). For example, anisotropic Nd–Fe–B magnets can also be produced by hot pressing and hot deformation of isotropic nanoscaled materials (see *Textured Magnets: Deformation-induced*). It is somewhat harder by this processing route to obtain high coercivities and remanences from HDDR materials compared with the properties obtained from melt-spun and mechanically alloyed materials and this can be attributed to the larger average grain size of the HDDR materials. However, the addition of grain growth inhibiting elements such as zirconium and the integral optimization of HDDR, hot pressing, and deformation still give room for improvements.

### 5. Future Prospects of the HDDR Process

Applications at moderate temperatures ($\sim 120\,^{\circ}C$) depend, amongst other things, on low irreversible magnetic losses at these temperatures. There is a question mark over the long-term magnetic stability of HDDR magnets at these temperatures which is much inferior compared with those of melt-spun and sintered magnets. Work is underway to try and improve the performance of the HDDR material.

Of all the known magnetically highly anisotropic RE–TM compounds, only the $RE_2Fe_{14}B$-based materials have been found to exhibit anisotropic features after the HDDR process. Magnets with RE = Pr exhibit promising properties with more relaxed processing conditions compared with those characteristic of $Nd_2Fe_{14}B$. HDDR magnets based on $Pr_2Fe_{14}B$ or $(Nd_{1-x}Pr_x)_2Fe_{14}B$ could be possible alternatives to neodymium-based anisotropic HDDR magnets.

The application of high hydrogen pressures opens the way to preparing a wider range of hard magnets by the HDDR process from highly stable materials such as Sm–Co based compounds. These studies might also help to find new insights into the mechanisms of the HDDR process.

Another way of extending the applications of the HDDR process is the combination with other preparation methods such as ball milling. Reactive milling in hydrogen can lead, after recombination at low temperature, to powders with grain sizes of only a few tens of nanameters. Such materials can exhibit remanence enhancement due to the effect of magnetic exchange coupling (see *Magnets: Mechanically Alloyed* and *Textured Magnets: Deformation-induced*).

## Magnets: High-temperature

High-temperature permanent magnets with an operating temperature of over 450 °C are required for future advanced power systems. Precipitation-hardened 2:17 $Sm(Co_{bal}Fe_wCu_yZr_x)_z$ magnets have large anisotropy fields and a high Curie temperature which make them optimal candidates for such high-temperature applications (Ray 1984). The $Sm(Co_{bal}Fe_wCu_yZr_x)_z$ magnets are characterized by a complex microstructure consisting of a cellular structure superimposed on a lamellar structure, which is formed after a lengthy aging at 800–850 °C followed by a slow cooling to 400 °C (Hadjipanayis 1996). The cellular/lamellar microstructure is formed during the aging period. Upon slow cooling copper diffusion takes place to the cell boundaries leading to the right microchemistry for optimum domain wall pinning.

The magnets represent a complicated system with four compositional ($x$, $y$, $w$, $z$) and five heat treating variables. Comprehensive and systematic studies were undertaken on bulk and nanocrystalline rare-earth cobalt-based magnets to understand their behavior and improve their high-temperature performance. These studies led to the development of new high-temperature magnets and to the discovery of some new effects in these magnets (Liu *et al*. 1999,

Tang *et al*. 2000). Also the studies helped to understand further the effects of composition and processing on the magnetic hardening behavior of the magnets, particularly on the coercivity and its temperature dependence. In the following the recent studies on Sm–Co-based high-temperature magnets in both the cast and nanograined powder form are summarized.

## 1. Bulk $Sm(CoFeCuZr)_z$ Magnets

### 1.1 Effect of Composition and Processing

In principle, high-temperature magnets must have a high Curie temperature, a high anisotropy field $H_A$ with a small temperature dependence, and high magnetization. In addition the magnets must have the right microstructure for optimum magnetic hardening. Comprehensive studies by Hadjipanayis and coworkers (Liu *et al*. 1999, Tang *et al*. 2000) on the microstructure and the magnetic properties of the precipitation-hardened 2:17 $Sm(Co_{bal}Fe_wCu_yZr_x)_z$ high-temperature magnets showed that the magnets must not only have a small (70–100 nm) and uniform cellular structure (2:17 cells surrounded by 1:5 cell boundaries) but also the right microchemistry, with a large gradient of copper at the cell boundaries. This is made possible by the presence of a thin lamellar phase (zirconium-rich Z phase), which facilitates the diffusion of copper to the 1:5 cell boundary phase during the slow cooling.

The large difference in copper content across the cell boundaries leads to a steep gradient in domain wall energy, which causes domain wall pinning, and gives rise to high coercivity. The microstructure and microchemistry strongly depend on the composition and processing of the magnets. Lower-ratio $z$ magnets have a smaller cell size (Fig. 1) because of the small percentage of 2:17 phase. A smaller cell size results in a lower coercivity at room temperature with improved temperature dependence (Hadjipanayis 1999). Since copper is concentrated at the 1:5 cell boundaries, an increase in copper content $y$ results in the formation of a greater amount of 1:5 cell boundary phase (and therefore smaller cells) with higher copper content and thus higher room-temperature coercivity. An increase in iron content $w$ results in an increase of the cell size because iron mainly goes into the 2:17 cells.

This leads to higher saturation magnetization magnets, but with a greater temperature dependence of coercivity because of the decrease in both the anisotropy and the Curie temperature of the iron-substituted 2:17 phase (Strnat 1988). The addition of zirconium promotes the formation of the lamellar microstructure, which leads to the optimum uniform microstructure (Tang *et al*. 2000), as explained before. The aging temperature controls the cell size with a higher aging temperature leading to a larger cell size. For a fixed copper content any change in the cell size will alter the copper content in the cell boundaries and therefore drastically affect the coercivity of the magnets and its temperature dependence.

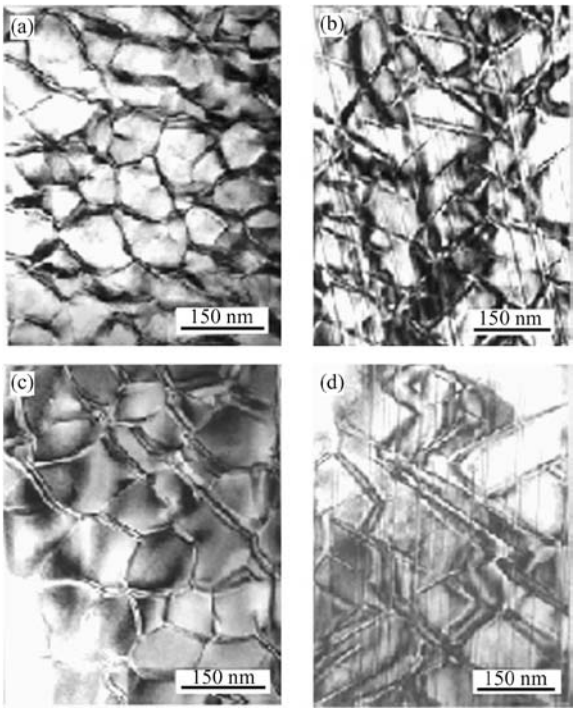

***Figure 1***
Dependence of cell size on ratio $z$: (a) and (b) $z = 7.0$; (c) and (d) $z = 8.5$. The left and right figures are microstructures perpendicular and parallel to the $c$ axis of the 2:17 phase, respectively.

The information derived from the above studies can be used to fine-tune the microstructure and microchemistry of the Sm–Co magnets through adjustments in the composition and processing parameters, and allows the designing of magnets for high-temperature applications.

### 1.2 New Magnets with a Record High Coercivity of 10 kOe at 500 °C

By changing the ratio $z$ and using an appropriate copper content, new magnets with a coercivity of 10 kOe at 500 °C were developed. Figure 2 shows the temperature dependence of coercivity for the new magnets (A and B) compared with a typical old commercial magnet. For magnet B, with a high ratio $z$ of 8.5 and a copper content of 0.088, the coercivity at room temperature is about 40 kOe. For magnet A, with a low ratio $z$ of 7.0 and a copper content of up to 0.128, a record high coercivity of 10.8 kOe at 500 °C is

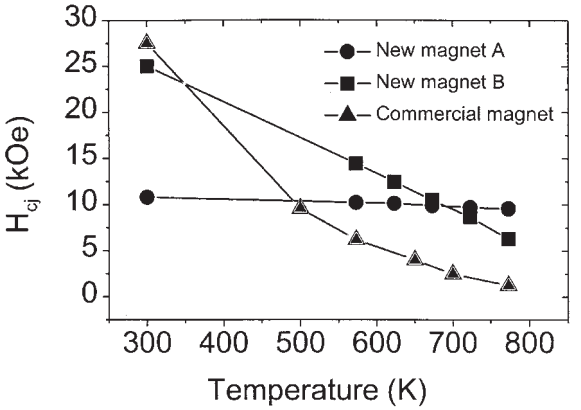

***Figure 2***
Temperature dependence of coercivity in different magnets.

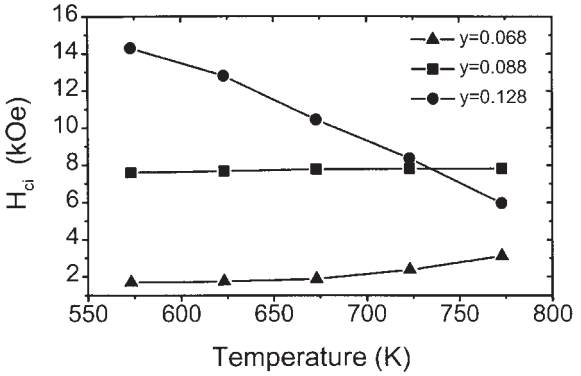

***Figure 3***
Temperature dependence of coercivity for $Sm(Co_{bal}Fe_{0.1}Cu_yZr_{0.02})_{7.5}$ with different Cu content.

obtained. The temperature coefficient of coercivity for magnet A is –0.03% °C$^{-1}$, which is more than eight times smaller than that of magnet B. The new magnets have a better temperature dependence of coercivity than the old commercial magnets. The microstructural data show that the cell size of magnet B is larger than that of magnet A (88 nm vs. 108 nm). These are smaller than the size of commercial magnets which is generally above 120 nm.

### *1.3 Temperature Dependence of Coercivity Controlled by the Copper Content*

The effect of composition on the temperature dependence of coercivity was studied systematically. Figure 3 shows the temperature dependence of coercivity for $Sm(Co_{bal}Fe_{0.1}Cu_yZr_{0.02})_{7.5}$ magnets with

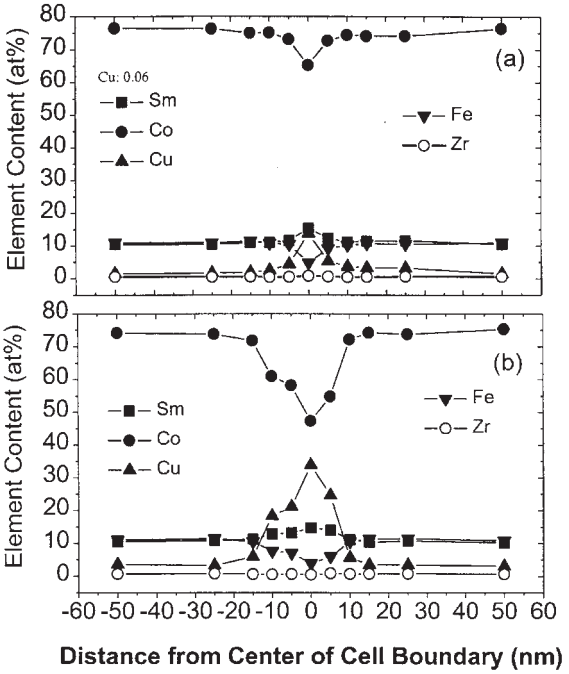

***Figure 4***
Nanoprobe analysis of $Sm(Co_{bal}Fe_{0.1}Cu_yZr_{0.02})_{7.5}$ magnets: (a) $y = 0.06$; (b) $y = 0.12$.

different copper content. The temperature coefficient of coercivity changes from a small positive to a large negative value with increasing copper content from $y = 0.068$ to 0.128. The microstructure of the copper-substituted magnets is similar showing a small decrease in cell size with increasing copper content (from 100 to 80 nm). However, a nanoprobe analysis (Fig. 4) shows that most of the copper goes into the $Sm(Co,Cu)_5$ cell boundary phase. When the copper content in the magnets changes from 0.06 to 0.126, the copper content at the cell boundaries increases from 13.7 to 33.8 at.%.

The difference in the copper content at the cell boundaries leads to a large domain wall energy gradient (associated with the chemical composition gradients) along the cell boundaries and thus to a different intrinsic coercivity, $H_c$,

$$\mu_o H_c = \mu_o \frac{1}{2J_s} \frac{(\gamma^{1:5} - \gamma^{2:17})}{\delta}$$

where $\gamma$ is the domain wall energy, $J_s$ the spontaneous magnetization, and $\delta$ the 1:5 cell boundary thickness (see *Coercivity Mechanisms*). Moreover, the domain wall energy gradient and effective pinning area in the case of low copper content are much smaller than

in the high-copper-content magnets. Chui (1999) explained the latter behavior in terms of repulsive pinning which leads to the positive temperature coefficient of coercivity. This abnormal temperature dependence of coercivity is of great practical importance, because the temperature coefficient of coercivity can be manipulated by controlling the copper content.

## 2. Nanograined RE–Co Powders Made by High-energy Mechanical Milling

An alternative way to produce high-performance RE–Co (RE = rare-earth element) high-temperature magnets is to develop a nanoscale microstructure in these magnets. The motivation originates from the well-known size dependence of coercivity which goes through a maximum value at the single-domain size, which is a fraction of a micron for most magnets such as $Nd_2Fe_{14}B$, $Sm_2Fe_{17}(NC)_x$ and $Sm_2Co_{17}$ (Manaf *et al.* 1993, Hadjipanayis 1999). Therefore, high coercivity is expected to develop in magnets with a nanoscale grain size. Furthermore, an enhanced $M_r/M_s$ ratio ($>0.5$) is also expected in nanoscale isotropic magnets due to the exchange coupling between neighboring nanograins (Fischer and Kronmüller 1999) (see *Magnets: Remanence-enhanced*). The mechanical properties of consolidated nanograin magnets are expected to be greatly improved. In general, the nanostructure can be obtained by using melt-spinning (Coehoorn *et al.* 1989, Manaf *et al.* 1993) and mechanical alloying (Schultz *et al.* 1991, McCormick *et al.* 1998) (see *Magnets: Mechanically Alloyed*).

### 2.1 Sm–Co-based Nanograined Magnets

Chen *et al.* (2000) carried out systematic studies on the development of nanocrystalline $Sm_2Co_{17}$-based magnets using mechanical milling. They found that a nanoscale 2:17 phase with an average grain size of about 30 nm is developed within the powders which have an average particle size of about 5 μm. Optimum magnetic properties of $M_s = 110.5$ emu $g^{-1}$, $M_r = 66.2$ emu $g^{-1}$, $M_r/M_s = 0.60$, $H_c = 9.6$ kOe, and $(BH)_{max} = 10.8$ MGOe have been obtained in stoichiometric $Sm_2Co_{17}$ powders. The observed magnetic hardening is believed to arise from the high anisotropy of the $Sm_2Co_{17}$ phase and its nanoscale grain size.

A small amount of substitution of zirconium for cobalt significantly increases the coercivity by increasing the anisotropy field of the $Sm_2Co_{17}$ phase. A copper substitution in Zr-containing samples further increases the coercivity by introducing a nanoscale 1:5 phase which forms a uniform mixture with the 2:17 nanograins. This is different from the cellular/lamellar structure observed in bulk magnets with the same composition. The highest coercivity of 20.6 kOe has been obtained in the $Sm_{12}(Co_{0.92}Cu_{0.06}Zr_{0.02})_{88}$ powders. Substituted iron enters the cobalt sublattice sites of the 2:17 structure, leading to an increase of the magnetization but a decrease of the coercivity. An optimum maximum energy product of 14.0 MGOe is obtained in the $Sm_{12}(Co_{0.7}Fe_{0.3})_{88}$ powders.

### 2.2 $PrCo_5$ Nanograined Magnets

On the basis of the above results, the studies were extended to the $PrCo_5$ system. $PrCo_5$ is known to have a high magnetization and a strong uniaxial magnetocrystalline anisotropy, and because of this it has attracted much attention as a promising candidate for less-expensive permanent magnets for high-temperature applications since its discovery in the 1960s (Strnat 1967). However, the coercivity developed in $PrCo_5$-based sintered magnets is only 4–7.4 kOe (Velu *et al.* 1989), which is rather low compared with the anisotropy field of 145–170 kOe (Strnat 1988) of the $PrCo_5$ phase. It has been established that magnetically hard nanograined $PrCo_5$-based powders can be successfully synthesized by mechanical milling and subsequent annealing (Chen *et al.* 1999).

As shown in Figs. 5 and 6, a high coercivity of 16.3 kOe along with a high $M_r/M_s$ ratio of 0.66 and medium-strength maximum energy product of 11.6 MGOe has been obtained in stoichiometric $PrCo_5$ powders. A coercivity of 23.7 kOe has been obtained

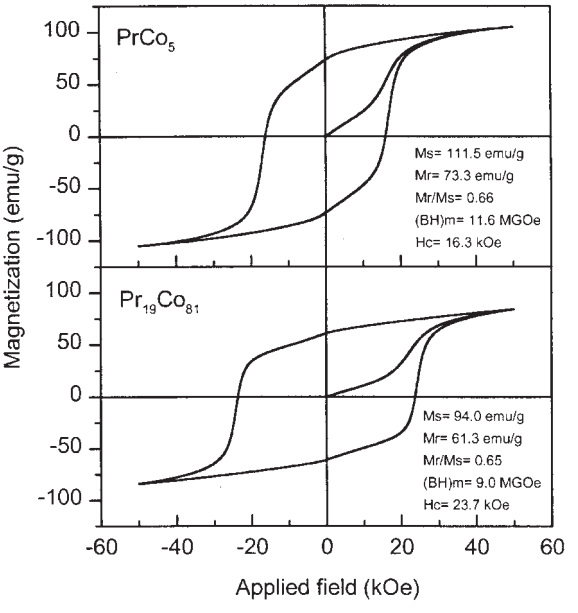

***Figure 5***
Hysteresis loops of $PrCo_5$ powders.

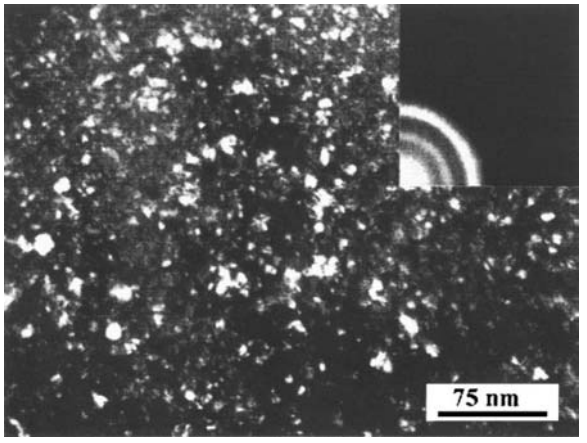

*Figure 6*
Dark-field TEM image of $PrCo_5$ powders.

in $Pr_{19}Co_{81}$ powders, which is the highest coercivity reported for $PrCo_5$-based magnets so far. A uniform $PrCo_5$ microstructure with an average grain size of about 15 nm is developed in the $PrCo_5$-based powders. The nanograined $Sm_2Co_{17}$ and $PrCo_5$ powders exhibit an excellent thermal stability. Both have a coercivity of about 5 kOe at 500 °C, which makes these nanostructured magnets promising candidates for high-temperature applications.

## 3. Conclusions

The microstructure and microchemistry of high-temperature magnets can be finely tuned through adjustments in the composition and processing parameters. For bulk $Sm(Co_{bal}Fe_{0.1}Cu_yZr_{0.02})_z$ magnets with $z = 7.5$, the temperature coefficient of coercivity changes from a small positive to a large negative value with increasing copper content. Changing the ratio $z$ and using an appropriate copper content lead to a new magnet with a record high coercivity of 10.8 kOe at 500 °C. Its temperature coefficient of coercivity is only $-0.03\,°C^{-1}$, which is much smaller than that of the old commercial magnets. On the other hand, mechanical milling has been found to be an effective technique to produce high-performance nanostructured RE–Co (RE = Sm, Pr) based powders. Magnetic properties of $M_s = 110.5\ \text{emug}^{-1}$, $M_r = 66.2\ \text{emu g}^{-1}$, $M_r/M_s = 0.60$, $H_c = 9.6$ kOe, and $(BH)_m = 10.8$ MGOe have been obtained in $Sm_2Co_{17}$ powders which have an average grain size of about 30 nm. A high coercivity of 16.3 kOe along with a high $M_r/M_s$ ratio of 0.66 and a medium-high maximum energy product of 11.6 MGOe have been obtained in $PrCo_5$ powders with an average grain size of about 15 nm.

# Magnets: Mechanically Alloyed

This contribution presents an overview of the ability of the mechanical alloying process to prepare nanocrystalline rare earth–transition metal (RE-TM) permanent magnet powders.

Reducing the grain size of the hard magnetic phase is an effective way to develop coercivity in RE-TM permanent magnets. Most suitable for the production of fine-grained magnets are nonequilibrium preparation techniques such as rapid quenching (RQ), hydrogenation–disproportionation–desorption– recombination (HDDR) (see *Magnets: HDDR Processed*) or mechanical alloying (MA). The latter method has been established by Schultz *et al.* (1987), where highly coercive NdFeB powders were developed by mechanically alloying the elemental constituents in a planetary ball mill and performing a subsequent heat treatment.

Nowadays, mechanical alloying or mechanical milling (MM, here the initial material is a prealloy) is applied to all technologically interesting hard magnetic systems, of which the iron-based intermetallic phases $Nd_2Fe_{14}B$, $Sm_2Fe_{17}N_x$, and its modified version $Sm_2Fe_{15}Ga_2C_x$ are discussed in this contribution. For an overview of SmCo(Fe) prepared by MA, see Wecker *et al.* (1991) and McCormick *et al.* (1998). Each of the mentioned RE-TM hard magnetic phases has its own advantages and disadvantages concerning the intrinsic properties, the preparation routes or simply the cost of the material (see *Rare Earth Magnets: Materials*). In all cases, mechanical alloying resulting in grain sizes as small as 20 nm leads to an effective magnetic hardening. The nanocrystalline microstructure of mechanically alloyed materials also allows the preparation of exchange-coupled materials, where neighboring grains are magnetically coupled across the grain boundary (Neu *et al.* 1996). This applies to single-phase material as well as to two-phase material, where an additional soft magnetic phase is coupled to the hard phase.

Magnetic materials prepared by MA are isotropic powders. These can be epoxy bonded or cold pressed to give compact magnets, but with a moderate remanence due to the low density and the isotropic easy axis distribution. In some cases, fully dense magnets can be prepared via hot pressing and texture can even be induced by hot deformation (see *Textured Magnets: Deformation-induced*), leading to highly remanent magnets (Schultz *et al.* 1991). The properties, which are very specific for the nanocrystalline microstructure, can also be achieved with rapid quenching. Here, MA is a technologically easy and cost-effective alternative for producing large quantities of powder.

## 1. The Principle of Mechanical Alloying

For MA, the starting material is sealed under an inert atmosphere in a milling container together with milling balls. The container movement can be a planetary motion, a vibrational motion or a simple rotation in the case of an industrial-sized attritor mill. In the NdFeB system, the intimate mixing and repeated fracturing of the material during milling leads to powder particles with a very fine layered structure of neodymium and iron and small embedded boron particles on a length scale of a few nanometers. A subsequent heat treatment causes a diffusional transformation towards the thermodynamically more stable crystalline intermetallic $Nd_2Fe_{14}B$ phase. The high activation mediated by the milling process (i.e., a large number of dislocations and stress) allows this transformation to take place at temperatures well below the melting temperature and enables the production of nanocrystalline powders.

The actual thermodynamics and kinetics of the process depend on composition, the energy input upon milling, and the choice of the initial material. For higher energy input, the formation of an amorphous phase, coexisting with α-Fe, has been observed upon MA and MM. In all cases, however, the $Nd_2Fe_{14}B$ phase develops only after a heat treatment, so that the optimum choice of annealing temperature $T_{ann}$ and time $t_{ann}$ is of crucial importance. Typically, for low $T_{ann}$ or short $t_{ann}$, an incomplete phase transformation limits $H_c$, whereas large grains reduce $H_c$ for too high $T_{ann}$ or too long $t_{ann}$.

Similar considerations hold for other RE-TM systems. Mechanical alloying of SmFe produces a mixture of nanocrystalline iron and an amorphous phase, which crystallizes into the 2:17-structure upon heating (Schnitzke *et al.* 1990). The same behavior is observed in SmFeGaC (Cao *et al.* 1996), whereas for mechanical milling with higher energy input, full amorphization is observed (Ding *et al.* 1993). In general, the degree of transformation, the occurrence of intermediate phases, and the resulting grain size depend strongly on the annealing treatment.

## 2. Highly Coercive Powders and Magnets

Besides reducing the grain size, decoupling of the hard magnetic grains is an effective approach to increase $H_c$. In the $RE_2Fe_{14}B$ system this can be obtained analogous to the case of sintered magnets by choosing a RE content above the stoichiometric value of 11.8 at%, leading to the formation of a RE-rich paramagnetic grain boundary phase. High coercive fields of $\mu_0 H_c = 2.0\,T$ are reported for a composition close to $Nd_{16}Fe_{76}B_8$ with a remanence $J_r = 0.73\,T$ (Schultz *et al.* 1991). The reported magnetic data refer to 100% density. The remanence value is slightly below $\frac{1}{2} J_s$ ($J_s$ is the saturation polarization) because of dilution with the additional phase. By substituting dysprosium for neodymium, values of $\mu_0 H_c$ as high as 5.6 T can be obtained (Schultz 1992); the remanence then drops to 0.29 T.

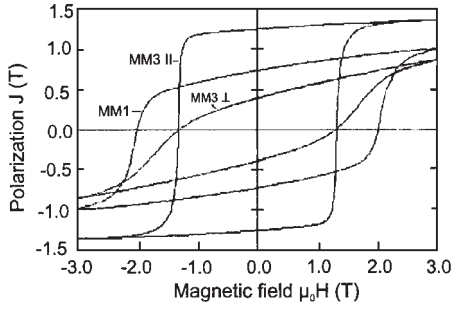

***Figure 1***
Hysteresis loop of a textured NdFeB magnet (MM3) prepared via hot pressing and die-upsetting of mechanically alloyed $Nd_{16}Fe_{76}B_8$-based powder (after Schultz *et al.* 1991). The magnet is measured parallel and perpendicular to the press direction. For comparison, the behavior of the annealed isotropic MA powder is shown (MM1).

Performing a die-upset experiment with a fully dense, hot-pressed sample allows the development of texture, and $J_r$ improves substantially (Fig. 1). With a $Nd_{16}Fe_{76}B_8$-based composition and additions of copper and gallium, an MA magnet prepared in this way exhibits $J_r = 1.31\,T$, an energy density $(BH)_{max} = 326\,kJm^{-3}$ and $\mu_0 H_c = 1.2\,T$. These values compare well with those of similar magnets prepared from rapidly quenched powders. It is again a property of the very small grains that allows the effective texturing.

$Sm_2Fe_{17}$ develops uniaxial magnetocrystalline anisotropy only after modification with interstitial atoms like carbon or nitrogen, usually introduced by a solid–gas reaction at temperatures around 500 °C (Coey and Sun 1990). Schnitzke *et al.* (1990) prepared $Sm_2Fe_{17}N_x$ powders with $\mu_0 H_c = 2.9\,T$ by nitriding nanocrystalline MA $Sm_2Fe_{17}$ powders. The remanence of 0.71 T is in accordance with $J_s = 1.54\,T$. Even higher coercive fields of 4.4 T are reported by Liu *et al.* (1994). A systematic study on the different crystallographic modifications of the $Sm_2Fe_{17}$-nitrides and their parent alloys is given by Teresiak *et al.* (1999). The use of the $Sm_2Fe_{17}N_x$-phase is, however, limited by its low thermal stability. Above 550 °C, $Sm_2Fe_{17}N_x$ disproportionates into SmN and α-Fe. Often, small amounts of partly unnitrided soft $Sm_2Fe_{17}$ or soft α-Fe are present in the material. For optimization, grain and particle sizes have to be considered in the kinetics of the solid–gas reaction (Coey and Smith 1999). The low thermal stability also prohibits a subsequent hot compaction.

The stability of the carbonized or nitrided $Sm_2Fe_{17}$ phase can be drastically improved by a substitution of iron with gallium, silicon or aluminum. Nanocrystalline, highly coercive $Sm_2Fe_{17-x}Ga_xC_2$ was prepared by MM with subsequent heat treatment, where carbon had already been introduced in the prealloy (Ding *et al.* 1994). The high stability also allows hot pressing, and fully dense $Sm_2Fe_{15}Ga_2C_2$ magnets with coercive fields of 1.5 T and remanences of 0.5 T can be prepared from MA powders (Cao *et al.* 1996). Texture via die upsetting was not obtained.

## 3. *Exchange-coupled Powders and Magnets*

Exchange coupling across the grain boundaries leads to an enhanced remanence compared to decoupled single-domain grains due to spin rotation in the grain boundary region (see *Magnets: Remanence-enhanced*). The effect increases with decreasing grain size. Nanocrystalline single-phase $Nd_2Fe_{14}B$ powders with exact stoichiometric composition and controlled grain size were prepared by mechanical milling and subsequent heat treatment (Neu *et al.* 1999). The grain-size dependence of the enhancement follows the prediction of a newly developed micromagnetic model (Neu *et al.* 1998).

In agreement with the consideration outlined above, the highest reduced remanence $J_r/J_s = 0.56$ is found in the $Nd_2Fe_{14}B$ powders with the smallest average grain size of 33 nm. Smaller grains (21 nm) were obtained in single-phase $Nd_2(FeCoGaNb)_{14}B$ powders and $J_r/J_s$ was further improved to 0.60. Suess *et al.* (2000) report even higher reduced remanences of 0.68 in mechanically alloyed and hot pressed $Pr_2Fe_{14}B$ magnets. These experiments show that exchange coupling, originally discovered in rapidly quenched ribbons, is as effective in MA or MM magnet powders, when a sufficiently small grain size is achieved.

If a second phase with higher $J_s$, e.g., iron, is coupled to the hard magnetic phase, the composite material shows a collective magnetization behavior, a further increased remanence, and a decreased but still considerable coercive field. Both the increase in $J_r$ and the decrease in $H_c$ scale with the amount of the soft phase. If, however, owing to large soft grains, the coupling is insufficient, magnetization reversal is initiated in the soft grains, coercivity is drastically reduced, and the demagnetization curve shows a two-step behavior. Milling of an iron-rich NdFeB composition and subsequent heat treatment leads to a $Nd_2Fe_{14}B + \alpha$-Fe composite with sufficiently small soft grains of about 20–30 nm.

Some additional elements, which dissolve in iron upon milling but are rejected upon annealing, can slow down the iron diffusion and therefore further reduce the iron grain size. Additional elements can also change the crystallization temperature of the 2:14:1 phase and thereby influence the grain size. Among the tested elements zirconium, niobium, and molybdenum are found to improve the coercive field via a reduced α-Fe grain size (Crespo *et al.* 1997, Cui *et al.* 2000). Important to the discussion of grain sizes and their influence on the magnetic properties is

consideration? of the degree of phase transformation. Especially when the annealing is performed at low temperatures, the advantage of small grain sizes is overcome by a residual amount of amorphous soft phase. There is no lower theoretical limit for grain size of the soft phase to give optimum $H_c$, but only the experimental difficulty of obtaining both small grains and a complete crystallization.

The substitution of cobalt for iron influences the intrinsic and extrinsic magnetic properties. Milling and annealing leads to the same iron:cobalt ratio in soft and hard phase. Curie temperature and saturation polarization in both phases are strongly improved and the remanence is increased. Also $J_r/J_s$ increases, indicating a more effective coupling of the grains, and the coercivity is rather constant. Upon cobalt substitution, a smaller α-(Fe,Co) grain size has been observed (You *et al.* 2000) and owing to the decrease in the magnetocrystalline anisotropy for both phases, an increase in the exchange length $l_{ex}$ is expected. This explains the improved coupling and also the stability of $H_c$, as the better coupling and the decreased anisotropy level off.

In comparing MA with MM, the second process often leads to better magnetic properties, attributed to a more homogeneous microstructure with a smaller grain size distribution (Miao *et al.* 1996). Consequently, exchange-coupled NdFeB magnet powders prepared by mechanical milling of a master alloy with additional cobalt and grain refining elements show very attractive magnetic properties, with $J_r \approx 1.2\,\mathrm{T}$, $\mu_0 H_c \approx 0.5\,\mathrm{T}$ and $(BH)_{max} \approx 150\,\mathrm{kJm^{-3}}$ (Fig. 2, Neu 1998). It is also possible to hot-press the as-milled powder and to prepare fully dense magnets with comparable properties (Wecker *et al.* 1995). As a rule

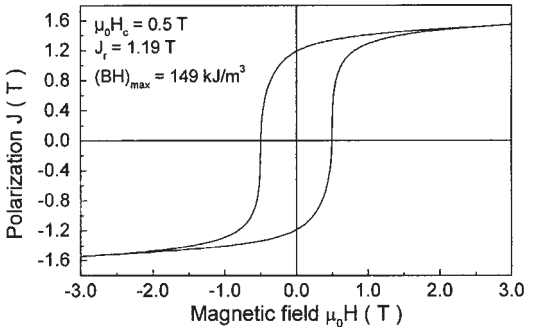

***Figure 2***
Hysteresis loop of exchange-coupled $Nd_8Fe_{78}Co_9Si_1B_4$ magnet powder prepared by mechanical milling of a stoichiometric master alloy blended with iron, cobalt, and silicon powder. Milling and optimum annealing leads to a nanocomposite of 70 vol.% $Nd_2(Fe,Co)_{14}B + 30$ vol.% (α-(Fe, Co)) with grain sizes of about 20 nm (after Neu 1998). $\mu_o H_c = 0.5\,\mathrm{T}$, $J_r = 1.19\,\mathrm{T}$, $(BH)_{max} = 149\,\mathrm{kJm^{-3}}$.

of thumb, in all these materials optimum energy densities are obtained for roughly 20–40 vol.% soft phase, which equals about 7–9 at.% neodymium.

Remanence enhancement in nanocrystalline SmFe-nitrides occurs for a samarium content below 11 at.%. MA of $Sm_7Fe_{93}$ powders, subsequent annealing and nitriding produces a two-phase mixture of $Sm_2Fe_{17}N_x$ and α-Fe with an iron grain size of about 20 nm. The powders show exchange-coupling behavior with a high remanence of $J_r = 1.13\,\mathrm{T}$ and a coercive field of $\mu_0 H_c = 0.39\,\mathrm{T}$ (Ding *et al.* 1993). As $H_c$ depends so critically on the grain size of the soft phase, optimum properties are only achieved in a very small window of the annealing temperature. Successful attempts to refine the α-Fe grain size down to 10–20 nm were reported by O'Donnel and Coey (1997) by adding 2 at.% zirconium or tantalum to a MA $Sm_7Fe_{93}$ powder. The addition of tungsten improves $H_c$, but without measurable effect on the average grain size (Kaszuwara *et al.* 2000). Here, an increase of the uniaxial anisotropy is assumed, as tungsten is observed to dissolve in the $Sm_2Fe_{17}N_x$ phase. MA two-phase $Sm_2Fe_{14}Ga_3C_2$/α-Fe magnets are discussed in Feutrill *et al.* (1996) with an emphasis on the magnetization behavior of exchange-coupled materials.

## 4. Conclusions

Mechanical alloying with subsequent heat treatment results in nanocrystalline permanent magnet powders with excellent properties. Hot compaction and hot deformation enables the production of highly anisotropic magnets. The most promising materials for cost effective resin-bonded magnets are isotropic exchange-coupled nanocomposites with high remanences of $J_r \geqslant 1.20\,\mathrm{T}$ and sufficient coercive field $\mu_0 H_c = 0.5\,\mathrm{T}$, which are based on NdFeCoB or PrFeCoB. The increase in the Curie temperature due to cobalt allows their use at elevated temperatures. Although diluted, these "lean" hard magnets based on low RE-content can achieve remanences exceeding 0.8 T.

Likewise, the SmFeN/C powders offer Curie temperatures above 450 °C, even without the expensive cobalt. Remanence and energy density, especially in the SmFeMC system, have still to be improved.
