# EDITOR'S PREFACE TO SECOND EDITION

The *Concise Encyclopedia of Magnetic and Superconducting Materials* combines in a single volume articles written by leading authorities in these fields, aiming at giving a complete cross-section of the science and technology of magnetic and superconducting materials. It is a successor of the *Concise Encyclopedia of Magnetic and Superconducting Materials* edited by Jan Evetts and published in 1992. In the present volume, the majority of articles deal with the advances of recent years, combining new developments in the field of magnetism and superconductivity with earlier articles describing the achievements reached in those topological areas that have kept their fires burning. Already many decades ago, physicists have abandoned the idea that the occurrence in the same material of localized magnetic moments and superconductivity is mutually exclusive. The advent of high-$T_c$ superconductors in particular has shown that magnetism and superconductivity are intimately connected and theoretical and experimental studies of the interplay between magnetism and superconductivity have become an area of its own right. But it is not only the strong mutual interest of scientists working in the field of magnetic and superconducting materials that has made it desirable to combine both issues in a single volume. Also from the applications side there is an increasing overlap between superconductivity and magnetism, magnetic bearings based on high-$T_c$ superconductors and superconducting permanent magnets being prominent examples. One can even go one step further and say that electrical conduction and magnetic polarization have increasingly become intertwined in many materials in recent years. The recognition that the magnetoresistive effect can advantageously be utilized in magnetic sensor and read head applications has led to a proliferation of research in this area, eventually culminating in the observation of the giant- and colossal magnetoresistance effects. New exciting phenomena have surfaced including spin-, charge- and orbital ordering in a variety of magnetic and superconducting materials.

The majority of articles contained in the present version of the *Concise Encyclopedia of Magnetic and Superconducting Materials* have been drawn from the *Encyclopedia of Materials: Science and Technology* (*EMSAT* for short). This encyclopedia consists of 10 volumes containing about 2000 articles. It was published only recently, in 2001. Included in the present volume are about 40 newly commissioned articles that will also appear in the electronic updated version of *EMSAT*. Bearing in mind that progress in materials technologies cannot occur without the benefit of the underlying science, both encyclopedias have aimed at a proper balance between articles dealing with technology of materials and fundamental science. The present volume has been tailored to meet the demands of smaller institutions, industrial companies and individual scientists for which research and development in the field of magnetic and superconducting materials is at a premium. In the last decade, research in the field of magnetism has received substantial impetus from information technology. Therefore, it is not surprising that a considerable number of magnetism articles in the present volume deal with magnetic and magneto-optic recording and the physics behind it. The articles in the present volume have been selected to provide the readership with a comprehensive coverage of materials properties, the design and principles of operation of devices in which particular materials have been applied and the fundamental phenomenology of magnetism and superconductivity. Each of the articles contains a reference list opening the way to more detailed and more deepened studies. Considerable attention has been paid to cross-reference various articles appearing in this volume with each other, providing as far as possible a coupling between materials, devices and phenomenology.

I wish to thank all authors who have responded affirmatively to my invitation to contribute an article on magnetism or superconductivity. In retrospect, I realize that I may have twisted the arms of some of my colleagues somewhat too strongly when convincing them to finish their article in time, presenting a comprehensive coverage of their specialistic topic and complying with the requirements of style and length set by the Publisher.

The task to provide the readership with an extensive coverage including novel trends and achievements in the areas of magnetism and superconductivity would have been extremely difficult without the professionalism of Pergamon Press. I am particularly indebted to Ms. Amanda Weaver and Mr. David Sleeman for their great help and expertise.

# HONORARY EDITORIAL ADVISORY BOARD
## FOR THE FIRST EDITION

# FOREWORD TO FIRST EDITION

In the time since its publication, the *Encyclopedia of Materials Science and Engineering* has been accepted throughout the world as the standard reference about all aspects of materials. This is a well-deserved tribute to the scholarship and dedication of the late Editor-in-Chief, Professor Michael Bever, to the Subject Editors and to the numerous contributors.

During its preparation, it soon became clear that change in some areas is so rapid that publication would have to be a continuing activity if the Encyclopedia were to retain its position as an authoritative and up-to-date systematic compilation of our knowledge and understanding of materials in all their diversity and complexity. Thus, the need for some form of supplementary publication was recognized at the outset. The Publisher has met this challenge most handsomely: both a continuing series of Supplementary Volumes to the main work and a number of smaller encyclopedias, each covering a selected area of materials science and engineering, are in the process of publication.

Professor Robert Cahn, the Executive Editor, was previously the editor of an important subject area of the main work and many other people associated with the Encyclopedia have contributed or will contribute to its Supplementary Volumes and derived Concise Encyclopedias. Thus, continuity of style and respect for the high standards set by the *Encyclopedia of Materials Science and Engineering* are assured. They have been joined by some new editors and contributors with knowledge and experience of important subject areas of particular interest at the present time. Thus, the Advisory Board is confident that the new publications will significantly add to the understanding of emerging topics wherever they may appear in the vast tapestry of knowledge about materials.

The appearance of the Supplementary Volumes and the series *Advances in Materials Science and Engineering* is an event which will be welcomed by scientists and engineers throughout the world. We are sure that it will add still more luster to a most important enterprise.

Walter S Owen

# EXECUTIVE EDITOR'S PREFACE TO FIRST EDITION

As the publication of the *Encyclopedia of Materials Science and Engineering* approached, Pergamon Press resolved to build upon the immense volume of work which had gone into its creation by embarking on a follow-up project. This project had two components. The first was the creation of a series of Supplementary Volumes to the Encyclopedia itself. The second component of the new project was the creation of a series of Concise Encyclopedias on individual subject areas included in the Main Encyclopedia to be called *Advances in Materials Science and Engineering*.

These Concise Encyclopedias are intended, as their name implies, to be compact and relatively inexpensive volumes (typically 400–600 pages in length) based on the relevant articles in the Encyclopedia (revised where need be) together with some newly commissioned articles, including appropriate ones from the Supplementary Volumes. Some Concise Encyclopedias offer combined treatments of two subject fields which were the responsibility of separate Subject Editors during the preparation of the parent Encyclopedia (e.g., dental and medical materials).

Eleven Concise Encyclopedias have been published. These and their editors are listed below.

| | |
|---|---|
| *Concise Encyclopedia of Advanced Ceramic Materials* | Prof. Richard J Brook |
| *Concise Encyclopedia of Building & Construction Materials* | Prof. Fred Moavenzadeh |
| *Concise Encyclopedia of Composite Materials* | Prof. Anthony Kelly CBE, FRS |
| *Concise Encyclopedia of Magnetic & Superconducting Materials* | Dr Jan Evetts |
| *Concise Encyclopedia of Materials Characterization* | Prof. Robert W Cahn FRS & Dr Eric Lifshin |
| *Concise Encyclopedia of Materials Economics, Policy & Management* | Prof. Michael B Bever† |
| *Concise Encyclopedia of Medical & Dental Materials* | Prof. David Williams |
| *Concise Encyclopedia of Mineral Resources* | Dr Donald D Carr & Prof. Norman Herz |
| *Concise Encyclopedia of Polymer Processing & Applications* | Mr Patrick J Corish |
| *Concise Encyclopedia of Semiconducting Materials & Related Technologies* | Prof. Subhash Mahajan & Prof. Lionel C Kimerling |
| *Concise Encyclopedia of Wood & Wood-Based Materials* | Prof. Arno P Schniewind |

Many of the new or substantially revised articles in the Concise Encyclopedias have been or will be published in one of the three Supplementary Volumes, which are designed to be used in conjunction with the Main Encyclopedia. The Concise Encyclopedias themselves, however, are "free-standing" and are designed to be used without reference to the parent Encyclopedia.

The Executive Editor was personally responsible for the selection of topics and authors of articles for the Supplementary Volumes. In this task, he has had the benefit of the advice of the Senior Advisory Editor and of other members of the Honorary Editorial Advisory Board. The Executive Editor was responsible for appointing the Editors of the various Concise Encyclopedias and for supervising the progress of these volumes.

Robert W Cahn FRS
*Executive Editor*

# EDITOR'S PREFACE TO FIRST EDITION

The *Concise Encyclopedia of Magnetic & Superconducting Materials* draws together in a single volume articles that cover all major aspects of the science and technology of magnetic and superconducting materials. When I was asked by Professor Robert W. Cahn, the Executive Editor of the series, to edit this volume, I was immediately attracted by the challenge of producing a unified and balanced work that would enable readers to draw parallels and experience contrasts in the conceptual treatment and practical technology of these materials. Having myself worked with magnetic and superconducting materials since the 1960s, I have become acutely aware that these two important classes of material have much in common, both in the phenomenology that underlies their behavior and in many of the issues that relate to their fabrication and optimization as bulk materials or thin films for application in technology. I believe that the treatment of these distinct materials, each at their own characteristic stage of development, in a single volume brings a conceptual freshness to our appreciation of both classes of material that helps to highlight deficiencies in our overall knowledge base and corresponding opportunities for new advances. Although the emphasis is on materials science and technology, the subject matter extends from physics to engineering design and applications and it is expected that the *Concise Encyclopedia of Magnetic & Superconducting Materials* will be useful to engineers, teachers, managers and scientists from a wide range of disciplines and many areas of manufacturing industry.

Because of the remarkable advances of recent years, this Concise Encyclopedia is based mainly on newly commissioned articles; about a third of the entries are drawn from the *Encyclopedia of Materials Science and Engineering* which was published in 1986, although many authors of articles in rapidly developing fields have rewritten or extensively updated their articles for this volume. In the area of magnetic materials there are 30 updated articles and 32 articles that are essentially new, while in the area of superconductivity three articles have been updated and 52 articles have been newly commissioned. The articles have been selected to give comprehensive and balanced coverage to each of three broad subject areas: first, there are articles devoted to particular classes of material; second, there are those that describe and elucidate material properties and phenomena that are common to different materials; and, third, there are articles that treat the general area of applications dealing with issues of materials selection and fabrication as well as the design and principles of operation of devices for particular applications. Extensive coverage has been given to articles concerned with the phenomenology of technical magnetism and superconductivity since the effective characterization and optimization of magnetic and superconducting materials depends critically on an understanding of the mechanisms underlying their various properties.

I am grateful to all the authors who responded to my invitation to write for this Concise Encyclopedia; they are all recognized authorities in their fields and I respect the special efforts they made with their contributions to accommodate the guidelines on length, style and content that were necessary to achieve a balanced and comprehensive coverage of the subject. Although the work is not intended as a source book for data on materials, an effort has been made to include, at every point, sufficient data to equip the reader with a reasonably quantitative understanding of the subject. An important part of each article is the list of references; these are selective rather than comprehensive and provide the reader with avenues for further study. At a time when much public attention has been focused on developments in the field of high-temperature superconductivity, considerable effort has been made to retain objectivity in the selection of topics and coverage. The aim has been to produce a work that will have lasting value and relevance over many years. In practice, this has not been too difficult as there is no area of high-temperature super-conductivity that cannot be seen, on pragmatic inspection, to have roots that go back over many years and, sometimes, over decades. In such an extensive work with so many contributing authors there is, inevitably, the occasional overlap; where this occurs articles are cross-referenced to each other. Considerable attention has been given to harmonizing notation, equations and preferred units, although I have

chosen not to force total uniformity where the common practice differs from one area of the subject to another. I have, however, insisted on the use of SI units as the primary unit throughout, although other units are sometimes given in parentheses.

I would like to acknowledge the encouragement and guidance of Professor Robert Cahn, the Executive Editor, and to thank Mr Michael Mabe and Mr Peter Frank of Pergamon Press for their support and advice. I am also particularly indebted to Mr Paul Aslin for his assistance in maintaining day-to-day contact with authors and in coordinating and assembling the manuscript copy. Finally, it is with sadness and regret that I acknowledge the valued contributions of two authors who are now deceased.

Professor John Bardeen, who inspired so many through his contributions to the theory of superconductivity over 35 years, completed a balanced and carefully worked article *Superconducting Materials: BCS and Phenomenological Theories* in January 1991, a few days before he died. Dr Gilbert Y. Chin, who recently retired as director of the Passive Components Research Laboratory at AT&T Bell Laboratories, passed away in May 1991. Dr Chin contributed the key introductory article *Magnetic Materials: An Overview* and coauthored with his friend and colleague Dr Jack Wernick a further ten articles on specialist magnetic materials.

Jan Evetts

# GUIDE TO USE OF THE ENCYCLOPEDIA

This Concise Encyclopedia is a comprehensive reference work covering all aspects of materials characterization. Information is presented in a series of alphabetically arranged articles which deal concisely with individual topics in a self-contained manner. This guide outlines the main features and organization of the Encyclopedia, and is intended to help the reader to locate the maximum amount of information on a given topic.

Accessibility of material is of vital importance in a reference work of this kind and article titles have therefore been selected not only on the basis of article content but also with the most probable needs of the reader in mind. An alphabetical list of all the articles contained in this Encyclopedia is to be found on pp. xvii–xix.

Articles are linked by an extensive cross-referencing system. Cross-references to other articles in the Encyclopedia are of two types: in text and end of text. Those in the body of the text are designed to refer the reader to articles that present in greater detail material on the specific topic under discussion at that point. They generally take one of the following forms:

> …which is fully described in the article *Magnetic Recording Devices: Future Technologies*.

> …other applications of this technique (see *SQUIDs: Magnetic Microscopy*).

The cross-references listed at the end of an article serve to identify broad background reading and to direct the reader to articles that cover different aspects of the same topic.

The nature of an encyclopedia demands a higher degree of uniformity in terminology and notation than many other scientific works. The widespread use of the SI system of units has determined that such units be used in this Encyclopedia. It has been recognized, however, that in some fields Imperial units are more generally used. Where this is the case, Imperial units are given with their SI equivalent quantity and unit following in parentheses. Where possible, the symbols defined in *Quantities, Units, and Symbols*, published by the Royal Society of London, have been used.

All articles in the Encyclopedia include a bibliography giving sources of further information. Each bibliography consists of general items for further reading and/or references which cover specific aspects of the text. Where appropriate, authors are cited in the text using a name/date system as follows:

> …as was recently reported (Smith 2002).

> Jones (1984) describes...

The contributors' names and the organizations to which they are affiliated appear at the end of all articles. All contributors can be found in the alphabetical List of Contributors.

The most important information source for locating a particular topic in the Encyclopedia is the multilevel Subject Index, which has been made as complete and fully self-consistent as possible.

## Actuator Materials for Small-scale Devices

The fabrication of a microsystem requires the processing of a large variety of different materials in order to realize their different electronic, sensor, and actuator components. The fabrication processes of these materials should be compatible with microsystem technologies, i.e., with silicon micromachining. One possibility for the realization of sensors and actuators in microsystems is the use of "smart" materials that directly transduce electrical, magnetic, or thermal energy into mechanical energy or vice versa. The related physical effects are the piezoeffect, magnetostriction, or the shape memory effect.

In general, thin film technologies are an attractive approach to integrate these materials into microsystems as this approach has almost no materials limitations, offers easy down-scaling into the micrometer range by a cost-effective manufacturing technology, avoids assembly and interconnection processes, allows the protection of the microsystem by protective layers (Quandt and Holleck 1998), and provides the possibility to design new materials as, for example, metastable phases, multilayers or gradient layers. Physical vapor deposition (PVD) techniques, in particular magnetron sputtering, offer the opportunity of tailoring the constitution of the thin films. Additionally, the interaction with the substrate enables fabrication of highly textured films which, in the case of piezoelectric materials, show improved properties compared to conventional polycrystalline bulk materials. Furthermore, it can be expected that the integrated sensing features of smart film actuators—e.g., the resistive effects present in all three classes of materials—will provide means to realize "intelligent" actuators by using thin film "smart" materials.

Thin film actuators in the case of piezoelectric or magnetostrictive materials are always used as compounds with micromachined substrates working as bending transducers, whereas in the case of shape memory thin films both free-standing thin film actuators and compounds with metallic or silicon substrates are realized. Since free-standing shape memory films have to be trained for the two-way effect to introduce internal stresses into the material, which is quite complicated in small dimensions, the film substrate compounds represent the generally more important approach for all smart film materials. In this case the materials development target has to be modified compared to bulk actuator materials. Whereas in bulk materials the strain has to be maximized, the resulting bending stress of a thin film substrate compound is proportional to the strain and Young's modulus of the film. As a consequence, this stress of the thin film actuator material should be as large as possible. In the following sub-sections the main results for magnetostrictive, piezoelectric, and shape memory thin films for actuators will be discussed in view of their main application areas.

### *1. Magnetostrictive Films*

The development of room temperature giant magnetostrictive bulk and thin film materials is based on the rare earth $Fe_2$ Laves phase, while at low temperatures the highest strains are found in hexagonal $Tb_xDy_{1-x}$ and body-centered $Tb_xDy_{1-x}Zn$ alloys. The giant magnetostrictive materials were optimized in terms of their magnetostriction to magnetic anisotropy ratio in order to attain large strains at reasonable magnetic fields (see *Magnetostrictive Materials*). Different approaches have been taken based on the Laves phases $(Tb,Dy)(Fe,Co)_2$ with positive or $Sm(Fe,Co)_2$ with negative magnetostriction. The fabrication of these rare earth based materials is restricted to PVD methods, the most prominent being magnetron sputtering.

Because the magnetic saturation field is proportional to the magnetic anisotropy constant and inversely proportional to the saturation magnetization, its reduction is achieved either by decreasing the magnetic anisotropy constant and/or by increasing the saturation magnetization. To reduce the macroscopic anisotropy, amorphous rare earth–iron thin film materials have been fabricated in a wide composition range. It was found that increasing the rare earth content compared to the Laves phase composition results in the highest low-field magnetostriction in amorphous thin films. For amorphous TbFe films with an inplane magnetic easy axis an important improvement of the low-field magnetostriction and the hysteresis can be observed in comparison to nanocrystalline $(Tb,Dy)Fe_2$ films.

Assuming the same local environment in the amorphous compared to the crystalline state, a further approach to lower the remaining anisotropy is by Tb/Dy substitution, which was investigated over a wide composition range for rare earth–iron or –cobalt thin film materials. This approach leads to a further reduction in the magnetic saturation field, but the lower Curie temperature due to the dysprosium alloying significantly reduces the saturation magnetostriction, resulting in negligible gain in low-field magnetostrictive strain of these ternary films.

The second route to lower the macroscopic anisotropy is by increasing the saturation magnetization. The magnetostrictive thin films discussed so far have rather low magnetizations, owing to their ferrimagnetic nature. Unfortunately, an increase of the saturation magnetization using amorphous homogeneous rare earth–transition metal materials is impossible, because the compositions of interest contain

30–45 at.% rare earth elements. The rare earth moments dominate and thus any decrease will further reduce the magnetization, while an increase of their content results in a lowering of the Curie temperature and consequently a lowering of the room temperature magnetization.

However, using multilayers, it is possible to develop new composite materials which show properties that overcome these limitations. One layer is composed of the giant magnetostrictive amorphous $Tb_{0.4}Fe_{0.6}$ alloy, while the other is magnetically very soft and has a very high magnetization as well as considerable magnetostriction itself ($Fe_{0.5}Co_{0.5}$). By fabricating these layers with thicknesses smaller than the ferromagnetic exchange length, domain wall formation at the interfaces is prevented and the magnetic properties of such an exchange-coupled multilayer system are determined by the average of those of each individual layer. The comparison of the magnetostriction of this multilayer with the state-of-the-art amorphous and nanocrystalline single-layer materials demonstrates that these novel multilayers give the highest magnetostrictions at very low fields with a saturation field of only 20 mT (Fig. 1).

The most important advantages of magnetostrictive actuators are the possibility of wireless operation and the anisotropic behavior of the magnetostriction. The former is especially attractive for ultrasonic motors and for valves or pumps operating in harsh environments or on rotating or moving parts. The anisotropy of the magnetostriction can be employed for the realization of a two-dimensional scanner using a simple cantilever geometry in combination with the excitation of bending and torsion modes.

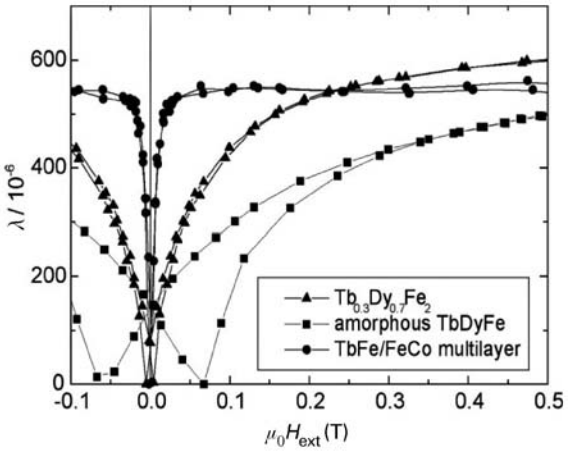

***Figure 1***
Magnetostriction ($\lambda$) versus external magnetic field ($H_{ext}$) of different thin film materials: nanocrystalline $Tb_{0.3}Dy_{0.7}Fe_2$ single layer, amorphous TbFe single layer, and TbFe/FeCo multilayer.

## 2. *Piezoelectric Films*

The development of piezoelectric thin films for actuators is related either to wurtzite-type structure materials (e.g., ZnO, AlN) or to ferroelectric perovskite materials (e.g., $Pb(Zr,Ti)O_3$). The general merits of piezoelectric thin film actuators are their low power consumption and their driving voltages compatible with transistor–transistor logic (TTL) signal levels. The drawbacks are their high fabrication temperatures, especially in the case of ferroelectric thin films, their comparably low sputtering rates, and the high precision of stoichiometry control required.

In the development of piezoelectric thin film materials, high piezoelectric strains, breakdown field strengths, electrical resistivity, Young's modulus, long-time stability and fatigue strength, and in the case of the ferroelectric materials high Curie temperature, are further important targets. The wurtzite-type piezoelectric films can be fabricated by chemical or physical vapor deposition (CVD or PVD) methods, the latter being mainly sputtering or laser-ablation routes. Even more fabrication methods exist in the case of ferroelectric thin film materials; the most prominently used are CVD, PVD and sol–gel methods.

Although their piezoelectric constants are one or two orders of magnitude lower than in $Pb(Zr,Ti)O_3$ (PZT), wurtzite-type thin films are of interest for many applications, predominantly because of their simpler fabrication, mainly owing to lower fabrication temperatures, their hysteresis-free response, and their higher temperature range of use. Furthermore, their much higher Young's moduli compensate in part for their lower piezoelectric constants in the case of bending-type thin film actuators. In order to obtain high piezoelectric constants, highly c-axis-textured wurtzite-type films are required having low resistivity perpendicular to the substrate. It has been found that the microstructure and the texturing depend critically on the deposition conditions. By adjusting the sputtering conditions, highly c-axis-oriented films can be obtained. Although ZnO shows the higher piezoelectric strain, AlN films are very promising owing to their higher resistivity and their better compatibility with microelectronics batch fabrication processes.

Ferroelectric thin films having a perovskite structure are of wide interest mostly because of their high dielectric constant and high remanence, e.g., as capacitors for dynamic random access memories (DRAMs). The high piezoelectricity in PZT materials leads to further interest in these materials for applications as microsystem actuators, especially as bulk PZT is widely used for high precision or ultrasonic actuators. In general, PZT films can be fabricated either by a single-step process with substrate temperatures of approx. 550 °C or by a two-step process using postdeposition crystallization for the

***Table 1***
Measured piezoelectric and dielectric coefficients. $d_{33,f}$ describes the strain $x_3$ in the normal direction ($x_3 = d_{33,f}E_3$), $e_{31,f}$ the in-plane strain ($\sigma_{1,2} = e_{31,f}E_3$) of thin film materials, where $E_3$ is the applied electric field in the normal direction (Muralt 1997).

| | AlN | PZT |
|---|---|---|
| $d_{33,f}$ | 3.9 | 90 … 200 |
| $e_{31,f}$ | −0.9 | −4 … −6 |
| $\varepsilon_{33}$ | 11 | 1100 … 1300 |

amorphous as-deposited films. Employing this two-step process, crystallization in the perovskite structure was found at temperatures between 550 and 600 °C, whereas the texture of the films depends strongly on the bottom electrode and the substrate being used. Owing to the inherent film stress and its texture the unpoled polycrystalline PZT films being fabricated by sputtering already exhibit a polarization and a piezoelectric response which reach approximately half the values of poled or single crystal thin film materials.

The piezoelectric data of both classes of materials are compared in Table 1, which demonstrates the special potential of PZT films provided that all fabrication issues are solved. The most important features of piezoelectric thin film actuators are the low voltage, low power, high-frequency operation being compatible to TTL signal levels. Consequently, high frequency applications such as surface acoustic wave (SAW) devices, ultrasonic motors, and resonant sensors for mechanical quantities are the domain of piezoelectric thin film actuators.

## 3. Shape Memory Thin Films

The development of shape memory thin films is based on TiNi, which is superior to other potential shape memory materials with respect to attainable strains and stresses. Owing to the low transformation temperatures of binary TiNi films, the materials research is concentrated on Ni/Pd substitution for an increase in transformation temperature and Ni/Cu substitution for a reduction in transformation hysteresis. Furthermore, it is known that TiNiCu films are much less sensitive in their transformation temperatures to variations in the titanium content. Further interest is related to the training procedures as well as to the actuator design to achieve the two-way behavior in either free-standing films or in combination with a substrate.

It has been found that Ni/Pd substitution is very effective in adjusting the transformation temperatures between room temperature and temperatures above 500 °C, whereas the measured austenite finish temperatures of sputtered films are in good agreement with the reported data of bulk materials (Fig. 2) (Quandt *et al.* 1996).

By Ni/Cu substitution it is possible to reduce the transformation hysteresis. In the case of the ternary system Ti–Ni–Cu this substitution affects almost only the martensite finish temperatures, which are raised by increasing the copper content. The martensite and austenite finish temperature ($M_f$, $A_f$, respectively), as well as the hysteresis $A_f$–$M_f$ are shown in Fig. 3 as a function of the copper content while the titanium content was kept constant. The results show that

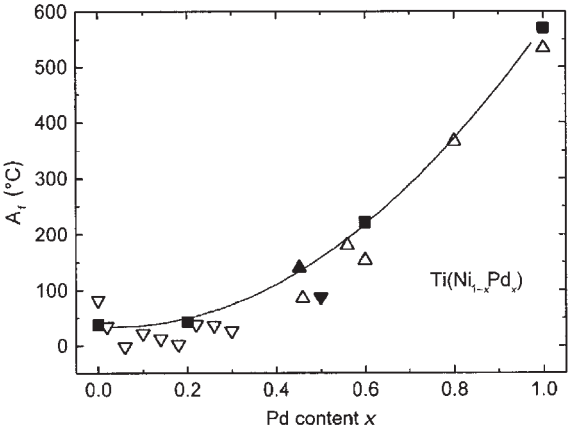

***Figure 2***
Austenite finish temperature $A_f$ of Ti($Ni_{1-x}Pd_x$) bulk (open symbols) and thin film (closed symbols) materials, as a function of palladium content (after Quandt and Holleck 1998).

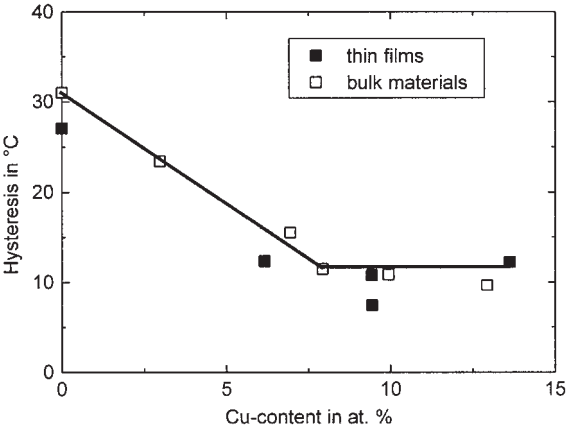

***Figure 3***
Hysteresis of Ti(Ni,Cu) bulk (open symbols) and thin film (closed symbols) materials (after Miyazaki *et al.* 1996).

Ni/Cu substitution of about 20% leads to a reduction of the hysteresis from 70 K to approx. 20 K for free-standing, stress-free thin-film materials, which is not further reduced by higher copper contents.

Compounds of substrates and shape memory films are an attractive approach to realize actuators that do not require a special training treatment, which is necessary in the case of free-standing films. The internal stress resulting in a two-way behavior is introduced after the crystallization upon cooling, owing to different thermal expansion coefficients of substrate and shape memory film. In the case of lower thermal expansion coefficients of the substrate (e.g., silicon, molybdenum) the shape memory films are under tensile stress while higher thermal expansion coefficients of the substrate (e.g. $Fe_{72}Cr_{18}Ni_{10}$) result in compressive film stress. Below the martensite start temperature these stresses vanish, owing to the formation of selected martensite variants corresponding to the lowest free energy of the system.

Upon heating, the shape memory effect leads to a restoration of the original stress state. Thus high stresses exceeding 400 MPa are restored in a narrow temperature range defined by the transformation hysteresis of the shape memory material (Fig. 4). Using these shape memory compounds it is possible to fabricate shape memory bending transducers in a fully batch technology by sputtering the metallic substrate layer in combination with sacrificial layers. This two-way actuator does not require any training procedures.

The unique feature of shape memory actuators is the very high energy density, which is considered to be of special importance, owing to the small volumes of actuators in microelectromechanical systems (MEMS). Applications realized so far make use of this feature, e.g., in the case of microvalves to be employed in pneumatics or hydraulics.

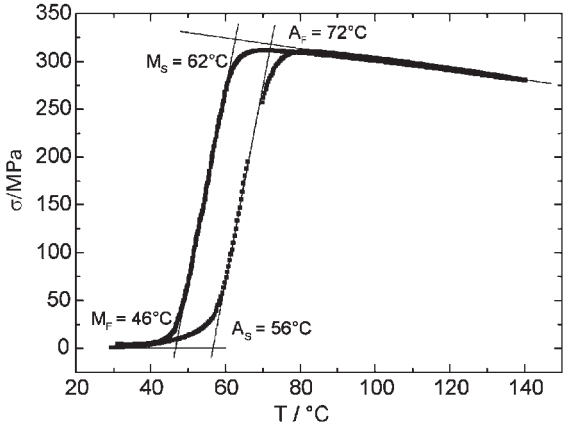

***Figure 4***
Stress–temperature curve of a TiNiCu shape memory film on molybdenum. $A_s$ and $A_f$ denote the austenite start and finish temperature; $M_s$ and $M_f$ are the martensite start and finish temperature.

## Alloys of 4*f* (R) and 3*d* (T) Elements: Magnetism

Ordered metallic alloys with a well-defined crystal structure are classified as intermetallic compounds, or intermetallics. Owing to the metallic character of bonding, the crystal structures of intermetallics tend to reach the highest symmetry, highest space filling, and highest coordination number.

The R–3*d* intermetallics are ordered alloys of rare earth (RE) and 3*d* transition (T) elements and can involve one or both elements with magnetic moments. These compounds exist in a relatively narrow compositional range, and the R and T atoms are distributed at proper and definite positions in the crystallographic cell. Accordingly, two magnetic sublattices (*f*- and *d*-electron subsystems) can be distinguished in R–3*d* intermetallics. While the number of pure magnetic 3*d* and 4*f* elements is about 20, there are several hundred binary R–3*d* intermetallics and thousands among the ternary R–3*d*–M systems. It has been established that in most cases the same crystal structure is stabilized for variable R elements and to some extent for variable T elements so that helpful comparison of magnetic properties can be made, giving enlightenment as to the basic interactions involved in various cases.

## *1. 4f and 3d Magnetism in R–3d Intermetallic Compounds*

The nature of magnetism is different in the two electron subsystems involved in the magnetic interactions in R–3*d* intermetallics. Most of the lanthanide ions retain the localized atomic character of the 4*f* orbitals and their magnetism can usually be well described by atomic characteristics, *L*, *S*, and *J*, of a free $R^{3+}$ ion (see *Localized 4f and 5f Moments: Magnetism*). In contrast, the 3*d* electrons of transition metals are itinerant and the 3*d* states form an energy band crossed by the Fermi level, $\varepsilon_f$, with natural consequences for magnetism (see *Itinerant Electron Systems: Magnetism (Ferromagnetism)*). The interaction between the RE and transition metal sublattices is mostly realized by the hybridization of the 5*d* (4*d* for Y) states of the RE and the 3*d* states of the transition metal, which mediates the strength of the 4*f*–3*d* exchange interaction.

The effect of the RE sublattice on the magnetic properties of the *d* subsystem is in most cases considered as resulting in an additional shift of the majority ("up," or "+") and minority ("down," or "–") *d* subbands, whereas the effect of the *d* electrons on the RE sublattice consists of a modification of the energy level scheme of the $R^{3+}$ ions.

Because of a spatial localization of the 4*f* electronic shells, no direct overlap between the 4*f* wave functions takes place in R–3*d* intermetallics. The *f*–*f* exchange occurs via the conduction electrons and is therefore weaker than the *f*–*d* and *d*–*d* exchange interactions. The interactions related to the *d* sublattice increase successively along with the content of the transition metal and the *d*–*d* interaction becomes dominant in T-rich compounds.

### *1.1 Itinerant Magnetism of the* d *Electrons*

A distinct feature of the *d* magnetism in R–3*d* intermetallics is the hybridization between the narrow 3*d* band (~3eV) of the transition metal with a high density of states (DOS), $N_{3d}(\varepsilon)$, and the broader 5*d* band (~10eV) of the lanthanide (the 4*d* band of yttrium) with a lower DOS. The contribution to the total DOS from the 6*s* (5*s*) band is negligible because of very low values of $N_s(\varepsilon)$. The magnetic properties of the *d*-electron subsystem are hence determined by the energy dependence of $N_d(\varepsilon)$ near the Fermi level, $\varepsilon_f$, and the position of $\varepsilon_f$ itself (Barbara *et al*. 1990, Franse and Radwanski 1993).

The electronic structure of the hybridized *d* band can be represented schematically by one of the three characteristic curves shown in Fig. 1. Figure 1(a) shows the weak (unsaturated) ferromagnetic case: the majority and minority subbands are both partly filled. This class involves all the iron intermetallics, the cobalt series $R_2Co_7$, $RCo_3$, $R_4Co_3$, and the nickel series $R_2Ni_7$, $RNi_3$. For these compounds $\varepsilon_f$ lies in the region with high DOS where the contribution from the 5*d* states is essentially important. Figure 1(b) illustrates the strong (saturated) ferromagnetic case. The majority subband is filled and the Fermi level is in the high DOS region where the contribution of the 3*d* states dominates. The cobalt-rich compounds $R_2Co_{17}$ and $RCo_5$ belong to this class. Figure 1(c) shows the paramagnetic case, for which $\varepsilon_f$ lies in the region with low DOS formed primarily by the 5*d* (4*d*) electron states of R.

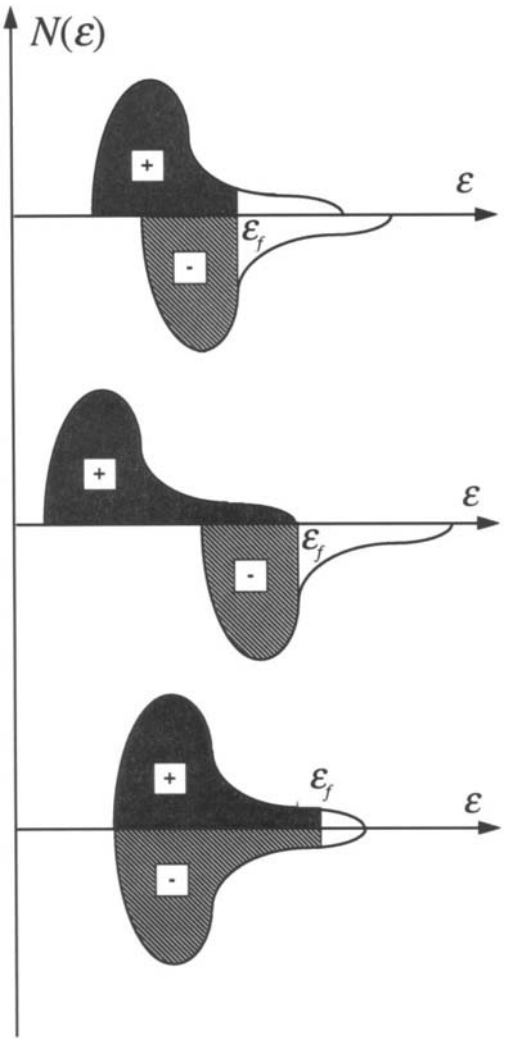

***Figure 1***
Schematic representations of the density of *d* states of the hybridized *d* band of R–3*d* intermetallic compounds for a weak, unsaturated, ferromagnetic (top), strong, saturated, ferromagnetic (center), and paramagnetic (bottom) states.

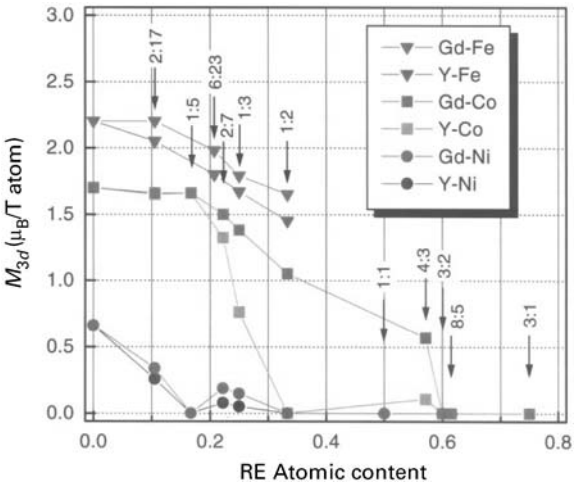

***Figure 2***
Magnetic moment of the *d*-electron subsystem per one T atom vs. RE content (data taken from Burzo *et al.* 1991).

The magnetic behavior of the *d* subsystem is found to be almost independent of the RE within each given $R_mT_n$ series. However, a strong variation of the *d* magnetism vs. stoichiometry is one of the most important factors, along with the crystal structure, in determining the magnetic properties of R–3*d* intermetallics with different chemical formulas.

The *d* magnetic moment vs. the chemical formula is depicted in Fig. 2 for compounds with nonmagnetic yttrium and magnetic gadolinium partner elements. While in the T-rich compounds $\mu_d$ is close to the value for the given partner T metal, with increasing RE content its value falls substantially. In the Y–Fe system, $\mu_d$ takes the value $1.45\mu_B$ ($YFe_2$), while in metallic iron it is $2.2\mu_B$. In the Y–Co and Y–Ni systems $\mu_d$ varies in a nonmonotonic way: $YCo_2$ and $YNi_5$ have paramagnetic ground states, whereas ferromagnetism appears in $Y_4Co_3$ ($T_C \approx 7$K), $Y_2Ni_7$ (58K), and $YNi_3$ (32K). With further increasing RE content the *d* subsystem becomes paramagnetic in both series.

In some series, substitutions of nonmagnetic yttrium by a magnetic RE can induce a substantial increase of $\mu_d$ (cf. yttrium and gadolinium systems in Fig. 2). Within the scope of the itinerant model, this is ascribed to the *f*–*d* exchange interaction. The total molecular field acting on the *d* subsystem is given by:

$$H_{\mathrm{mol}}^{(d)} = n_{dd} M_d + n_{\mathrm{R}d} M_{\mathrm{R}} \qquad (1)$$

where

$$n_{dd} = \frac{z_d I_{dd}}{2\mu_{\mathrm{B}}^2}$$

and

$$n_{\mathrm{R}d} = \frac{(g_{\mathrm{R}} - 1) z_{\mathrm{R}} I_{\mathrm{R}d}}{2 g_{\mathrm{R}} \mu_{\mathrm{B}}^2}$$

are the corresponding molecular field coefficients, $I_{dd}$ and $I_{\mathrm{R}d}$ denote the *d*–*d* and R–*d* exchange integrals, and $z_d$ and $z_{\mathrm{R}}$ are the numbers of T and R atoms in the nearest neighbor surrounding a T atom.

The description of the *d*-electron subsystem in the itinerant model presumes the existence of spin fluctuation (SF) excitations at elevated temperatures. In T-rich intermetallics with stable *d* moments and high values of $T_C$, the mean square SF amplitude, $\langle m_{\mathrm{SF}}^2 \rangle$ (in the paramagnetic state), and the local spin density amplitude, $\langle m_{\mathrm{loc}}^2 \rangle$ (in the ordered state), at the T-atom positions are both almost temperature independent and also depend weakly on external fields. Hence, the *d* subsystem can be considered to a good approximation as a stable magnetic sublattice. In the molecular field approach, the following expression for $T_C$ is derived:

$$T_{\mathrm{C}} = \frac{1}{2}\left( T_d + T_{\mathrm{R}} + \sqrt{(T_d - T_{\mathrm{R}})^2 + 4T_{\mathrm{R}d}^2} \right) \qquad (2)$$

where $T_d$, $T_{\mathrm{R}}$, and $T_{\mathrm{R}d}$ represent the contributions to $T_C$ arising from the *d*–*d*, R–R, and R–*d* interactions, respectively. The characteristic temperatures are given by $T_{dd} = n_{dd} C_d$, $T_{\mathrm{RR}} = n_{\mathrm{RR}} C_{\mathrm{R}}$, and $T_{\mathrm{R}d} = n_{\mathrm{R}d}\sqrt{C_{\mathrm{R}} C_d}$, where $C_{\mathrm{R}}$ and $C_d$ are the corresponding Curie constants.

For weakly magnetic and exchange-enhanced paramagnetic *d* subsystems, the temperature and field dependence of the *d* magnetization is substantial. In these systems, temperature-induced SF as well as critical fluctuations near $T_C$ become important. In weakly ferromagnetic itinerant electron systems both $\langle m_{\mathrm{SF}}^2 \rangle$ and $\langle m_{\mathrm{loc}}^2 \rangle$ are substantially temperature dependent in a wide region around $T_C$ (Brooks and Johansson 1993). Therefore, the spontaneous magnetovolume effect, $\omega_s = (V_m - V_0)/V$, reaches $10^{-3}$–$10^{-2}$ in intermetallics with unsaturated *d* magnetism (see *Itinerant Electron Systems: Magnetism (Ferromagnetism)* and *Magnetoelastic Phenomena*), whereas a much lower magnetovolume effect originates from the RE sublattice ($\sim 10^{-4}$). The thermal expansion is therefore widely used in investigating aspects of the *d* magnetism in R–3*d* intermetallics (see *Magnetoelastic Phenomena*).

### *1.2 Localized RE Magnetism*

Electronic properties of the 4*f* ions can be described within a single-ion Hamiltonian including the spin–orbit (SO), crystal field (CF), and exchange (EX) interactions:

$$H_{\mathrm{R}} = H_{\mathrm{SO}} + H_{\mathrm{CF}} + H_{\mathrm{EX}} \qquad (3)$$

For most of the RE ions, the spin–orbit term dominates in the Hamiltonian of Eqn. (3). Thus, the *L–S* coupling scheme remains valid in R–3*d* intermetallics (*J* is said to be a "good quantum number"). The expectation value of $J_z$ varies then between $L+S$ and $|L–S|$. In agreement with Hund's rules, for the heavy (light) RE the ground-state multiplet has the highest (lowest) value of $J=L+S$ ($J=|L–S|$). The level scheme is determined by a combined action of the CF and the exchange interaction (see *Magnetism in Solids: General Introduction*; *Electron Systems: Strong Correlations*).

In the molecular field approximation, the molar magnetization of the RE sublattice as a function of the external field, $H_{\text{ext}}$, and $T$, expressed through the partition function, $Z_{\text{R}}(\mathbf{n})$ ($n_i = x, y, z$), takes the form:

$$M(\mathbf{n}, T, H_{\text{ext}}) = NkT\,\frac{\partial Z_{\text{R}}(\mathbf{n})/\partial H_{\text{ext}}}{Z_{\text{R}}(\mathbf{n})} \qquad (4)$$

The free energy, $F_{\text{R}}(T, \mathbf{n}) = -NkTZ_{\text{R}}(\mathbf{n})$, and hence the energy level scheme, depend on the crystallographic direction. The anisotropic part of the free energy determines the magnetocrystalline anisotropy that is responsible for the spontaneous orientation of the magnetization vector in the crystal. This direction is called the easy axis (EA). For a weak exchange interaction energy, $E_{\text{EX}}$, the CF anisotropy—single-ion anisotropy—can lead to a reduction of the 4*f* moment. In these intermetallics, anisotropy of the magnetization is observed under strong magnetic fields.

### *1.3 Exchange Coupling Between the 4f and d Sublattices*

The models suggested for the *f–d* exchange involve a direct on-site 4*f*–5*d* exchange interaction and take into account the space localization of the *d*-electron states (Yamada 1988). Since the intra-atomic exchange integral on a T atom is larger than that on an R atom, the exchange splitting of the local density of *d* states of T atoms with up and down spins is substantially larger than the splitting of the local DOS of R atoms. Then, the difference, $\Delta\varepsilon$, between the effective atomic potentials on R and T atoms for up-spin electrons becomes larger than that for down-spin electrons. As the strength of hybridization weakens with increasing value of $\Delta\varepsilon$, the *d* states in the up-spin subband mix with each other less than those in the down-spin subband. This difference in mixing is of prime importance for the sign of the 4*f*–3*d* magnetic coupling (Brooks and Johansson 1993).

Under the external magnetic field the numbers of *d* electrons of R-atom character with spins up and down are not equal, $n_{d\uparrow}(\text{R}) < n_{d\downarrow}(\text{R})$, and the *d* polarization, $m_d(\text{R}) = (n_{d\uparrow}(\text{R}) - n_{d\downarrow}(\text{R}))\mu_{\text{B}}$, is negative (if considering $m_d(\text{T}) = (n_{d\uparrow}(\text{T}) - n_{d\downarrow}(\text{T}))\mu_{\text{B}}$ positive). Thus, the molecular fields on R atoms created by

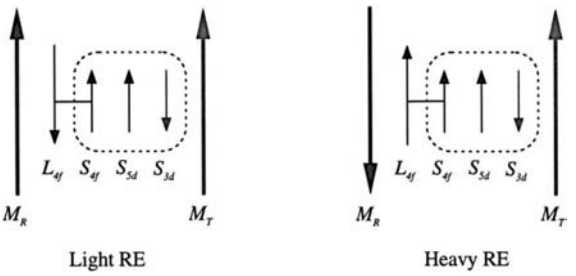

***Figure 3***
Schematic illustration of the 4*f–3d* exchange coupling between the R and T magnetic moments. The dashed areas show that part of the interactions for which the sign remains unchanged. Note that the magnetic moments are antiparallel to the corresponding mechanic moments.

$m_d$(R) and $m_d$(T) are opposite to each other, and the local DOS of the R atoms with up and down spins will split in the opposite direction with respect to the local DOS of T atoms. This scheme remains also valid for the R–3*d* compounds with a magnetic RE. Numerical calculations as well as Mössbauer data give the value of $m_d$(R) as about $-0.3\mu_{\text{B}}$ per T atom in R–Fe compounds.

In R–3*d* intermetallics with a magnetic RE the spin moments, $\mathbf{S}_{4f}$, of the R atoms are always oriented parallel to the 5*d* spin moments, $\mathbf{S}_{5d}$, owing to the positive intra-atomic exchange interaction. This means that the 4*f* spin moment is oriented antiparallel to the 3*d* moment. Therefore, the total magnetic moment, $M_{\text{R}} = g_{\text{R}}\mu_{\text{B}}J_R$, is oriented opposite (parallel) to $M_{\text{T}}$ for heavy (light) RE elements, as shown in Fig. 3.

## *2. Basic Properties of Binary R–3d Intermetallics*

The Curie temperatures of binary Gd–3*d* and Y–3*d* intermetallics are given in Table 1. Since the molecular fields due to the *f–f* and *f–d* interactions reach their maximum in the gadolinium compounds ($S_{\text{Gd}}$ is a maximum among all RE), $T_{\text{C}}$ of $\text{R}_m\text{T}_n$ with other magnetic RE range between the respective values for the compounds with R = Y and Gd. These data show the weakening of the RE contribution (primarily through the *f–d* interaction) in the total exchange energy with increasing content of the T partner element.

### *2.1 Compounds with a Nonmagnetic 3d Sublattice*

In these compounds the magnetic properties are almost exclusively determined by the 4*f* electrons. The itinerant *d* states contribute only because of a polarization induced by the *f–d* exchange interaction. Among various magnetic states and magnetization processes, one may quote metamagnetic transitions

***Table 1***

a Only $R_3Co$, $R_3Ni$, $RFe_2$, $RCo_2$, $RNi_2$, $RCo_5$, $RNi_5$, and $R_2Ni_{17}$ exist with any R and with the same crystal structure. The following stoichiometries have nonmagnetic *d* sublattices and exist with very limited R and T: 5:2 (m, *C*2/*c*, R = Pr, Nd, Sm, T = Co); 7:3 (h, $P6_3/mc$, R = La, Ce, Pr, Nd, T = Ni); 24:11 (h, $P6_3/mc$, R = Ce, T = Co); 12:7 (m, $P2_1/c$, R = Gd, Tb, Dy, Ho, Er, T = Co); 1:1 $-\delta$ ($\delta \approx 0.85$, h, $P6_3/mmc$, R = La, Pr, Nd, T = Co); 2:3 (o, *Cmca*, R = La, T = Co, Ni). $LaCo_{13}$ (c, *Fd*3*m*, $T_C = 1290$K). PM = Pauli paramagnet. b c, cubic; h, hexagonal; m, monoclinic; o, orthorhombic; r, rhombohedral; t, tetragonal. c In $GdCo_2$ the cobalt subsystem is magnetic due to itinerant electron metamagnetism.

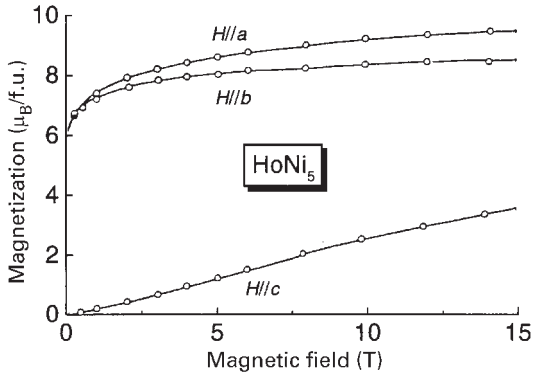

***Figure 4***
Magnetization curves of the hexagonal compound $HoNi_5$ at 1.5K measured along different crystallographic axes, orthorhombic set (data taken from Franse and Radwanski 1993).

associated with a field-induced crossing and anticrossing of CF energy levels in paramagnetic systems (as in $PrNi_5$), metamagnetic transitions in ferromagnetic compounds associated with a crossing of the CF levels, spin-flop transitions in low-anisotropy systems, and stability of long-period and incommensurate structures owing to the oscillation character of the indirect exchange interactions.

The magnetization curves of hexagonal $HoNi_5$ ($T_C = 5$K) represent an example of large anisotropy of magnetization originating from CF effects (Fig. 4). The theoretical curves are calculated with the use of the perturbing Hamiltonian (Eqn. (3)) and give the following CF parameters (in $Ka_0^n$) : $A_2^0 = -686$, $A_4^0 = -56$, $A_6^0 = 0.3$, and $A_6^6 = +55.0$.

### *2.2 Compounds with a Magnetic 3*d *Sublattice (Unstable 3d Moments)*

The strong field dependence of the magnetic characteristics of the *d*-electron system implies a strong field-induced change of DOS in the vicinity of $\varepsilon_f$. Hence, the *d*-electron subsystem may exhibit a magnetic instability. A first-order-type change of the magnetic state induced by an external magnetic field is known as itinerant electron metamagnetism (IEM), which can occur both from paramagnetic and weakly ferromagnetic ground states (see *Magnetic Units*).

In combination with a magnetic RE, the metamagnetic *d* subsystem can be the cause of a number of intriguing effects, e.g., a first-order-type transition at $T_C$ and its controlled transformation into a second-order type by RE substitutions. By varying the second term in Eqn. (1), conditions for magnetic instability at a low external critical field, $H_{crit}$, can be reached in pseudobinary compounds of the $(R_{1-x}Y_x)_mT_n$ type:

$$H_{crit} = |n_{Rd}x\mu_R - H_M| \qquad (5)$$

where $H_M$ is the critical field in the absence of the intersublattice interaction, $\mu_R$ is the magnetic moment of the R ion, and $x$ is the RE concentration.

### *2.3 Compounds with a Magnetic 3*d *Sublattice (Stable 3*d *Moments)*

Owing to a strong *f–d* exchange interaction, most of the R–3*d* intermetallics are collinear ferrimagnets. They have, therefore, all the attributes that collinear ferrimagnets can show. Figure 5 illustrates the regular change of the magnetic compensation point in the

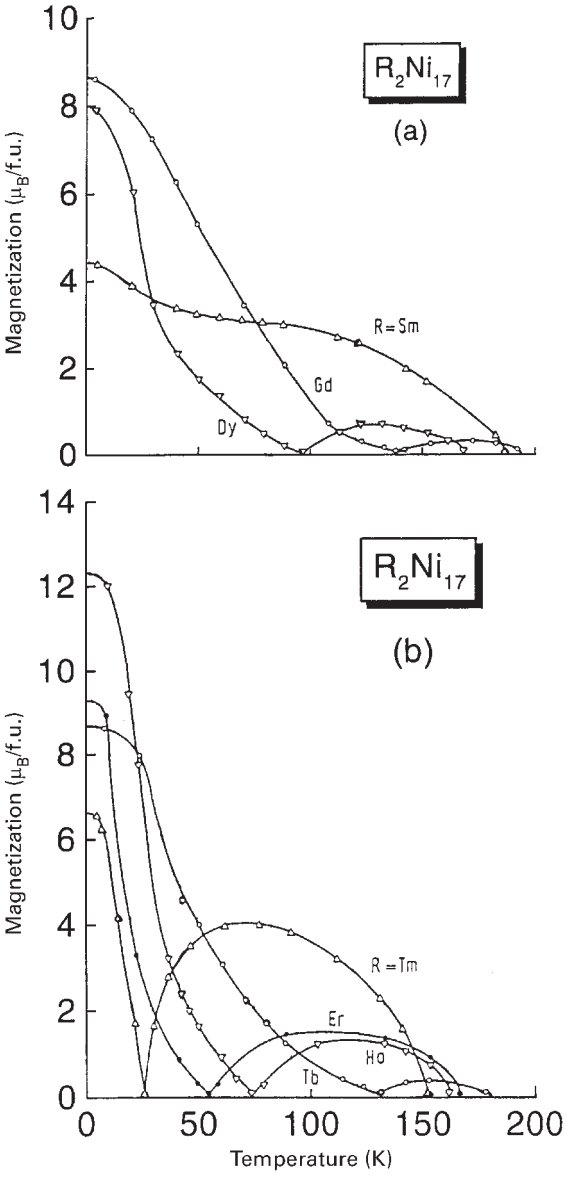

***Figure 5***
Temperature dependence of the spontaneous magnetization of the $R_2Ni_{17}$ compounds (data taken from Burzo *et al.* 1991).

***Table 2***

a PM = Pauli paramagnet.

$R_2Ni_{17}$ series. Within a two-sublattice approximation the basic intra- and intersublattice exchange interactions can be determined by analyzing the temperature dependence of the spontaneous magnetization, paramagnetic susceptibility, and values of $T_C$.

Values of the molecular field, $H_{RT}^{(R)} = n_{RT}M_T$ and $H_{TT} = n_{TT}M_T$, are listed for some Gd–T and Y–T intermetallics in Table 2. They show the role of a magnetic RE in compounds with stable 3*d* sublattices. The *f–f* interaction is weak in these compounds. The strength of the *f–d* interaction for other R–3*d* intermetallics can be estimated from these data using the respective relations between $n_{RT}$ and $I_{RT}$ and considering $I_{RT}$ to be weakly dependent on R within the same $R_mT_n$ stoichiometry (Franse and Radwanski 1993).

A direct determination of the strength of the intersublattice exchange interaction in the ferrimagnetic R–3*d* compounds can be made by the observation of field-induced noncollinear magnetic structures. When the anisotropy effects are neglected, the magnetization process is characterized by a critical field, $H_{C1}$, of a spin-flop transition into a noncollinear magnetic phase, given by:

$$H_{C1} = -n_{RT}|M_R - M_T| \tag{6}$$

The magnetic saturation is then reached at the second critical field:

$$H_{C2} = -n_{RT}(M_R + M_T) \tag{7}$$

In the intermediate state, $H_{C1} < H_{ext} < H_{C2}$, the magnetic configuration is canted, and the net magnetization, $M = |M_R - M_T|\cos\theta$, varies linearly as $M = H_{ext}/n_{RT}$.

In the R–3*d* intermetallics the *d*-electron subsystem is responsible for high $T_C$, whereas the large magnetic anisotropy and the anisotropic magnetostriction are considered mainly due to the RE sublattice. Nevertheless, the contribution of the *d* sublattice to anisotropic interactions is not negligible. In $YCo_5$ the

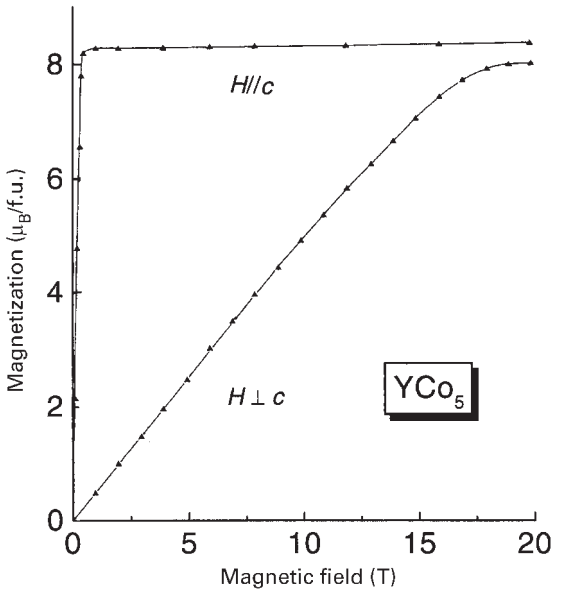

***Figure 6***
Magnetization curves of the hexagonal compound $YCo_5$ at 4.2K for fields applied parallel and perpendicular to the *c*-axis (data taken from Franse and Radwanski 1993).

anisotropy field, $H_A$, reaches about 16.5T (Fig. 6) and the anisotropy constant $K_1 = 47.0\,\text{K f.u.}^{-1}$. These values are comparable with the total anisotropy of highly anisotropic $SmCo_5$: $H_A = 60\text{T}$ and $K_1 = 162.0\text{K f.u.}^{-1}$. In the $RCo_5$ series the cobalt anisotropy explains the existence of temperature-induced spin-reorientation phase transitions. The transitions take place around the temperatures where the absolute value of the R and cobalt sublattice anisotropies are equal (for R = Nd, Tb, Dy, and Ho).

Combination of high $T_C$ with a high anisotropy energy in R–Co intermetallics was the basis for development of a new generation of permanent magnets in the 1960s using $SmCo_5$ as the basic component (see *Rare Earth Magnets: Materials*). In the 1980s ternary compounds based on $Nd_2Fe_{14}B$ were discovered as prospective permanent magnet materials (Buschow 1997). Another instructive example of exploiting for practical purposes the magnetic properties of both the sublattices is provided by the cubic $RFe_2$ intermetallics (Clark 1986). These compounds show large anisotropic magnetostriction originating from the R sublattice, the high $T_C$ being provided by the iron sublattice (see *Magnetoelastic Phenomena*).

Manganese-based intermetallics are characterized by antiferromagnetic Mn–Mn exchange coupling. As a result of the competition with the negative *f–d* exchange along with geometrical frustration (see *Magnetic Systems: Lattice Geometry-originated Frustration*) often present in the manganese crystallographic sublattice, various complex magnetic structures are stabilized in these intermetallics. The noncollinear magnetic structure of $YMn_{12}$ ($T_N = 110\text{K}$) is characterized by a moment arrangement which cancels the effects of possible *f–d* exchange interactions (Ballou 1994). When yttrium is replaced by a magnetic RE, the R sublattice orders only due to the *f–f* exchange interaction, leading to two distinct ordering temperatures. In the $R_6Mn_{23}$ intermetallics, $Y_6Mn_{23}$ has the highest $T_C$ in contrast to the general characteristics found for iron, cobalt, and nickel compounds. The magnetic ordering temperatures in this series are around 450K, which indicates that the magnetism is primarily controlled by the Mn–Mn exchange interactions. The interplay of exchange interactions results in complex magnetic structures.

A magnetic structure with a long-wavelength helical component, strongly distorted by a large local anisotropy, is stabilized in $YMn_2$ through a first-order transition. The existence of long-range order in $RMn_2$ with a magnetic RE depends on several

### *3. Ternary Compounds Containing R and 3*d *Elements*

In the search for novel magnetic compounds the ternary intermetallics containing both RE and T elements provide wide possibilities (Li and Coey 1991, Szytula 1991). Some crystal structures which do not exist in R–T binary phase diagrams can be stabilized by substitutions. An example of this approach is the stoichiometry 1:13 in which only $LaCo_{13}$ ($T_C = 1290$K) crystallizes. The pseudobinary systems $La(Fe_{1-x}Me_x)_{13}$ with Me = Al ($0.08 \leqslant x \leqslant 0.54$) and Si ($0.12 \leqslant x \leqslant 0.19$) have higher iron concentration than the binary $R_2Fe_{17}$. A number of new intermetallics with iron and cobalt have been synthesized with the 1:12 stoichiometry existing only in binary R–Mn systems. Iron-rich $R(Fe_{1-x}Me_x)_{12}$ compounds are known with Me = Al, Si, Ti, V, Cr, Mn, Mo, Ta. Their magnetic properties determined by the R and T sublattices follow in general the regularities established for binary intermetallics with stable 3*d* moments.

The intermetallics with true ternary structure types, $R_mT_nM_p$, form the biggest group. They can also be synthesized with chromium. Another way of generating a ternary structure is by introducing small, interstitial atoms X, such as carbon or nitrogen, into binary compounds, e.g., $R_2Fe_{17}X_{3-\delta}$, which are interstitial ternary phases. Tables 3 and 4 give the crystal structures and Curie temperatures of some of the most studied ternaries with nonmagnetic yttrium. The effect of the magnetic RE sublattice is similar to the case of binary R–3*d* intermetallics.

***Table 4***
Symmetry of the crystal cell and the Curie (Neel) temperatures of R–T–Me intermetallics with ternary structure types formed by nonmagnetic RE (notations as Table 1).

## Alnicos and Hexaferrites

The traditional permanent magnets based on ferrites and Al–Ni–Co alloys are still of substantial commercial importance because of their low cost, although some of their magnetic properties are much inferior

to those of rare earth permanent magnets (see *Rare Earth Magnets: Materials*).

Hard ferrites are ceramic materials that have hexagonal crystal structures. Their formula composition can be represented as $n(\mathrm{MeO}) \cdot m(\mathrm{Fe_2O_3})$, where $n$ and $m$ are natural numbers and Me is a divalent metal. For $n=1$ and $m=6$ one obtains the formula for the so-called M-type ferrites, $\mathrm{MeO} \cdot 6(\mathrm{Fe_2O_3})$, which can also be written as $\mathrm{MeFe_{12}O_{19}}$. The most common M-type ferrites are those where Me = Ba, Sr, or Pb. For $n=3$ and $m=8$ one obtains the formula composition 3(MeO) $8(\mathrm{Fe_2O_3})$. There are usually two (or more) types of divalent metals, Me, involved. The formula composition of the so-called W-type ferrites is therefore most conveniently represented by $\mathrm{Me_1\underline{Me}_2Fe_{16}O_{27}}$. Well-known examples of such compounds are formed with Me = Ba or Sr and Me consisting of Fe(II) and large amounts of magnesium, zinc, copper, nickel, cobalt, or manganese. Most applications deal with the M-type ferrites. For this reason only this type will be discussed below. A more detailed description of both types of hard ferrites can be found in the review by Buschow (1997). (See also *Ferrites*.)

Alnico magnets are composed of iron, cobalt, nickel, aluminum, and various types of additives. These are magnets of metallic character obtained by casting. One of the advantages of alnico alloys is that the melting can be performed in air, although sometimes an apron of inert gas is blown over the melt. Alnico alloys can also be prepared by sintering powders of the raw materials, aluminum being always added in the form of a prealloy with one or more of the other constituent metals.

Compared to hard ferrites, alnico alloys have a rather insignificant magnetocrystalline anisotropy. They derive their magnetic hardness from shape anisotropy. This implies that the microstructure of the alloys is of paramount importance. Alnico magnets can be characterized as fine-particle alloys in which elongated ferromagnetic particles are dispersed in a basically nonmagnetic matrix. This particular microstructure can be attained by a heat treatment leading to the so-called spinodal decomposition of the alloy, which is described briefly below. For more details the reader is referred to the review by McCaig and Clegg (1987).

## 1. Alnico Alloys

It has been mentioned already that alnico alloys are multicomponent systems. All these systems have in common the fact that they form homogeneous solid solutions at high temperatures. At lower temperatures there is a miscibility gap. This miscibility gap leads to phase separation of the homogeneous alloy into two phases, $\alpha_1$ and $\alpha_2$, where $\alpha_1$ represents a strongly ferromagnetic b.c.c. phase rich in cobalt and iron. By contrast, $\alpha_2$ is a nonmagnetic or only weakly ferromagnetic b.c.c. phase rich in aluminum and nickel.

The standard heat treatment of alnico alloys usually consists of a homogenization treatment at about 1250 °C at which temperature the alloys still consist of a single phase ($\alpha$). The alloy is subsequently annealed under conditions corresponding to the region within which decomposition into two phases can occur. This spinodal decomposition of the $\alpha$ phase into the $\alpha_1$ and $\alpha_2$ phases can occur spontaneously, but its rate is diffusion controlled. It can proceed therefore only at relatively high temperatures (above 800 °C). The concentrations of the Fe(Co) atoms show a periodic variation (assumed to be sinusoidal after decomposition has set in) and the amplitude of the composition fluctuations increases with time until the phase separation into $\alpha_1$ and $\alpha_2$ is complete. The whole process takes only a very short time. Depending on the temperature, it can be completed in a matter of seconds or minutes. Formation and subsequent growth of the ferromagnetic $\alpha_1$ particles to their final shape and size occurs almost completely during the spinodal decomposition reaction at 800–850 °C. The driving force for the growth is the decrease of the interfacial energy between the particles ($\alpha_1$) and the matrix ($\alpha_2$).

Optimization of the magnetic properties requires a further tempering treatment generally performed at 600 °C. Its main purpose is to increase the difference in magnetic saturation polarization, $J_s$, between the somewhat elongated Fe(Co)-rich particles and the surrounding matrix (Ni–Al-rich). During this low-temperature anneal a continuous change in the composition takes place owing to diffusion of iron and cobalt atoms into the ferromagnetic particles. The spinodal decomposition alone does not produce a sufficiently large shape anisotropy in the ferromagnetic $\alpha_1$ phase particles. This is because the difference in the saturation magnetizations between the $\alpha_1$ particles and the matrix is relatively modest so that the effective shape anisotropy field of the particles (proportional to $J_s(\alpha_1) - J_s(\alpha_2)$, see below) is also modest in spite of the elongation. The heat treatment at 600 °C is therefore desirable for producing a sufficiently high magnetization anisotropy, which makes it possible to obtain the highest coercivities and the optimum permanent magnet properties. The latter treatment commonly consists of an anneal for several hours.

The interfacial energy of the alloy depends on the crystallographic orientation of the boundaries between the $\alpha_1$ and $\alpha_2$-type particles. Particle growth is therefore anisotropic, and results in an elongation parallel to the $\langle 100 \rangle$ directions. This opens the possibility of obtaining substantial improvements in magnetic properties by controlled cooling of the alloys after the homogenization treatment at about 1200 °C to about 800 °C in the presence of a

saturating magnetic field. This so-called thermomagnetic treatment promotes the formation of anisotropic magnets in which the easy magnetization direction of the grains formed during the spinodal decomposition is parallel to the direction of the magnetic field applied during cooling. The elongation of the particles in the field direction originates from the decrease of the magnetic free energy of the particles when the axis with the lowest demagnetizing factor is along the direction of the applied field. For an oriented single crystal, optimum properties would be obtained when the thermomagnetic field is applied parallel to one of the $\langle 100 \rangle$ directions. In practice, use is made of so-called columnar crystallized alnico alloys instead of expensive single crystals.

It is possible to obtain such highly textured alloys by a grain orienting process preceding the thermomagnetic and tempering treatment. The alloys are then cast in heated or exothermic molds onto water-cooled steel or copper slabs. During solidification of the alloy on the cold surface, the grains tend to grow with their long axis parallel to the $\langle 100 \rangle$ directions, perpendicular to the cold surface. This leads to a semicolumnar alloy in which the columnar axes are parallel to one of the $\langle 100 \rangle$ directions, for instance, parallel to the [001] direction. It has become common practice to refer to alloys manufactured in this way as alnico DG (directed grain). The thermomagnetic treatment for this type of textured alloy is applied with the magnetic field parallel to the elongated direction of the columnar particles, i.e., parallel to the [001] direction. As mentioned above, the magnetic properties in the easy magnetization direction can be further improved by subsequent tempering of the ingots for several hours at about 600 °C.

The relatively high coercivities and remanences in alnico alloys are due to the shape anisotropy associated with the elongated Fe(Co)-rich particles imbedded in the nonferromagnetic matrix. The Stoner–Wohlfarth theory predicts that the coercivity is proportional to the saturation polarization, $J_s$, of the Fe(Co)-rich particles and also proportional to a factor related to the difference in the effective demagnetization factors perpendicular ($N_\zeta$) and parallel ($N_\psi$) to the preferred direction of magnetization in the particles. For magnetization reversal proceeding by uniform rotation, this leads to the formula

$$\mu_0 H_A = \mu_0 H_c = f(\theta)[N_\psi - N_\zeta]J_s \qquad (1)$$

where $f(\theta)$ is an averaging factor that accounts for the various orientations of the preferred axes of the particles with respect to the direction in which $H_c$ is measured.

For an assembly of noninteracting uniaxial single-domain particles arranged at random, $f(\theta)$ has the value 0.5. In highly elongated particles $f(\theta)$ may approach unity. In the case of spheroid particles there is a considerable difference in the demagnetizing factor for particles magnetized perpendicular or parallel to the flat surface of the spheroid. In the limit of an extremely flat and elongated spheroid one has $N_\psi - N_\zeta = 1 - 0 = 1$. Equation (1) shows that the coercivity in such materials may reach an upper limit equal to $H_c = J_s/\mu_0 = M_s$. With $M_s = 1.7\,\mathrm{MAm^{-1}}$, this upper limit becomes $H_c = 1.7\,\mathrm{MAm^{-1}}$. Even for the less favorable case $N_\psi - N_\zeta = 0.5$, the coercivity could become $850\,\mathrm{kAm^{-1}}$. The latter value is much higher than the actual values found in alnico materials, as listed in Table 1.

***Table 1***
Nominal chemical compositions and magnetic properties of cast alnico magnets. The balance of composition is iron for all alloys. Taken from Magnetic Producers Association listing.

| | Composition (wt.%) | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| Type | Al | Ni | Co | Cu | Ti | $BH_{max}$ ($\mathrm{kJm^{-3}}$) | $B_r$ (T) | ${}_JH_c$ ($\mathrm{kAm^{-1}}$) |
| 1 | 12 | 21 | 5 | 3 | | 5.6 | 0.72 | 38.4 |
| 2 | 10 | 19 | 13 | 3 | | 13.6 | 0.75 | 46.4 |
| 3 | 12 | 25 | | 3 | | 10.8 | 0.70 | 40.0 |
| 5 | 8 | 14 | 24 | 3 | | 44.0 | 1.28 | 51.2 |
| 5DG | 8 | 14 | 24 | 3 | | 52.0 | 1.33 | 53.6 |
| 6 | 8 | 16 | 24 | 3 | 1 | 31.2 | 1.05 | 64.0 |
| 8 | 7 | 15 | 35 | 4 | 5 | 42.4 | 0.82 | 148.8 |
| 9 | 7 | 15 | 35 | 4 | 5 | 81.0 | 1.06 | 120.0 |

The comparatively low values of the coercivity in alnico alloys can partly be attributed to the less ideal shape of the thin ferromagnetic particles and also to the fact that the matrix is magnetic to some extent. Considerable experimental evidence exists, showing that the magnetization reversal does not proceed by uniform rotation, as is assumed in the discussion above. Instead magnetization reversal can occur by a complex incoherent mechanism known as "curling" (McCurrie 1982). It can proceed in lower fields, which accounts for the lower observed coercivities.

The various grades of alnico-type alloys are usually referred to by plain numbers, as indicated in the first column of Table 1. More details of the preparation and second quadrant characteristics of these and other alnico-type permanent magnet materials can be found in the review of McCaig and Clegg (1987). One of the favorable magnetic properties of alnico alloys is their very high Curie temperature (700–850 °C). The small negative reversible temperature coefficient, $\delta(B_r) \sim -0.02\%\,\mathrm{K^{-1}}$, leads to excellent flux stability at elevated temperatures. Alnico alloys are chemically and metallurgically very stable. In fact, alnico 5 is the only magnet material that has some long-term utility at temperatures up to 500 °C (see also *Magnets: High-temperature*).

As may be inferred from Table 1, a drawback of alnico alloys is that their coercivity is low in comparison to rare earth-based magnets (see *Rare Earth Magnets: Materials*). Generally, the $B(H)$ curves of alnico magnets in the second quadrant display a nonlinear behavior. This implies a serious disadvantage in device design and dynamic operation. Also it limits the attainable energy products, in spite of the high remanences that are comparable to NdFeB-type magnets (see *Magnets: Sintered*).

Alnico magnets are best suited in applications involving magnetic circuits of high permeance because the maximum energy product corresponds to permeance ratios larger than five. In practice, this implies that alnico magnets have to be comparatively long in the easy direction and that their cross-sectional area has to be relatively small. Alnico magnets are used as sensors and in devices such as electron tubes or watt hour meters (see also *Permanent Magnets: Sensor Applications*). They are also applied in several types of motors and in generators operating at high temperatures.

## 2. Hard Ferrites

The hard magnetic properties of hexaferrites originate from their comparatively large magnetocrystalline anisotropy. Hard ferrites still play a dominant role in the permanent magnet market owing to the low price per unit of available energy, the wide availability of the raw materials, and the high chemical stability.

The so-called M-type ferrites crystallize in the magnetoplumbite structure characterized by close packing of oxygen and Me ions with iron atoms at the interstitial positions. The structure can be described as consisting of cubic blocks with the spinel structure and hexagonal blocks containing the Me ions. There are two formula units $MeFe_{12}O_{19}$ per unit cell and the $Fe^{3+}$ ions are distributed over five nonequivalent crystallographic positions.

An important feature governing the occurrence of hexagonal ferrites is that substitutions are only possible when the rule of charge conservation is obeyed. Two well-known examples demonstrating this charge conservation are $BaFe_{12-2x}Ti_x^{4+}Co_x^{2+}O_{19}$ and $Ba_{1-x}La_x^{3+}Fe_{12-x}Fe_x^{2+}O_{19}$, where iron is trivalent when not indicated differently. A detailed survey of various types of substitution in M-type ferrites is given in the reviews of Kojima (1982) and Kools (1986).

The complicated nature of the magnetic couplings in hard ferrites may be illustrated by means of $BaFe_{12}O_{19}$. Each of the $Fe^{3+}$ ions in this compound carries a large magnetic moment equal to $5\,\mu_B$ at 4.2 K. The moments of the iron ions occupying the same crystallographic position are ferromagnetically aligned. By contrast, the coupling between iron moments belonging to different crystallographic positions is ferromagnetic for some sites and antiferromagnetic for other sites. All these couplings are determined by a superexchange interaction, mediated by the oxygen atoms. As described in detail in the review of Kojima (1982), there is a strong preference for ferromagnetic coupling when the Fe–O–Fe angle approaches 180° and the Fe–O–Fe distance is comparatively small. The resultant spin structure is ferrimagnetic. The partly antiparallel coupling of the iron moments leads to a net moment per unit cell of only $40\,\mu_B$ (at 4.2 K), which is considerably below the value $12 \times 5\,\mu_B = 60\,\mu_B$ expected for ferromagnetic alignment.

The Curie temperatures of hexagonal ferrites are fairly high and fall into the temperature range 700–750 K. Of particular interest is their temperature dependence of the saturation polarization $J_s$. Results for $BaFe_{12}O_{19}$ are shown in Fig. 1. The value of $J_s$ is seen to decrease with increasing temperature much faster than would be expected on the basis of a Brillouin function. This is the main reason that these materials have a relatively low value of $J_s$ at room temperature, much lower than the value corresponding to the saturation moment of $40\,\mu_B$ per formula unit mentioned above. The temperature coefficient of $J_s$ is fairly high ($-0.2 \times K^{-1}$), being

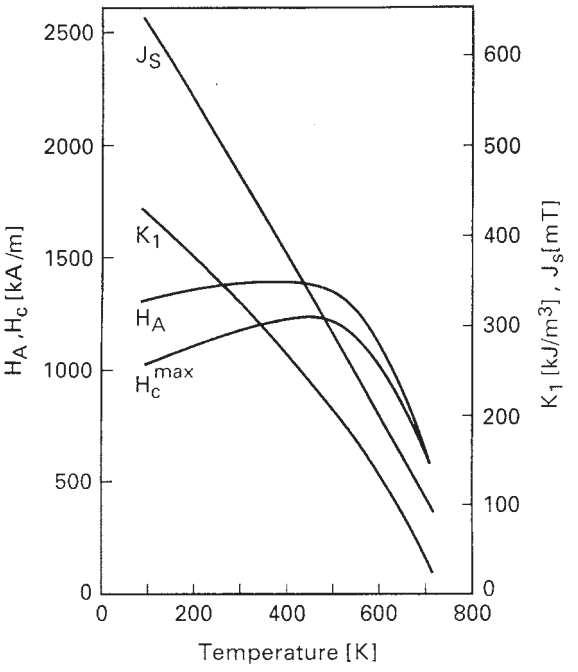

***Figure 1***
Temperature dependence of saturation polarization, $J_s$, anisotropy constant, $K_1$, anisotropy field, $H_A$, and maximum attainable coercivity, $H_c^{max}$, for M-type barium ferrite (after Kools 1986).

roughly an order of magnitude higher than that found in alnico magnets.

The magnetocrystalline anisotropy in hard ferrites is generally considered as arising from spin–orbit coupling. The anisotropy energy is characterized by a comparatively high positive value of the anisotropy constant $K_1$ (for a definition, see *Hard Magnetic Materials, Basic Principles of*), higher order constants ($K_2$, $K_3$, etc.) being negligibly small. This corresponds to an easy magnetization direction along the *c*-axis.

The temperature dependence of $K_1$ for $BaFe_{12}O_{19}$ is included in Fig. 1, together with the temperature dependence of the anisotropy field $H_A = 2K_1/J_s$. The magnetic polarization, $J_s$, decreases more strongly with temperature than $K_1$ in the lower temperature range. This leads to the rather peculiar case that $H_A$ first (slightly) increases with temperature before it eventually decreases. A similar temperature dependence is expected for the maximum attainable coercivity, $H_c^{max}$.

Compounds of M-type ferrites are usually formed by calcination of appropriate mixtures of $Fe_2O_3$, $BaCO_3$, or $SrCO_3$ and minor additives at high temperatures (about 1250 °C). After this so-called prefiring process the resulting product is milled to very fine particles (below 1 μm), which is usually performed in water. The slurry is dried by heating in ovens or by spray drying. After mixing the dried ferrite powders with lubricants and small amounts of additives the material is compacted by pressing. The pressed magnet bodies are sintered in air at high temperatures. This operation is commonly indicated as firing. The magnets obtained in this way are isotropic, meaning that the orientation of the powder particles has a random distribution.

Anisotropic sintered magnets can be manufactured by wet pressing and sintering. Compound formation proceeds in the same way during prefiring as described above. Contrary to dry pressing, a different choice of additives ($SiO_2$ and/or $B_2O_3$) is used in order to better control grain growth and densification. The hard, prefired material is wet milled in water using steel balls. The result of this process is a thick suspension, the so-called slurry. The fine powder particles (preferably single crystals) have sufficient mobility in this slurry to align themselves along the preferred magnetization direction in an external field during wet pressing. The pressed compacts are first dried and then sintered in air at about 1250 °C. Considerable anisotropic shrinkage occurs during the sintering process. Therefore, the pole faces of the sintered magnet bodies have to be ground afterwards when accurate dimensional control of the magnets is desired. More details regarding general processing can be found in the review of Stäblein (1982). Several optimization procedures for reaching higher performances have been described by Horiishi and Yamamoto (1992), Taguchi *et al.* (1992), and Harada (1992).

Mechanical alloying has also been proposed as a method to produce ferrite magnets of high coercivities (Ding *et al.* 1995). The starting material is $BaO_2 + 6Fe_2O_3$. After high-energy ball milling the material is annealed at temperatures between 750 °C and 1000 °C, resulting in coercivities close to 450 $kAm^{-1}$.

Castro *et al.* (1996) have prepared nanostructured particles of barium hexaferrite by means of the combustion method, starting from a solution of the metal nitrates and using a reducing agent (tetraformal trisazide or oxalic acid dihydrazide) as a fuel. For the submicrometer-sized particles of $BaFe_{12}O_{19}$ thus prepared, coercivities of 425 $kAm^{-1}$ and magnetizations of 57.8 $Am^2kg^{-1}$ are obtained.

The coercivity in ferrite magnets is usually described in terms of nonuniform magnetization reversal. It has been mentioned briefly above that the main purpose of some additives is to control the microstructure of the ultimate magnets by reducing the grain growth during prefiring as well as during sintering. For describing the relationship between coercivity and microstructural parameters, Kools (1986) uses the expression

$$_JH_c = \alpha H_A - N_{eff}(J_s + B_r)/\mu_0 \qquad (2)$$

where $\alpha$ depends on the grain size and $N_{eff}$ depends on the grain shape (see also *Coercivity Mechanisms*). Also the fraction of the ferrite phase present in the magnet and the degree of alignment are important since they largely determine the value of the remanence $B_r$. For more details the reader is referred to the reviews of Kools (1986) and McCaig and Clegg (1987). A most helpful tool in studying the coercivity mechanism in permanent magnet materials is the magnetic aftereffect (Givord *et al.* 1990). From a study of the field and temperature dependence of the magnetic aftereffect constant in M-type strontium and barium ferrite magnets, it was concluded that the coercivity mechanism (see also *Coercivity Mechanisms*) in these sintered magnets is of the nucleation type.

Hard ferrite magnets can be classified as low-cost, low-performance magnets. Their application is widespread, including anisotropic segments for electric motors, anisotropic rings for loudspeakers, and large anisotropic blocks for ore separators. Applications in which the temperature can become substantially higher than room temperature may profit from the fact that the ferrite magnets have a high chemical stability. Another advantage is that they are electrical insulators. Furthermore, the coercivity increases rather than decreases with temperature. This is again beneficial for high-temperature applications, although the temperature coefficients of coercivity and remanence are undesirably high. The most prominent disadvantage of magnets made of hard ferrites is their low $(BH)_{max}$ value, remaining below 30 $kJm^{-3}$ even for anisotropic sintered magnets. This generally

requires magnets of comparatively large size, excluding application of magnetic devices in which weight and space are at a premium. The unequalled low cost of ferrite magnets is because of the very inexpensive raw materials.

## Amorphous and Nanocrystalline Materials

Amorphous metals (often also referred to as metallic glasses) are characterized by the absence of atomic long-range order and reveal only a short-range order (SRO) with a structural correlation length in the order of atomic distances (O'Handley 1987). Nanocrystalline materials have a limited long-range order (which is the same as the short-range order) with a structural correlation length (the grain size) on the nanometer scale, typically 5–20 nm.

Regarding their magnetic properties, the key point for amorphous and nanocrystalline 3*d* metals is that their structural correlation length $D$ in many cases is smaller than the ferromagnetic correlation length $L_0 = \sqrt{A/K_1}$, which is determined by the exchange interaction constant $A$ and the local magnetocrystalline anisotropy $K_1$. $L_0$ is closely related to the domain wall width and defines the minimum length scale over which the direction of the magnetization can vary appreciably. For iron-based alloys, as an example, typical values are $L_0 = 20$–$40$ nm.

As a consequence, if $D < L_0$, the magnetization cannot follow the randomly oriented magnetic easy axis defined by the SRO, but is increasingly forced to align parallel by exchange interaction. Thus, the anisotropy effective for the magnetization process is an average over the randomly fluctuating local anisotropies scaling down like $(D/L_0)^6$ and, hence, is considerably reduced in magnitude (see *Nanocrystalline Materials: Magnetism*).

As a result, amorphous and many nanocrystalline alloys reveal virtually no or only a very small macroscopic magnetocrystalline anisotropy which is the precondition for superior soft magnetic behavior as observed in these material classes.

As an example, Fig. 1 summarizes the typical variation of the coercivity, $H_c$, over the whole range of structural correlation lengths starting from atomic distances in amorphous alloys over grain sizes, $D$, in the nanometer regime up to macroscopic grain sizes—the permeability shows an analogous behavior being essentially inversely proportional to $H_c$ (Herzer 1990, 1997). The $1/D$-dependence of coercivity for large grain sizes (Pfeifer and Radeloff 1980) reflects the conventional rule that good soft magnetic properties require very large grains ($D > 100\,\mu$m). Thus, the reduction of particle size to the regime of the domain wall width increases the coercivity towards a maximum controlled by the anisotropies present. Lowest coercivities, however, are again found for structural correlation lengths smaller than the domain wall width like in amorphous alloys ("grain size" of the order of atomic distances) and in nanocrystalline alloys for grain sizes $D < 20$ nm.

An interesting consequence of the exchange softening mechanism at small structural correlation lengths is that these materials simultaneously combine magnetic soft and mechanical hard behavior (like high yield strength and high hardness) unlike conventional soft magnetic crystalline alloys.

Apart from a low magnetocrystalline anisotropy superior soft magnetic behavior additionally requires a low or vanishing magnetostriction, $\lambda_s$, which

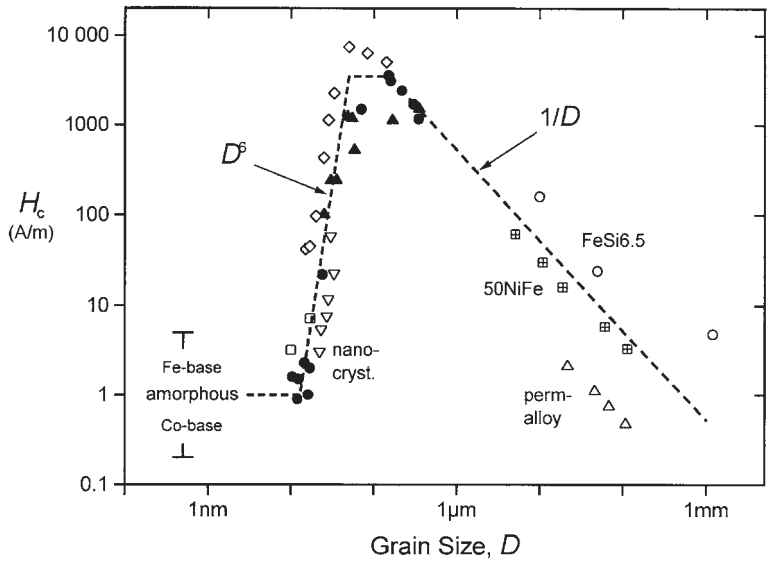

***Figure 1***
Coercivity, $H_c$, vs. grain size, $D$, for various soft magnetic metallic alloys: Fe–Nb–Si–B (▲), Fe–Cu–Nb–Si–B (●), Fe–Cu–V–Si–B (▽), Fe–Zr–B (□), Fe–Co–Zr (◇), NiFe-alloys (⊞ and △) and FeSi6.5 wt% (○).

reduces magnetoelastic anisotropies arising from internal or external mechanical stresses. While magnetocrystalline anisotropy (characterized by a second rank tensor) is randomly averaged out at small structural correlation lengths, magnetostriction (characterized by a fourth rank tensor) is not. Thus, amorphous and nanocrystalline magnetic materials, except from certain compositional ranges, generally exhibit magnetostriction and, accordingly are grouped into magnetostrictive and near-zero magnetostrictive alloys. The latter are of particular interest for application since they reveal highly reproducible and superior soft magnetic properties comparable or even better than those of permalloys. Still, the exchange softening at small structural correlation lengths results in an isotropic magnetostrictive behavior, i.e., it can be described by a single coefficient—the saturation magnetostriction $\lambda_s$. As a consequence, zero saturation magnetostriction really results in stress-insensitivity of the magnetic properties, unlike large-grained crystalline systems where an average zero saturation magnetostriction does not generally imply stress-insensitivity of the hysteresis loop.

Fig. 2 gives an example for the typical magnetic properties of near-zero magnetostrictive amorphous, nanocrystalline, and crystalline soft magnetic alloys. The clear advantage of nanocrystalline alloys is that they combine the highest achievable permeabilities (up to $\mu_i \approx 200 \times 10^3$) and the simultaneously highest saturation magnetization of typically $J_s \approx 1.2$–$1.3$ T. The benefit of amorphous materials is that they allow a much wider range of property variation by alloying.

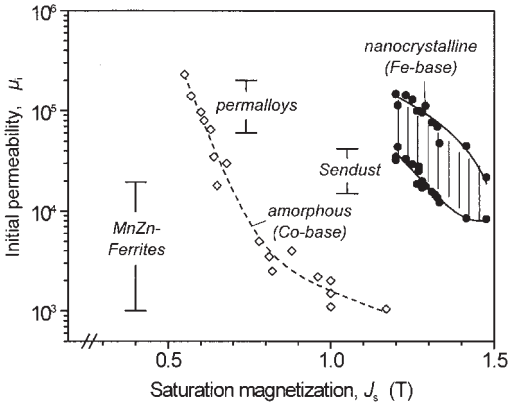

***Figure 2***
Typical initial permeabilities and saturation magnetization for near-zero magnetostrictive, soft magnetic materials with flat-type hysteresis loop.

Thus, the initial permeability of near-zero magnetostrictive amorphous alloys can be varied continuously by more than two orders of magnitude from about $\mu_i \approx 1 \times 10^3$ up to $\mu_i \approx 300 \times 10^3$.

Due to the absence of an appreciable magnetocrystalline anisotropy both amorphous and nanocrystalline materials are very susceptible to magnetic field annealing which induces a uniaxial anisotropy with an easy axis parallel to the direction of the magnetic field applied during the heat treatment.

Indeed, field induced anisotropies have a tremendous practical impact for tailoring the soft magnetic properties according to the demands of various applications. As an example, Fig. 3 shows the hysteresis loop and the impedance permeability for various heat treatments with and without magnetic field. Thus, almost perfect rectangular or flat shaped hysteresis loops can be obtained after annealing in a magnetic field along or transverse to the magnetic path in the application. Conventional annealing without magnetic field typically results in a more round shaped hysteresis loop. Even in this case uniaxial anisotropies are induced although with an angular distribution of directions which is defined by the domain structure during annealing. The induction of a magnetic anisotropy along the axis of the spontaneous magnetization is related to directional atomic pair ordering along this axis, which minimizes spin-orbit coupling energy. The induced anisotropy energy $K_u$ directly controls the soft magnetic properties. Thus, for example, transverse field annealing results in a permeability $\mu$ which is constant up to ferromagnetic saturation and inversely proportional to $K_u$, i.e., $\mu = J_s^2/(2\,\mu_0 K_u)$. For a rectangular loop, for example, low induced anisotropies facilitate domain refinement which results in good dynamic properties like, e.g., reduced anomalous eddy current losses. Moreover, the mechanisms responsible for anisotropy formation also control the thermal aging of the material. Hence, good thermal stability of the magnetic properties requires a possibly high activation energy and slow kinetics of anisotropy formation.

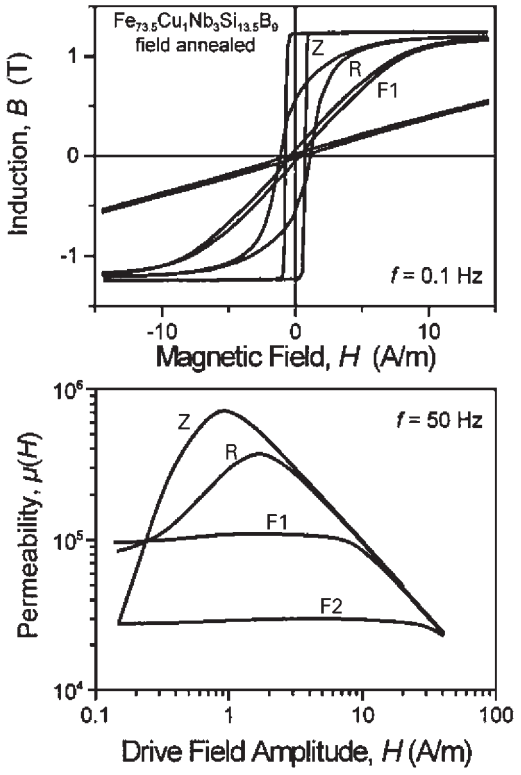

***Figure 3***
Typical d.c.-hysteresis loops and 50 Hz permeability after various forms of field annealing. The material shown is nanocrystalline $Fe_{73.5}Cu_1Nb_3Si_{13.5}B_9$ annealed for 1 h at 540 °C without (R) and with a magnetic field applied parallel (Z) and transverse (F2; $K_u \approx 20\,Jm^{-3}$, $\mu \approx 30 \times 10^3$) to the magnetic path. Sample F1 ($K_u \approx 6\,Jm^{-3}$, $\mu \approx 100 \times 10^3$) was first crystallized at 540 °C and subsequently transverse field annealed at 350 °C.

Finally, both amorphous and nanocrystalline alloys generally reveal low losses and a high permeability even at elevated frequencies up to several hundred kilohertz. The favorable high-frequency behavior, comparable to or even better than in Mn–Zn ferrites (see *Ferrites*), is essentially related (i) to the thin ribbon gauge of $d \approx 20\,\mu m$ inherent to the production technique, and (ii) to a relatively high electrical resistivity of typically $\rho \approx 100$–$130\,\mu\Omega$ cm, which both reduce eddy current losses. In particular, low remanence ratio materials show the best dynamic properties due to the homogeneous change of magnetization by rotation, which avoids *anomalous* eddy current losses. Lowest losses are hereby found in near zero-magnetostrictive alloys due to (i) their low coercivity which minimizes the hysteresis losses and (ii) to the absence of magnetoelastic resonances, which in magnetostrictive alloys can produce very significant excess losses.

## 1. Preparation and Alloy Systems

Amorphous materials can be principally synthesized by a variety of techniques such as rapid solidification from the liquid state, mechanical alloying, plasma processing, and vapor deposition. For soft magnetic applications the material is mostly produced by rapid solidification from the melt (Cahn 1993) as thin ribbons usually about 20–30 μm thick and about 1–100 mm wide.

Nanocrystalline soft magnetic alloys, actually, are also cast as an amorphous ribbon which is subsequently annealed above its crystallization temperature to produce the nanocrystalline state. Actually, controlled crystallization from the amorphous state seems to be the only method presently available to synthesize nanocrystalline alloys with attractive soft magnetic properties.

The range of compositions which can be prepared in the glassy state by rapid solidification from the melt is wide. Typical compositions are given by the formula $T_{70-90}X_{10-30}$ (at.%). Here, T stands for a practically arbitrary combination of transition metals

which, for magnetic applications, are of course given by Fe, Co, and Ni. The letter X refers to metalloid atoms like Si and B and/or refractory metals like Nb, Mo, Zr, Hf, etc. These "nonmagnetic" additions are necessary for glass formation and in order to stabilize the amorphous structure.

The most common compositions for soft magnetic applications either in the amorphous or in the nanocrystalline state are metal-metalloid based (Fe,Co, Ni)-(Si,B) alloys with small additions of manganese, niobium, carbon, and, for the nanocrystalline case, copper. This alloy system has a good glass forming ability and is easily accessible by rapid solidification as a thin ribbon in large-scale production.

The final alloy design is largely determined by (i) the desired magnetic properties, (ii) good glass forming ability, (iii) thermal stability, and, for the nanocrystalline alloys (iv), a well-defined crystallization behavior.

## 2. *Amorphous Alloys*

The saturation magnetization $J_s$ is the highest in the iron-rich alloys and decreases with increasing nickel and cobalt content. It is generally lower than in crystalline alloys due to the nonmagnetic additions of silicon and boron necessary for glass formation. The $J_s$ maximum observed for crystalline Fe–Co alloys is only weakly developed and shifted to the iron-rich side.

For the iron-rich alloys the saturation magnetostriction $\lambda_s$ is positive, typically $\lambda_s \approx 20$–$40$ ppm, while for the cobalt-rich alloys, $\lambda_s$ is negative, typically $\lambda_s \approx -5$ to $-3$ ppm (Fig. 4). The decrease of $\lambda_s$ with increasing nickel content is correlated to the simultaneous decrease of the saturation magnetization ($|\lambda_s| \propto J_s^2$). Thus, the apparent disappearance of $\lambda_s$ at high nickel contents (Fig. 4) occurs because the system becomes paramagnetic. A true zero of magnetostriction only occurs on the cobalt-rich side of Co–Fe (Fujimori *et al.* 1976) or Co–Mn (Hilzinger and Kunz 1980) based systems at iron or manganese concentrations of about 3–8 at.% (Fig. 4).

According to their magnetostriction, amorphous materials are commonly divided into two major groups: iron-based and cobalt-based alloys. The iron-based amorphous alloys are based on inexpensive raw materials, have a high saturation magnetization, but their magnetostriction is large which limits their soft magnetic behavior. On the other hand, cobalt-based amorphous alloys with small additions of iron or manganese reveal nearly zero magnetostriction. Accordingly, they can offer a superior soft magnetic behavior, but their saturation magnetization is considerably lower than that of the iron-based materials.

Apart from the metallic components, the magnetic properties are also significantly influenced by the metalloid-contents. Fig. 5 gives an example for near-zero magnetostrictive cobalt-based alloys. For example, a saturation magnetization up to 1.2 T can be achieved in cobalt-based alloys by reducing the metalloid contents below 20 at.%. However, these high $J_s$ alloys are close to the boundary of glass formation and reveal a low crystallization temperature, $T_x$, which at the same time diminishes the thermal stability of the magnetic properties.

Fig. 6 shows the characteristic features of field-induced anisotropies in amorphous metals which can

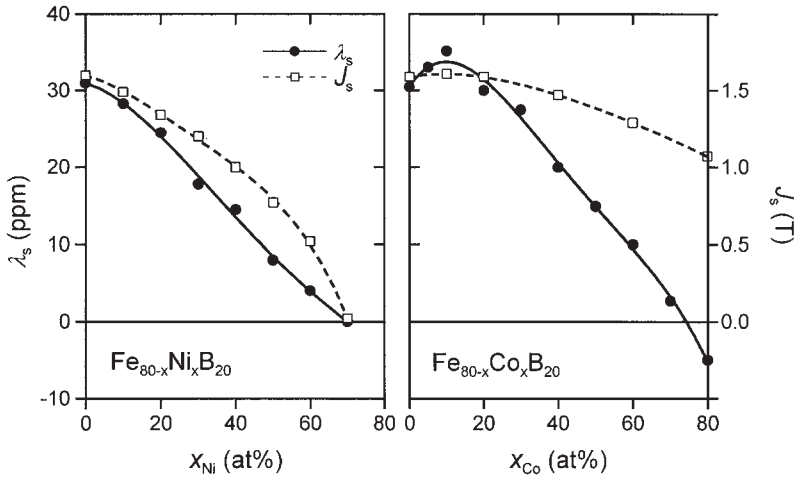

***Figure 4***
Saturation magnetostriction, $\lambda_s$, (——) and saturation magnetization, $J_s$, (- - -) in amorphous Fe–Ni and Fe–Co-base alloys (after Boll *et al.* 1983 and references cited therein).

be summarized as follows (Fujimori 1983). (i) An anisotropy is only formed by annealing below the Curie temperature $T_c$, i.e., the driving forces are magnetic interactions. The equilibrium value of $K_u$ achieved after infinite time of annealing approximately scales with the square of the saturation magnetization at the given annealing temperature. (ii) The anisotropy formation is governed by thermal activation. At lower annealing temperatures the kinetics are too slow to reach the equilibrium value, which results in the typical maximum of $K_u$ at a certain annealing temperature. (iii) Alloys with two or more different kinds of magnetic metallic elements show considerably stronger field-induced anisotropies than amorphous alloys with only one transition element.

Principally any level of $K_u$ can be adjusted by appropriate choice of the annealing temperature and time. The annealing conditions which can be realized in practice, however, only allow a $K_u$ variation of about a factor 3–5 around the maximum in the $K_u$ vs. $T_a$ curve in Fig. 6. The latter is determined by the alloy composition. Accordingly, low values of $K_u$, i.e., high permeabilities, are only achievable in alloys with preferably only one magnetic transition metal and a possibly low Curie temperature, which at the same time means a low saturation magnetization (Fig. 5). Thus, highest permeabilities of $\mu_i > 100 \times 10^3$ can only be obtained in cobalt-base alloys with $J_s < 0.6\,T$ and $T_c < 250\,^\circ C$ and an accordingly high metalloid content.

The spectrum of amorphous alloys used in application is wide and ranges from inexpensive iron-base or Fe–Ni-base alloys over Fe–Co–Ni-alloys to the extremely soft magnetic near-zero magnetostrictive cobalt-base alloys. Accordingly wide is the spectrum of magnetic properties. Permeability, for example, can be adjusted from less than one thousand to several hundred thousand with the help of induced anisotropies and proper alloy design.

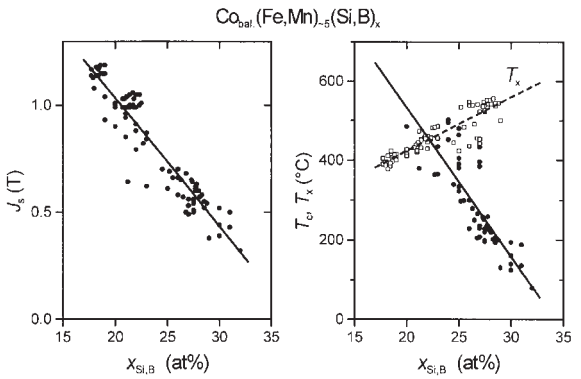

***Figure 5***

## 3. *Nanocrystalline Alloys*

The first example of soft magnetic behavior in the nanocrystalline state was given by O'Handley *et al.* (1985) for a devitrified glassy *cobalt* base alloy. However, the soft magnetic properties were inferior to the

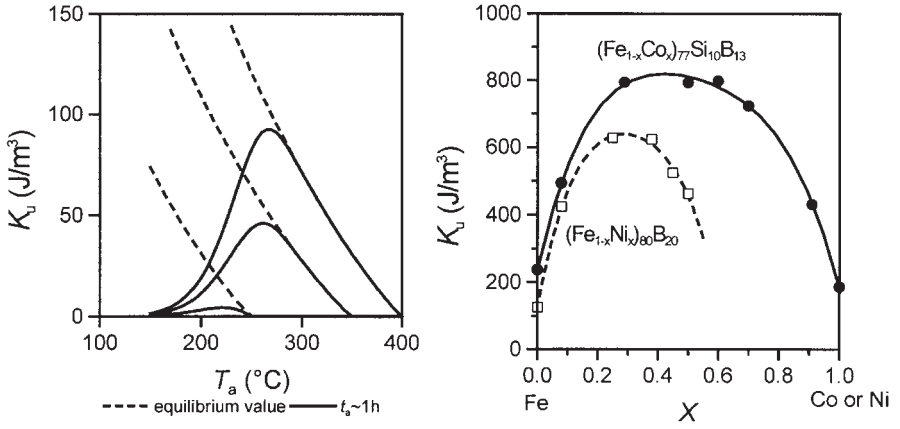

***Figure 6***
Dependence of the field induced anisotropy, $K_u$, in amorphous alloys on the annealing temperature, $T_a$, and the composition. The $K_u$ vs. $T_a$ curves on the left are a sketch of the typical behavior in near-zero magnetostrictive Co-base alloys with different Curie temperatures. The figure on the right shows the equilibrium $K_u$ of Fe–Ni-base and Fe–Co-base alloys annealed at 225 °C and 300 °C, respectively (after Fujimori 1983).

amorphous state and, thus, not very attractive, which actually seems to be typical for cobalt-based nanocrystalline materials. Indeed, the most promising properties so far have been found in iron-based alloys. This is related to the fact that the magnetostriction in iron-based alloys can be virtually reduced to zero by nanocrystallization. Another aspect of iron-based nanocrystalline materials is the low raw material costs of iron, which ultimately makes this system highly attractive for application.

The crystallization of conventional metallic glasses optimized for soft magnetic applications usually yields a relatively coarse grained microstructure of several crystalline phases with grain sizes of about 0.1–1 μm and, correspondingly, deteriorates the soft magnetic properties. A typical nanocrystalline structure with good soft magnetic properties occurs only if the amorphous state is crystallized by the primary crystallization of b.c.c. iron, before intermetallic phases like Fe–B compounds may be formed. Both an extremely high nucleation rate and slow growth of the crystalline precipitates are needed to obtain a nanoscaled microstructure. Such crystallization characteristics seem to be rather the exception than the rule and can be obtained only with a particular alloy design.

The optimum alloy composition originally proposed (Yoshizawa *et al*. 1988) and subsequently not much changed is $Fe_{73.5}Cu_1Nb_3Si_{13.5}B_9$ (at.%) and can be considered as a typical Fe–Si–B metallic glass composition with small additions of copper and niobium (or other group IV to VI elements). The combined addition of copper and niobium is essentially responsible for the formation of the particular nanocrystalline structure: copper enhances the nucleation of the b.c.c. grains while niobium impedes grain coarsening and, at the same time, inhibits the formation of boride compounds.

The nanocrystalline state is achieved by annealing above the first crystallization temperature, typically for 1 h at temperatures between about 500 and 600 °C which leads to primary crystallization of b.c.c. iron. The resulting microstructure is characterized by randomly oriented, ultrafine grains of b.c.c. Fe–Si-20 at.% with typical grain sizes of 10–12 nm embedded in a residual amorphous matrix which occupies about 20–30% of the volume and separates the crystallites at a distance of about 1–2 nm. These features are the basis for the excellent soft magnetic properties indicated by the high values of the initial permeability of about $10^5$ and correspondingly low coercivities of less than 1 $Am^{-1}$. The magnetic properties and the underlying microstructure are rather insensitive to the precise annealing conditions within a wide range of annealing temperatures, $T_a$, of about $\Delta T_a \approx 50$–100 °C. They develop in a relatively short period of time (about 10–15 min) and do not much alter even after prolonged heat treatment of several hours. Only annealing at more elevated temperatures above 600 °C leads to the precipitation of small fractions of boride compounds like $Fe_2B$ or $Fe_3B$ with typical dimensions of 50–100 nm, while the ultrafine grain structure of b.c.c. Fe–Si still persists. Further increase of the annealing temperature above 700 °C, finally yields grain coarsening. Both the formation of Fe-borides and grain coarsening deteriorates the soft magnetic properties significantly (Herzer 1997).

The small grain size in $Fe_{73.5}Cu_1Nb_3Si_{13.5}B_9$ or similar alloy compositions is decisive for its soft magnetic behavior, but is only a prerequisite. The actual highlight of the nanocrystalline iron-base alloys is that the phases formed on crystallization simultaneously can lead to low or vanishing saturation magnetostriction, $\lambda_s$. Fig. 7 summarizes the

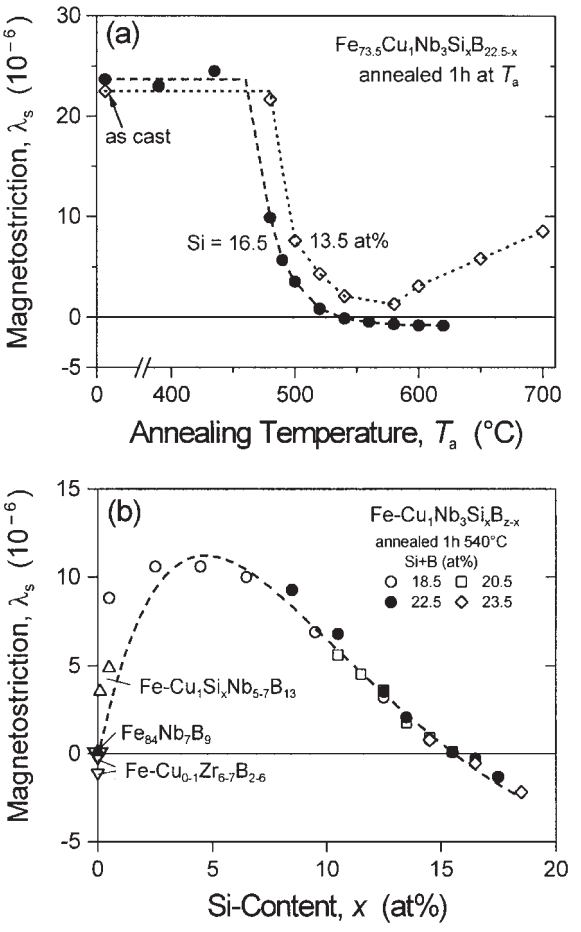

***Figure 7***
Saturation magnetostriction, $\lambda_s$, of Fe–Cu–Nb–Si–B alloys: (a) influence of the annealing temperature, $T_a$, and (b) influence of the Si-content in the nanocrystalline state. The figure includes the data for Fe–Nb–B (▲) and Fe–(Cu)–Zr–B alloys (▽) from Suzuki *et al*. (1991).

situation in the Fe–Cu–Nb–Si–B system. It is the decrease of $\lambda_s$ that is ultimately responsible for the simultaneous increase of the initial permeability upon nanocrystallization. Otherwise, the soft magnetic properties would be only comparable to that of stress-relieved amorphous iron-based alloys.

While $\lambda_s$ is high and fairly independent of the composition in the amorphous state it depends sensitively on the silicon content in the nanocrystalline state. Zeros of magnetostriction are realized at low silicon concentrations in Fe–Zr–B alloys (Suzuki *et al.* 1991) and at high silicon concentrations around 16 at.% in the Fe–Cu–Nb–Si–B system. The detailed behavior of $\lambda_s$ can be understood from the balance of magnetostriction among the structural phases present in the nanocrystalline state (see *Nanocrystalline Materials: Magnetism*, Herzer 1997).

A major driving force in the search for further alloy compositions was to increase the saturation magnetization towards the value of pure α-iron while maintaining near-zero magnetostriction. The major hindrance towards such high iron content alloys results from the requirement of a good glass forming ability. Thus, for the sake of a good glass forming ability, the silicon content in the Fe–Cu–Nb–Si–B alloys cannot be simply reduced without substituting other glass formers for it. A relatively low boron content is a further requirement in order to inhibit the formation of Fe–B compounds, which would degrade the soft magnetic properties (Herzer 1997).

Ultimately, the only way to reduce the silicon content is to add refractory metals with large atoms and low *d*-electron concentrations, i.e., particularly zirconium, hafnium, niobium, and tantalum.

In this way the second family of near-zero magnetostrictive, nanocrystalline alloys has been established which is based on $Fe_{\sim 84-91}(Cu_1)$–$(Zr,Nb)_{\sim 7}B_{2-9}$ and exhibits a very high saturation magnetization up to 1.7 T (Suzuki *et al.* 1991). Although the outstanding soft magnetic properties of the original Fe–Cu–Nb–Si–B alloys could not be reached up to now, the soft magnetic properties are better than those of amorphous iron-base alloys or comparable to those of crystalline 50–60% Ni–Fe but combined with low magnetostriction and lower losses. These alloys and derivatives are currently still under intensive research. Their major drawback is a lower glass forming ability and/or castability due to the oxygen reactivity of the zirconium addition. Thus, these alloys presently are still restricted to the laboratory scale, since they require a far more sophisticated production technology than the more conventional Fe–Si–B compositions.

It should be finally mentioned that the spectrum of accessible nanocrystalline systems can still be considerably expanded by thin film sputtering techniques. One example is hafnium carbide dispersed nanocrystalline Fe–Hf–C films crystallized from the amorphous state (Hasegawa *et al.* 1993). They combine good thermal stability, good high frequency properties in the megahertz range with low magnetostriction and high saturation induction of $J_s = 1.7$ T which can be even increased up to 2.0 T by multilayering these films with iron. Another example is (Fe,Co,Ni)–(Si,B)–(F,O,N) granular alloy films (Fujimori 1995) which at a saturation induction of about 1 T possess a uniquely high electrical resistivity of $10^3$–$10^4$ μΩcm.

Similar to amorphous alloys, the final adjustment of the soft magnetic properties is achieved with uniaxial anisotropies induced by magnetic field annealing. The principal features of anisotropy formation in nanocrystalline alloys are summarized in Fig. 8.

If the material is nanocrystallized first without applied field and subsequently field annealed at lower temperatures, the resulting anisotropy $K_u$ depends on the annealing temperature, $T_a$, and time, $t_a$, and behaves similar to the amorphous case. However, the kinetics are considerably slower (Yoshizawa and

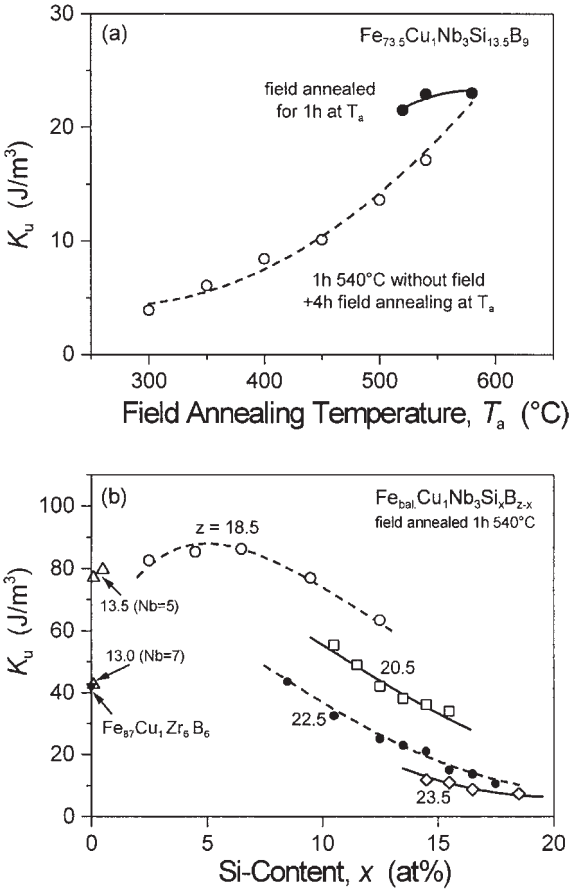

***Figure 8***
Field induced anisotropy, $K_u$, in nanocrystalline Fe–Cu–Nb–Si–B alloys as a function of (a) the annealing conditions and (b) the composition.

Yamauchi 1990) which shifts the maximum of the $K_u$ vs. $T_a$ curve to considerably higher annealing temperatures. This circumstance allows to tailor lowest induced anisotropies, i.e., highest permeabilities but with a significantly better thermal stability than in amorphous alloys, or even in permalloys.

If the field annealing is performed during nanocrystallization, the induced anisotropy reaches a maximum value which is relatively insensitive to the precise annealing conditions and, thus, corresponds to the equilibrium value characteristic for the alloy composition.

The Curie temperature of the b.c.c. grains ranges from about $T_c = 600$–$750\,^{\circ}C$ (depending on composition) and is considerably higher than the $T_c$ of the amorphous matrix (200–400 °C). Thus, the anisotropy induced by a magnetic field applied during nanocrystallization at 540 °C primarily originates from the b.c.c. grains (Herzer 1994). Accordingly, the induced anisotropy in nanocrystalline Fe–Cu–Nb–Si–B alloys is mainly determined by the silicon content and the fraction, $v_{cr}$, of the b.c.c. grains.

A more detailed analysis (Herzer 1994) shows that the dependence of $K_u/v_{cr}$ on the silicon content in the b.c.c. grains is comparable with that observed for conventional $\alpha$-FeSi single crystals where the formation of the field induced anisotropy has been proposed to arise from the directional ordering of silicon atom pairs. The decrease of $K_u$ with increasing silicon content, in terms of (Néel's 1954) theory, can be related to the formation of a $DO_3$ superlattice structure for silicon concentrations above about 10 at.%: for completely ordered $Fe_3Si$, the lattice sites for the iron and silicon atoms are entirely determined by chemical interactions, allowing no degree of freedom for an orientational order. However, for a composition $Fe_{1-y}Si_y$ with less than 25 at.% Si a complete $DO_3$ order cannot be reached and iron atoms will occupy the vacant sites in the silicon sublattice. The way the latter is done provides the necessary degrees of freedom for an orientational order.

The low $K_u$-level due to the superlattice structure at higher silicon contents is an additional key factor for the high initial permeabilities which can be achieved in these alloys despite their high Curie temperature and their high saturation induction.

In contrast to amorphous alloys the spectrum of nanocrystalline alloys presently used in soft magnetic application is relatively narrow and essentially limited to the low magnetostrictive compositions around $Fe_{bal}Cu_1Nb_3Si_{13-16}B_{6-9}$ with a saturation magnetization of 1.2–1.3 T. The initial permeability in these alloys can be adjusted in a range between $\mu_i \approx 20 \times 10^3$ and $\mu_i \approx 200 \times 10^3$ by magnetic field annealing.

## 4. Conclusions

In summary, the best static and dynamic soft magnetic properties are presently achieved as well in amorphous cobalt-base as in nanocrystalline iron-base alloys. Both alloy systems reveal isotropic near-zero magnetostriction. Apart from its higher saturation induction, however, the nanocrystalline material shows a much better thermal stability of its magnetic properties than its amorphous counterpart and, additionally, is based on the inexpensive raw materials iron and silicon. Accordingly, nanocrystalline alloys provide an invaluable supplement to the existing soft magnetic materials manifested in a steadily increasing number of applications. Yet, the variability of their soft magnetic properties, as well as their form of delivery so far, is still restricted compared to amorphous or other soft magnetic materials. Thus, amorphous alloys may reveal good soft magnetic properties already in the as quenched state or after moderate annealing. They can be delivered as a semi-finished, ductile product useful for, e.g., flexible magnetic screening or for sensor applications, most noticeably in electronic article surveillance. Accordingly, the major drawback of the nanocrystalline materials is the severe embrittlement upon crystallization, which requires final shape annealing and restricts their application mainly to toroidally wound cores. Yet, the situation is similar for highly permeable amorphous alloys due to the necessary stress relief treatment, which also causes embrittlement.

# Amorphous Intermetallic Alloys: Resistivity

Many intermetallic alloys can be prepared in a glassy or amorphous state simply by quenching rapidly from the melt at rates of the order of $10^6\,\mathrm{K s^{-1}}$ using, amongst other techniques, melt spinning and splat quenching to produce bulk samples, or sputtering, evaporation, and electrodeposition to produce thin films. The resulting material is rich in unusual and often unique phenomena and for the last 30 years of the twentieth century amorphous alloys were the focus of extensive experimental and theoretical interest, particularly in the investigation of the effects of extreme atomic disorder on conductivity, electron localization, magnetic order, spin fluctuations, and even superconductivity. In this context the anomalous resistivity of amorphous alloys has, perhaps, received the most attention and, although the resistivity is not fully understood, it reveals a fascinating and complex interplay of structural scattering processes and quantum corrections arising principally from weak localization and electron–electron interactions. In this section the general features of the temperature dependence of the resistivity of amorphous intermetallic alloys will be briefly reviewed, and the major contributions to the resistivity introduced.

## 1. Resistivity, Order, and Disorder

According to Bloch theory, an electron in a perfect periodic potential experiences no collisions, and therefore no resistance. The familiar features of the temperature-dependent resistivity of structurally ordered metals and alloys are therefore a consequence of modest deviations from the underlying translational and orientational periodicity of a perfect crystalline lattice. On the one hand static defects, such as impurities, vacancies, or dislocations, act as localized scattering centers, contributing to an essentially temperature-independent residual resistivity, $\rho_o$. On the other hand, thermal vibrations result in dynamic displacements of the atoms from their equilibrium positions thereby perturbing the lattice periodicity and contributing a temperature-dependent term, $\rho_L(T)$, to the resistivity. The latter term, generally known as the ideal or lattice resistivity, is well described by the Gruneisen formula (see, e.g., Ziman 1972)

$$\rho(T) = 4A\left(\frac{T}{\theta_D}\right)^5 \int_0^{\theta_D/T} \frac{e^x x^5}{(e^x-1)^2}\,dx \qquad (1)$$

where $\theta_D$ is the Debye temperature.

Because $\rho_o$ and $\rho_L(T)$ result from entirely independent scattering processes they can be linearly combined, through Mattheissen's rule, to give a total resistivity of

$$\rho(T) = \rho_o + \rho_L(T) \qquad (2)$$

For most crystalline metals and alloys $\rho_L(T)$ is generally the dominant contribution and consequently Eqn. (2) predicts a resistivity, which tends to $\rho_o$ at the lowest temperatures, but varies as $T^5$ below $\theta_D$ and increases linearly with $T$ at and above $\theta_D$.

For rapidly quenched amorphous intermetallic alloys, however, the deviations from perfect periodicity arising from static topological disorder are extreme. Although the near neighbor distances between constituent atoms in an amorphous alloy may vary randomly by only a few percent about those of their crystalline counterparts, and local atomic coordinations and configurations may remain closely similar to the corresponding crystalline phases (Fig. 1), any translational symmetry of the lattice is entirely lost (Elliot 1983).

It might be expected that such pronounced topological disorder would lead to a considerably enhanced residual resistivity. Indeed, the measured resistivities of amorphous metals and alloys are much greater than those of ordered crystalline phases of similar composition, but additionally the experimentally determined temperature dependence of the resistivity is observed to be highly anomalous. Marked deviations from the simple form of Matthiessen's rule, given by Eqn. (2), are found in which the temperature coefficient of resistivity, $\alpha\ (=\rho^{-1}(\partial\rho/\partial T))$, is

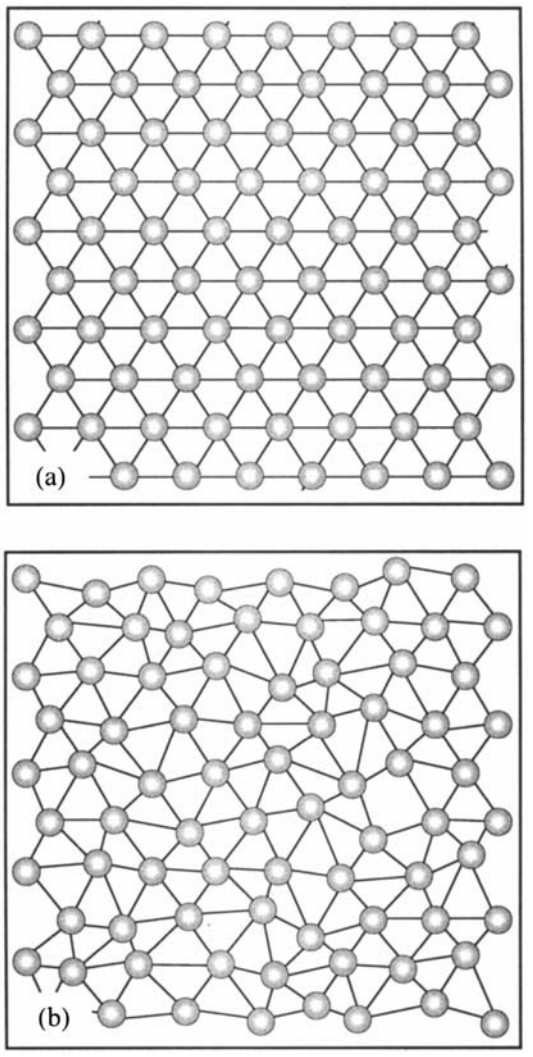

***Figure 1***
A schematic representation of (a) a crystalline lattice and (b) the corresponding amorphous lattice formed by applying small random deviations to the atomic bond lengths. Note that in (b) translational symmetry is lost, although a vestige of orientational symmetry remains.

generally very small ($\sim 10^{-4}\,K^{-1}$) and can be either positive or negative (Mooij 1973).

## 2. The Mooij Correlation

Mooij (1973) was the first to note an approximate but striking "universal" correlation between the anomalous temperature coefficient, $\alpha$, and the magnitude, $\rho$, of the resistivity for amorphous metallic alloys. Experimental resistivity data collected over a wide range of transition metal-based amorphous alloys revealed

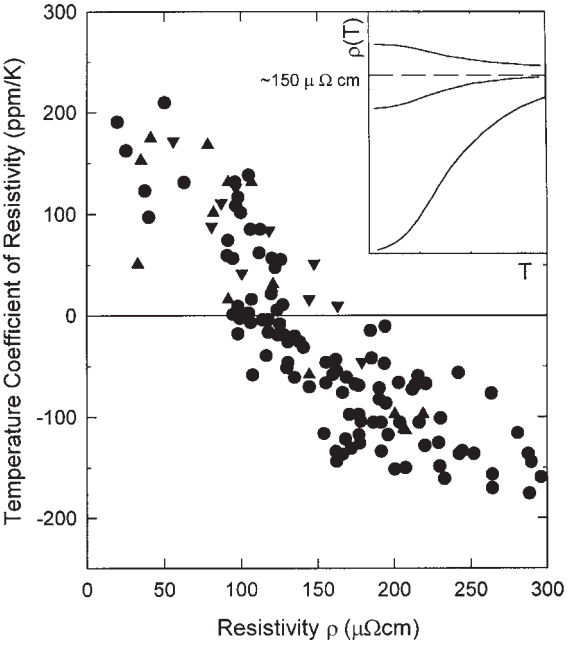

***Figure 2***
The Mooij correlation showing the variation of the temperature coefficient of resistivity with the magnitude of the resistivity for several amorphous alloys (▼), thin films (●), and bulk alloys (▲). The inset provides a schematic illustration of the temperature dependence of the resistivity of amorphous compounds corresponding to the Mooij correlation (after Cote and Meisel 1981).

that the sign of $\alpha$ changes from positive to negative as the room-temperature resistivity exceeds a threshold magnitude of approximately 150 μΩcm. Moreover, for both positive and negative $\alpha$, the resistivity is always found to approach to a similar limiting value of 150 μΩcm at high temperatures. A schematic representation of the Mooij correlation is given in Fig. 2.

The limiting or threshold value for the resistivity is close to that expected when the effective mean free path of the conduction electrons approaches a length scale comparable to the mean interatomic near neighbor distance (0.3–0.5 nm). This implies that the Mooij correlation should be quite generally applicable to materials with short mean free paths. Extensive surveys of amorphous intermetallic alloys do indeed show the Mooij correlation to be effectively independent of either atomic or electronic structure, and this correlation is even followed by many highly resistive disordered *crystalline* alloys.

## 3. The Faber–Ziman Theory

Despite the apparent insensitivity of the Mooij correlation to the underlying atomic structure, many

theoretical treatments of the resistivity of amorphous alloys have focused entirely upon this underlying structure (Cote and Meisel 1981).

The absence of translational symmetry in amorphous alloys necessitates a probabilistic description of the atomic positions in terms of a radially averaged distribution function dominated by short-range atomic correlations. Such radial distributions are very similar to those used to describe the structure of liquids. Consequently a particularly useful starting point for theory has been the generalized Faber–Ziman model based upon modifications to the Ziman diffraction theory of conductivity in *liquid* metals and alloys (Cusak 1987).

The Faber–Ziman theory is a nearly free electron approach. It treats the conduction electrons as plane waves with a wave vector $k_F$, corresponding to the Fermi momentum, which are coherently diffracted by the amorphous structure. Within this formalism the resistivity, $\rho$ is given by

$$\rho = \frac{12\pi\Omega}{e^2\hbar v_F^2}\int_0^1 S^{\rho}(k)|t(k)|^2\left[\frac{k}{2k_F}\right]^{3d}\left[\frac{k}{2k_F}\right]\mathrm{d}k \qquad (3)$$

where $\Omega$ is the atomic volume, $v_F$ the Fermi velocity and $|t(k)|$ the scattering matrix element or t-matrix. In Eqn. (3), the resistivity static structure factor $S^{\rho}(k)$ is approximately related to the equilibrium structure factor $S(k)$, as measured directly in conventional neutron or x-ray structural studies, through

$$S^{\rho}(k) \approx 1 + [S(k) - 1]e^{-2W(k,T)} \qquad (4)$$

where the Debye–Waller factor, $e^{-2W(k,T)}$, introduces the important effects of thermal vibrations (Rao 1983).

The structure factor, $S(k)$, takes the typical form shown schematically in Fig. 3. Of particular significance is the extremely large first peak in $S(k)$ at $k = k_p$. There is considerable evidence that for most amorphous alloys $2k_F$ lies close to $k_p$, generally within the range $0.9 < 2k_F/k_p < 1.1$. This situation leads directly to back scattering of conduction electrons, a process that correspondingly dominates the integral in Eqn. (3) and leads to the characteristic high resistivity.

Within the diffraction theory the Mooij correlation is thus a consequence of the relative position of $2k_F$ with respect to $k_p$. Compositional effects are related to $2k_F$ moving through $k_p$ as the concentration of the alloy is changed, whilst Eqn. (4) shows that the negative $\alpha$ observed at high values of resistivity is associated with the back scattering condition $2k_F \approx k_p$, and is a direct reflection of the reduction in scattering due to the temperature dependence of the Debye–Waller factor for situations where $S(k = 2k_F) > 1$.

More precisely, the Faber–Ziman diffraction theory predicts a $T^2$ increase in resistivity at low

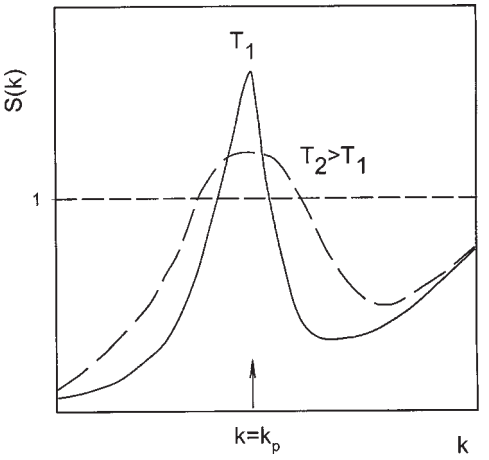

***Figure 3***
A schematic representation of the equilibrium structure factor, $S(k)$ at low ($T_1$) and high ($T_2$) temperatures.

temperatures ($T < \theta_D/2$) and a positive or negative linear dependence with $T$ at higher temperatures ($T > \theta_D/2$), according to the proximity of $2k_F$ to $k_p$. Correspondingly, a shallow maximum is predicted in the resistivity of those alloys at the crossover from positive to negative $\alpha$ (Rao 1983).

These predictions are certainly in broad agreement with experimental measurements and provide a simple qualitative explanation for the general features of the temperature dependence of the resistivity and also for the Mooij correlation (Fig. 4). A more quantitative agreement can be achieved when additional modifications, such as a limitation of the effectiveness of the electron–phonon interaction with decreasing electron mean free path, are introduced (Cote and Meisel 1981). However, even with such modifications the diffraction theory does seem better suited to those alloys with lower resistivity for which $\alpha$ is positive rather than negative.

As the particular characteristics of the atomic structure of amorphous materials lies at the heart of the Faber–Ziman approach, the diffraction theory unfortunately provides little insight into the generalization of the Mooij correlation beyond amorphous alloys to disordered crystalline materials. This issue was elucidated to some extent by a simple but elegant approach suggested by Markowitz (1977) in which the temperature-dependent Debye–Waller factor is introduced multiplicatively in Mattheissen's rule, i.e.,

$$\rho(T) = [\rho_o + \rho_L(T)]e^{-2W(k,T)} \qquad (5)$$

to account for higher order phonon processes. This correction is entirely negligible for the general case of $\rho_o \ll \rho_L(T)$ but becomes increasingly important for

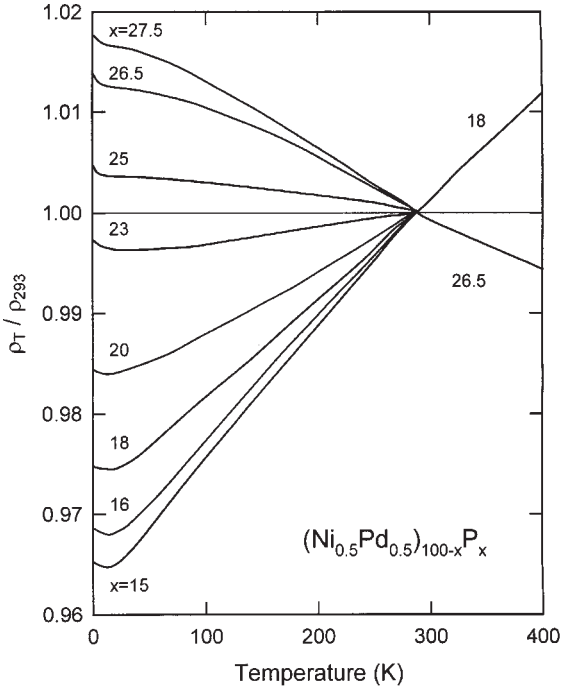

***Figure 4***
Temperature dependence of the resistivity (normalized to the value at $T = 293\,\mathrm{K}$) of the amorphous alloy series $(Ni_{0.5}Pd_{0.5})_{100-x}P_x$. Note the crossover from $\alpha > 0$ to $\alpha < 0$ with increasing $x$, and also the occurrence of a low-temperature logarithmic term at all concentrations (after Harris and Strom-Olsen 1983).

$\rho_o \gg \rho_L(T)$ causing the sign of $\alpha$ to change from positive to negative, in line with the Mooij correlation.

A more severe limitation of the Faber–Ziman approach is the inability of the diffraction theory to account for an "additional" prominent feature observed in the low-temperature ($T < 50\,\mathrm{K}$) resistivity of many amorphous metals (Fig. 4). This feature, which can be loosely characterized as a logarithmic increase in the resistivity towards low temperatures, is seemingly uncorrelated with the sign of $\alpha$ (although there are very few examples of materials with positive $\alpha$ for which no logarithmic term is observed) (Harris and Strom-Olsen 1983).

The apparent $-\ln(T)$ dependence of the low-temperature resistivity, which leads to a distinctive minimum for those alloys with positive $\alpha$, has provoked comparisons with Kondo processes observed in crystalline alloys. However, unlike the conventional Kondo effect, the $-\ln(T)$ term observed for the amorphous alloys is entirely insensitive to the presence of either spin glass or ferromagnetic order.

The $-\ln(T)$ description of the low-temperature resistivity is only approximate and the heuristic form, $-\ln(T^2 + \Delta^2)$, with $\Delta \sim 1\,\mathrm{K}$, often provides a better description. It has been widely suggested that this term is not magnetic in origin, but is instead a structural analogue of the Kondo effect. This model assumes that the liquid-like structure of the amorphous state provides internal degrees of freedom allowing atoms to tunnel between two local equilibrium positions (Harris and Strom-Olsen 1983). However it is not clear that such two-level scattering processes are sufficiently effective to produce contributions of the magnitude observed experimentally.

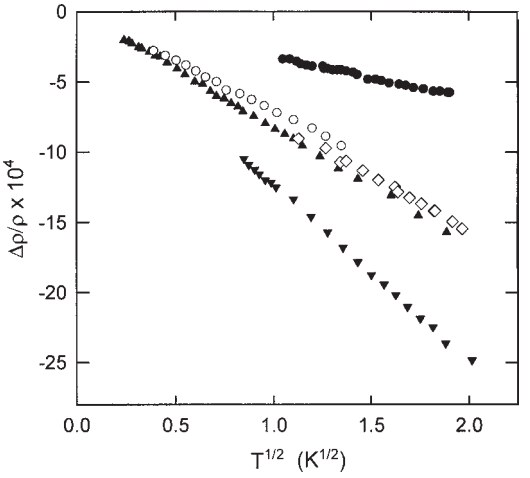

***Figure 5***
Relative low-temperature resistivity as a function of $T^{1/2}$ for (▼) $Y_{77.5}Al_{22.5}$, (▲) $Fe_{40}Ni_{40}(P, B)_{20}$, (◇) $Cu_{60}Zr_{40}$, (○) $Fe_{79}Cr_1B_{20}$, (●) $Pd_{82}Cr_{18}$ (after Cusak 1987).

Some authors have argued convincingly that the low-temperature logarithmic term is better described as a $T^{1/2}$ term, as illustrated in Fig. 5. This will be discussed in the next subsection.

## *4. Quantum Corrections: Localization and Interaction Effects*

The theoretical models discussed so far have all been based upon conventional "Boltzmann" transport theory, a weak-scattering approximation in which the nearly free electrons are considered to follow classical trajectories between scattering events (see *Boltzmann Equation and Scattering Mechanisms*). Unfortunately, such assumptions are of questionable validity for topologically disordered amorphous alloys in general and for the highly resistive alloys with negative $\alpha$ in particular.

In the strong scattering regime, where the electron mean free path is comparable to the interatomic spacing, it becomes necessary to consider quantum corrections to the conductivity, and in some cases

these corrections can dominate the temperature dependence of the resistivity.

Mechanisms of electron localization resulting from a high degree of structural disorder have been extensively discussed in the literature (Howson and Gallagher 1988, Dugdale 1987). In addition to the possibility of weak incipient localization of electron states, the weak localization that arises from a quantum interference effect known as "$2k_F$-scattering" is of particular relevance to amorphous alloys. This phenomenon is associated with a diffusing conduction electron returning to its primary scattering point, after a series of intermediate elastic scattering collisions with nearby ions, with a probability that is significantly enhanced due to the phase coherence between scattered partial waves. The higher than classical probability of the electron being found at its starting point is interpreted as a tendency towards localization. These quantum considerations increase the probability of back- (hence "$2k_F$"-) scattering, a process that has already been shown to be significant in amorphous alloys.

This quantum interference mechanism is particularly sensitive to any factor that is effective in suppressing the coherent summation of the amplitudes of the scattered partial waves. So, for example, inelastic electron–phonon scattering, spin-orbit effects, or external magnetic fields can inhibit localization by changing the phase of the electron wave function on its closed path.

An appropriately corrected form of the Boltzmann conductivity, $\sigma_B = e^2 k_F^2 l_e / 3\pi^2 \hbar$, is therefore

$$\sigma = \sigma_B \left[ 1 - \frac{3}{(k_F l_e)^2} \left( 1 - \frac{l_e}{L} \right) \right] \qquad (6)$$

where $l_e$ is the elastic mean free path, and $L$ is the inelastic diffusion length (related to the inelastic mean free path, $l_i$, through $L^2 = l_i l_e/2$) or the cyclotron radius, $(c\hbar/2eH)^{1/2}$, in a magnetic field $H$, whichever is the shorter (Howson and Gallagher 1988).

Using a scaling approach to localization, and with some simplifications, it is found that the correction to the Boltzmann conductivity arising from the temperature dependence of the mean free path for inelastic scattering, i.e., $\Delta\sigma_{wl} = e^2/3\pi^2\hbar L(T)$, takes the form

$$\Delta\sigma_{wl} \propto T \qquad \text{for } T < \theta_D/3$$

$$\Delta\sigma_{wl} \propto T^{1/2} \qquad \text{for } T > \theta_D/3.$$

The quantum interference effects leading to weak localization do not include electron–electron interactions. However localization processes can significantly enhance the effective Coulombic electron–electron interaction causing a gap, or at least a minimum, to form in the density of states at the Fermi energy and leading to a further correction to the Boltzmann conductivity of

$$\Delta\sigma_{ee} \propto T^{1/2}$$

This electron–electron interaction correction term is significant only at low temperatures below a limit (typically 15–20 K) determined by the electron diffusion coefficient, the dynamic screening of the Coulomb interaction and the temperature-dependent mean free path for inelastic scattering, $l_i(T)$. It is this contribution that has been identified with the Kondo-like $-\ln(T)$ term in the resistivity discussed in the previous section (Howson and Gallagher 1988), and shown in Fig. 5.

The unmodified Boltzmann conductivity is here associated with the Faber–Ziman weak scattering model that predicts either a positive or negative thermal coefficient of resistivity, $\alpha$. However, each of the quantum corrections to the conductivity increases with temperature and therefore contributes a negative $\alpha$. Moreover, in the strong scattering regime, for which $l_e \ll l_i$, the temperature dependence of the resistivity will be entirely dominated by the quantum "corrections," thereby reinforcing the Mooij correlation for the highly resistive amorphous alloys. It should also be emphasized that the quantum corrections discussed above are not based upon considerations of the structure of amorphous alloys and are thus equally valid for disordered *crystalline* alloys, providing that the appropriate conditions for weak localization are met.

The low-temperature $T^{1/2}$ behavior has already been encountered in Fig. 5, whereas a typical progression from the $T^{1/2}$-, through a $T$-, then back to a $T^{1/2}$-dependence of the correction to the Boltzmann conductivity with increasing temperature can be clearly seen in Fig. 6 where the data for several amorphous $(Ni_{0.5}Zr_{0.5})_{1-x}Al_x$ alloys is shown (Nath and Majumdar 1997).

It therefore appears that the quantum corrections can account for all the principal features in the conductivity of the highly resistive amorphous alloys, at least up to $\theta_D$. Beyond this it is likely that other processes, such as phonon assisted tunneling, thermal expansion effects, and thermal smearing of the Fermi function will become increasingly significant.

Finally, a particular shortcoming of the Faber–Ziman diffraction model has been is its inability to explain satisfactorily the magnitude of the magnetoresistivity observed for many amorphous alloys. A fractional magnetoresistance of the order of $10^{-4}$ at 1 T is often measured at low temperatures, even for those alloys which contain no magnetic constituents. This is some four orders of magnitude greater than the effect calculated using nearly free electron models. However, both the weak localization and electron–electron interaction models predict magnetoresistivities of this order (Howson and Gallagher 1988).

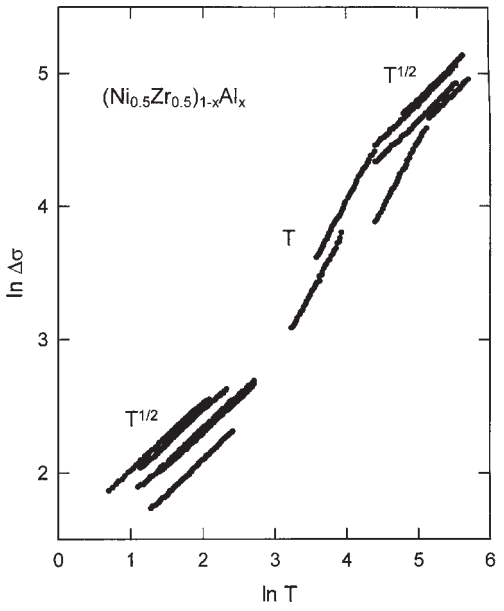

***Figure 6***
The logarithm of the correction to the Boltzmann conductivity as a function of ln($T$) for several amorphous $(Ni_{0.5}Zr_{0.5})_{1-x}Al_x$ alloys. The progressive transitions from $T^{1/2}$- to $T$- then back to $T^{1/2}$-dependence are clearly seen (after Nath and Majumdar 1997).

## 5. *Magnetism, Spin Fluctuations, and Superconductivity*

The magnetic properties of amorphous intermetallic compounds are extremely varied. Manifestations of almost all of the classes of magnetic behavior found in crystalline alloys and compounds are represented and, as in crystalline alloys, are determined by the magnitude and stability of the magnetic moment, and the balance between the exchange interaction and magnetic anisotropy. The superposition of topological disorder and consequent randomization of local magnetic anisotropy axes can additionally lead to magnetic phenomena which are peculiar to the amorphous state, particularly in those alloys containing non-S-state rare earth ions (for a review see, e.g., Chudnovsky 1995). In most cases, however, the transition from a low-temperature magnetically ordered state to a high-temperature paramagnetic state is accompanied by an increase in resistivity associated with spin disorder scattering, similar to that observed for crystalline alloys. In comparison with the underlying resistivity of the amorphous alloy this contribution is relatively modest.

However, in several amorphous transition metal alloys, 3d elements that are normally considered as "magnetic" (e.g., Fe, Co, Ni) do not support localized magnetic moments over relatively wide compositional ranges. For example in amorphous $Fe_{1-x}Zr_x$ the loss of weak itinerant ferromagnetism with increasing zirconium composition is accompanied by a collapse of the iron moment itself. Close to and at either side of the critical concentration for ferromagnetism (approximately 65 at.% Zr) the resistivity shows clear evidence of spin fluctuations (see *Spin Fluctuations*), with a large contribution of the characteristic form

$$\rho_{sf} \propto AT^2$$

At higher Zr concentrations in the $Fe_{1-x}Zr_x$ system, in common with other $TM_{1-x}Zr_x$ amorphous alloys (with TM = Co, Ni, Cu, Rh), a low-temperature ($T_c < 3$ K) superconducting phase is recovered. The observed spin fluctuations are generally held responsible for the suppression of superconductivity, a view reinforced by resistivity measurements under pressure, which show a reduction in the spin fluctuation contribution, and a concomitant rapid increase in the superconducting transition temperature with increasing applied pressure (Hamed *et al.* 1995 and references therein, Poon 1983).

## 6. *Summary and Conclusions*

Even the simplest nonmagnetic amorphous intermetallic alloys exhibit an anomalous temperature-dependent resistivity that reflects a complex combination of electron scattering, localization, and interaction processes. Nevertheless, the general features of the temperature dependence of the resistivity and the widely applicable Mooij correlation that relates the magnitude and temperature coefficient of resistivity are generally well explained by a combination of the Faber–Ziman amorphous structural diffraction model and the appropriate quantum corrections.

However, in the literature, there remains a tendency, on the one hand, to emphasize the importance of the topologically disordered structure of amorphous alloys, and on the other hand to categorize the alloys as either weak scattering ($\rho < 150\,\mu\Omega$cm, $\alpha > 0$) or strong scattering ($\rho > 150\,\mu\Omega$cm, $\alpha < 0$) and to develop theoretical models accordingly. This belies the Mooij observations that the characteristic features of the resistivity of amorphous intermetallic alloys can also be found in highly disordered but nevertheless fully crystalline alloys, and that the progression from the weak to the strong scattering limit is entirely continuous.

It is apparent that there is considerable scope for further theoretical and experimental studies of electron transport in these fascinating materials.

## Amorphous Materials: Electron Spin Resonance

Electron spin resonance (ESR) is a spectroscopic technique that uses the spin magnetic moment of the electron as a probe of its local environment. Only unpaired electrons can participate in ESR. In most insulating materials virtually all electrons are paired and their magnetic moments cancel. However, a few unpaired electrons may be present in the form of electrons or holes trapped at point defects or located in partially filled *d* or *f* shells of transition group ions. ESR is sufficiently sensitive to detect unpaired electrons in concentrations sometimes as low as a few parts per billion.

### *1. ESR Theory and Practice*

The spin **S** and spin magnetic moment $\mu$ of the electron are related quantum mechanical vectors:

$$\boldsymbol{\mu} = -g\beta\mathbf{S} \tag{1}$$

where $\beta = |e|h/4\pi mc$ is the Bohr magneton, $e$ is the charge of the electron, $m$ is its mass, $h$ is Planck's constant, $c$ is the speed of light, and $g$ is a dimensionless number. For the free electron $g = g_e = 2.00232$, and $\boldsymbol{\mu} = \boldsymbol{\mu}_e \equiv -g_e\beta\mathbf{S}$. When any magnetic dipole $\boldsymbol{\mu}$ is placed in an external magnetic field **H**, its Zeeman interaction energy is given by the scalar product

$$E_{\text{Zeeman}} = -\boldsymbol{\mu}\cdot\mathbf{H} \tag{2}$$

A quantum-mechanical property of spin angular momentum is that its projections on the direction of **H** are limited to the values $M_S = S, S-1, \ldots, -S$, where the scalar quantity $S$ is termed the "spin." For the free electron, $S = \frac{1}{2}$. In general, atoms or assemblies of atoms binding $N$ electrons may assume net spins as large as $N/2$, but in practice $S = \frac{1}{2}$ for most point defects, and $S$ for transition group ions can be no larger than $\frac{1}{2}$ multiplied by the number of electrons in *d* and/or *f* orbitals.

The most common ESR spectrometer exposes samples to microwaves of a fixed frequency $\upsilon$ and an applied magnetic field **H**. The allowed transitions between the Zeeman levels of Eqn. (2) are those for which $\Delta M_S = \pm 1$. Near thermodynamic equilibrium there are more electrons in the lower energy Zeeman states than the higher ones, resulting in a net absorption of microwave power when $|\mathbf{H}| = H_{\text{res}}$, given by the "resonance condition"

$$H_{\text{res}} = \frac{h\upsilon}{g\beta} \tag{3}$$

There is also a magnetic moment associated with the orbital angular momenta of electrons circling about atoms. However, when atoms are embedded in solids, local electric fields ("crystal fields") tend to "quench" the orbital angular momentum of their ground states leaving a magnetic moment due mostly to the spin, i.e., $\boldsymbol{\mu} \approx \boldsymbol{\mu}_e$. Nevertheless, the spin-orbit and orbit-Zeeman interactions admix small amounts of orbital angular momentum back into the ground state. These residual orbital effects require the

replacement of $g\mathbf{S}$ in Eqn. (1) with $\mathbf{g}\cdot\mathbf{S}$. The so-called "$g$ matrix" is expressed by (e.g., Weil *et al.* 1996)

$$\boldsymbol{g} = g_e\mathbf{1} + 2\lambda\boldsymbol{\Lambda} \tag{4}$$

where $\mathbf{1}$ is the unit matrix and $\lambda$ is the spin-orbit coupling constant. The elements of the matrix $\boldsymbol{\Lambda}$ take the form (correct to second order in perturbation theory):

$$\Lambda_{ij} = \sum_n \frac{\langle 0|L_i|n\rangle\langle n|L_j|0\rangle}{(E_n - E_0)} \tag{5}$$

where $L_i$ and $L_j$ are orbital-angular-momentum operators and $|0\rangle$ and $|n\rangle$ are the ground- and $n$th-excited-state wavefunctions, respectively, of the paramagnetic species and $E_0$ and $E_n$ are their energies.

The energetics of unpaired electrons subjected to electric and/or magnetic fields are contained in the "spin Hamiltonian" $\mathscr{H}$ operator, (e.g., Weil *et al.* 1996). For the case of the Zeeman interaction in the presence of crystalline electric fields

$$\mathscr{H} = \beta\mathbf{H}\cdot\mathbf{g}\cdot\mathbf{S} + \mathbf{S}\cdot\mathbf{D}\cdot\mathbf{S} \tag{6}$$

where $\mathbf{g}$ is given by Eqns. (4) and (5) and the second term on the right (sometimes called the fine-structure interaction) is nonzero only for $S > \frac{1}{2}$. When $|\mathbf{H}| = 0$, $\mathbf{S}$ is quantized along the set of axes which diagonalize $\mathbf{D} = \lambda^2\boldsymbol{\Lambda}$, where $\boldsymbol{\Lambda}$ is given by Eqn. (5). In its diagonalized form, the diagonal elements of $\mathbf{D}$ are commonly expressed as $\frac{1}{3}D - E$, $\frac{1}{3}D + E$, and $-\frac{2}{3}D$, where $D$ and $E$ ($|E| \leqslant |\frac{1}{3}D|$) are the axial and orthorhombic fine-structure splittings, respectively.

In general, solutions of Schrödinger's equation using Eqn. (6) as the energy operator yield resonance conditions which depend on the angles between the direction of the applied field $\mathbf{H}$ and the principal axes of $\mathbf{g}$ and $\mathbf{D}$ (which in turn relate to axes of crystalline symmetry). For example, in the case of a paramagnetic center with $S = \frac{1}{2}$ located on a high-symmetry site in a crystal with a three-fold axis of symmetry or higher (i.e., a $c$ axis), the value of $g$ to be used in the resonance condition of Eqn. (3) is found to be

$$g = \sqrt{g_\parallel^2\cos^2\theta + g_\perp^2\sin^2\theta} \tag{7}$$

where $\theta$ is the angle between $\mathbf{H}$ and the $c$ axis.

Many atomic nuclei have nonzero quantum mechanical spin vectors $\mathbf{I}$ and, by analogy with Eqn. (1), nuclear magnetic moments $\boldsymbol{\mu}_N \equiv g_N\beta_N\mathbf{I}$, where $g_N$ is the nuclear $g$ factor and $\beta_N = |e|h/4\pi Mc$ is the nuclear magneton ($M$ is the proton mass). The projections of $\mathbf{I}$ on the direction of an imposed magnetic field can take only integral or half-integral values given by $M_I = I, I-1, \ldots, -I$, where the scalar quantity $I$ is called the "nuclear spin." A single unpaired electron whose ground-state orbital bears a fixed geometric relationship to a companion "magnetic" nucleus ($I \neq 0$) is therefore subjected to the vector sum of the applied magnetic field $\mathbf{H}$ and one of $2I+1$ possible magnetic field values corresponding to the $2I+1$ possible orientations of the nuclear magnetic moment vector $\boldsymbol{\mu}_N$. In these cases, a hyperfine term $\mathscr{H}_{hf} = \mathbf{S}\cdot\mathbf{A}\cdot\mathbf{I}$, must be added to the spin Hamiltonian of Eqn. (6). In an actual experiment (usually involving $> 10^{13}$ unpaired electrons) a paramagnetic species with $S = \frac{1}{2}$ which is associated with a single nuclide of spin $I$ gives rise to a manifold of $2I+1$ equally intense hyperfine lines with spacings which depend on the angles between the field $\mathbf{H}$ and the principal axes of the hyperfine matrix

$$\mathbf{A} = A_{iso}\mathbf{1} + \mathbf{T} \tag{8}$$

where $A_{iso}$ is the isotropic hyperfine coupling constant and $\mathbf{T}$ is a traceless matrix accounting for the angular dependence. A second-order-perturbation-theory resonance condition for $\mathscr{H} = \beta\mathbf{H}\cdot\mathbf{g}\cdot\mathbf{S} + \mathbf{S}\cdot\mathbf{A}\cdot\mathbf{I}$ assuming axial symmetry and collinear $g$ and $A$ matrices can be found, e.g., in Griscom (1990) or Weil *et al.* (1996). For the special case of a $p$ orbital centered on the magnetic nucleus, $\mathbf{T}$ is diagonal with elements $-B$, $-B$, and $2B$.

Many point defects in insulators are characterized by $sp$ hybrid-molecular-orbital ground-state wavefunctions of the form

$$\psi_0 = c_s|ns\rangle + c_p|np\rangle + \sum c_i|k_i\rangle \tag{9}$$

where $|ns\rangle$ and $|np\rangle$ are, respectively, $s$- and $p$-state valence orbitals of an atom at the apex of a triangular or trigonal-pyramidal cluster of atoms and $|k_i\rangle$ are the remaining valence orbitals of the cluster. Where the apex atom incorporates a magnetic isotope, the coefficients $c_s$ and $c_p$ can be determined from the experimental hyperfine coupling constants according to $c_s^2 = A_{iso}/A_0$ and $c_p^2 = B/B_0$, where $A_0$ and $B_0$ are $s$-state and $p$-state coupling constants of the free atom, respectively, available from tables (e.g., Weil *et al.* 1996). In general, there is a direct relationship between the hybridization ratio $c_p/c_s$ and the apex bond angles (see, for example, references in Griscom 1990).

## 2. *ESR in Crystals and Powders*

Figure 1(a) exhibits a plot of the expected positions of $H_{res}(\theta)$ specified by Eqns. (3) and (7) for a particular set of parameters ($g_\parallel = 2.185$, $g_\perp = 1.999$, and $\nu = 9.23$GHz). If this crystal were to be crushed into a fine powder, the resulting ESR signal would become "smeared" between the field values $H_{min} = h\nu/g_\parallel\beta$ and $H_{max} = h\nu/g_\perp\beta$. However, this smearing is not random. In practice, all solid-angle orientations $\Omega$ of the particle's $c$ axes with respect to the direction of $\mathbf{H}$ are represented with equal probability. This uniform orientational distribution, $P_\Omega(\Omega) = constant$, transforms into a function $P_H(H_{res}) = P_\Omega(\Omega)\cdot|J_H(\Omega)|$,

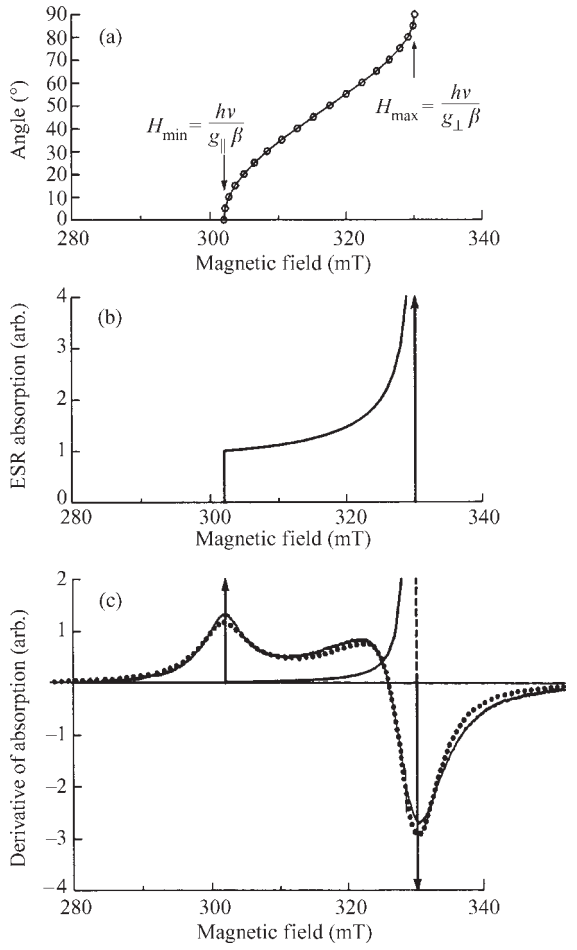

***Figure 1***
ESR of crystals and powders using the example of a resonance condition specified by Eqns. (3) and (7): (a) simulated angular dependence data for a hypothetical single crystal; (b) "powder pattern" absorption in the case of an infinitesimally narrow single-crystal linewidth; (c) first derivative of the powder pattern (bold curves) with superposed experimental (thin curve) and simulated (dots) spectra due to $O_2^-$ ions in polycrystalline $Na_2O_2$. The simulation assumed an axially symmetric $g$ matrix (which is only approximately true of the experimental spectrum) and a Lorentzian single-crystal line-broadening function whose (finite) width was used as a fitting parameter.

where $J_H(\Omega)$ is the Jacobian of the transformation $\Omega \rightarrow H$. $P_H(H_{res})$ is called a powder pattern and expresses the probability of resonance absorption per unit interval of $H$.

Figure 1(b) is the powder pattern for the case in point, where $J_H(\Omega) = [\partial H_{res}(\cos\theta)/\partial \cos\theta]^{-1}$ and $H_{res}$ is given by Eqns. (3) and (7) (the vertical arrow marks a mathematical singularity which would occur if the single-crystal linewidth were infinitesimally narrow). The first derivative of this envelope is shown as the bold lines in Fig. 1(c). The thin curve in Fig. 1(c) is an experimental first-derivative spectrum (solid curve) arising from superoxide ions ($O_2^-$) in polycrystalline $Na_2O_2$. The dotted curve is a computer simulation based on the (approximately valid) assumption of an axially symmetric $g$ tensor. This simulation is the result of convoluting the powder pattern with a Lorentzian single-crystal line shape of an appropriate finite width (Griscom 1990).

## 3. ESR in Amorphous Materials

Glasses and other amorphous materials differ from powdered crystals in a fundamental way. Whereas each particle of a crystalline powder has a structure and density identical to all others, the structure of each nanoregion of a glass differs randomly from other nanoregions of equivalent size. In particular, glasses display spatial density fluctuations. Thus, a simplistic but instructive way to visualize a glass would be as a nanocrystalline solid wherein the ensemble of randomly oriented nanocrystallites is characterized by a statistical distribution of densities.

### *3.1 How ESR Spectra of Amorphous Materials Differ from Those of Powders*

It can be shown theoretically that an $O_2^-$ ion in free space (or in a material of zero density) is characterized by $g_{\parallel} = 4$, $g_{\perp} = 0$, whereas in a hypothetical material of infinite density $g_{\parallel} = g_{\perp} = g_e$. Figure 2(a) illustrates the predicted angular dependencies of the ESR spectra of $O_2^-$ ions in a material of finite density subjected to ten incrementally different isostatic pressures. The decreases of $g_{\parallel}$ and correlated increases of $g_{\perp}$ with increasing pressure were calculated from the theory of Känzig and Cohen (1959) by approximating their formulae to axial symmetry. Figure 2(b) shows the result of adding together the powder patterns corresponding to each of these 10 cases according to a bell-shaped weighting function. The subtly rounded shape of the "glass pattern" which would be obtained by replacing the 10-element summation of Fig. 2(b) with a continuous integral over the same weighting function contrasts with the sharply angular powder pattern of Fig. 1(b).

Figure 2(c) (unbroken curve) illustrates the experimental first-derivative spectrum of $O_2^-$ ions in an amorphous peroxyborate material (Griscom 1990). The dotted curve in Fig. 2(c) is a computer simulation based on the correlated skew-symmetric $g$-value distributions of Fig. 2(d), which in turn were derived by assuming a Gaussian distribution $P_{\Delta}(\Delta)$ in the crystal-field-imposed splittings $\Delta$ of the $2p\pi_g$ energy levels of the $O_2^-$ ion in a solid (Känzig and Cohen 1959).

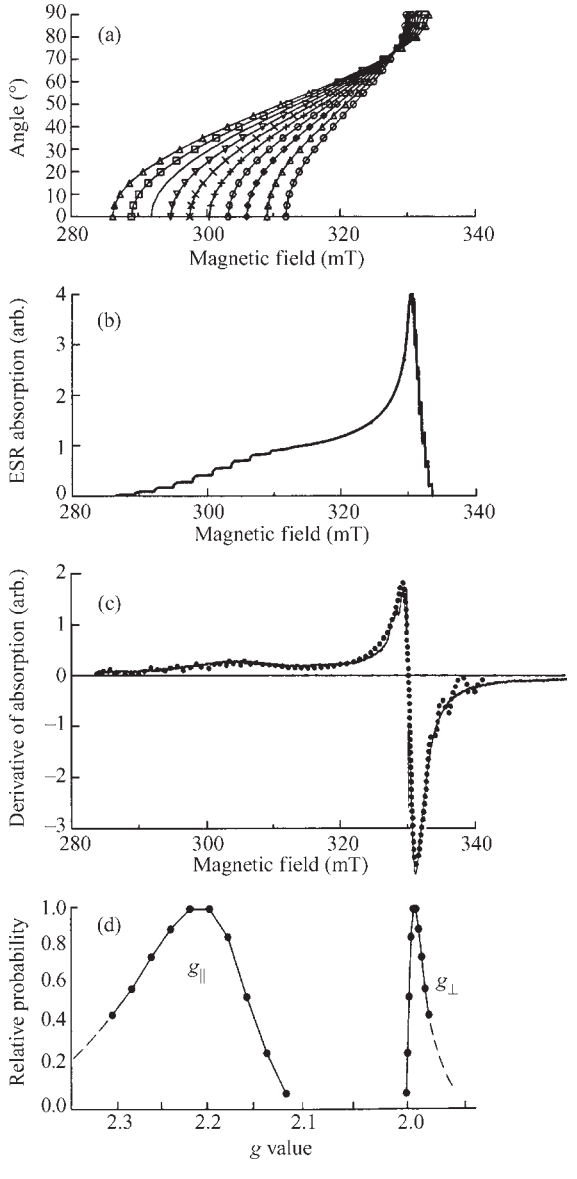

***Figure 2***
Conceptualization of the ESR spectrum of a glass: (a) simulated angular dependencies of the spectra of $O_2^-$ ions in a hypothetical single crystal subjected to a range of isostatic compressions; (b) powder patterns of the foregoing ten cases summed according to a bell-shaped weighting function; (c) experimental spectrum of $O_2^-$ ions in an amorphous peroxyborate preparation (solid curve) and its computer simulation (dots) based on a statistically weighted set of powder patterns deriving from (d) correlated distributions of $g_\parallel$ and $g_\perp$ values semiempirically determined under the constraints of the $g$-value theory of Känzig and Cohen (1959).

The $O_2^-$ ion is a special case used above for illustrative purposes because $g_\parallel$ and $g_\perp$ depend in different ways on a single energy difference $\Delta$. In more common cases where the ground-state wavefunction is given by Eqn. (9), $g_\parallel \approx g_e$ while $g_\perp$ is calculated from Eqns. (4) and (5). Redefining $\Delta$ as $E_1 - E_0$ in Eqn. (5), skew-symmetric distributions in $g_\perp$ can result according to $P_g(g) = P_\Delta(\Delta) \cdot |J_g(\Delta)|$, where $J_g(\Delta) \equiv (\partial g/\partial\Delta)^{-1}$ is the Jacobian of the transformation $\Delta \rightarrow g$ (Peterson *et al.* 1974) and again $P_\Delta(\Delta)$ is taken to be a Gaussian. Skew-symmetric $g$-value distributions arising in this way are endemic to glasses.

### *3.2 Use of Hyperfine Interactions to Determine the Ground State of a Point Defect in an Amorphous Material*

One of the common radiation-induced point defects in amorphous $SiO_2$ is the so-called "peroxy radical" (POR). As discovered from ESR (Friebele *et al.* 1979, Stapelbroek *et al.* 1979, Griscom 1990), the POR comprises an $O_2^-$ molecular ion covalently bonded to a silicon in the glass network. The most important knowledge concerning the POR derives from measurements of its hyperfine interactions with the magnetic nuclides $^{29}Si$ ($I = \frac{1}{2}$, natural abundance 4.7%) and $^{17}O$ ($I = \frac{5}{2}$, natural abundance 0.038%). Figure 3(a) shows the experimental spectrum of a neutron-irradiated $SiO_2$ sample enriched to 36 at.% $^{17}O$. The inset to Fig. 3 shows the structural model of the POR; this model implies that oxygens O(1) and O(2) are chemically inequivalent. For finite amounts of both isotopes, there are four distinguishable cases which must simultaneously contribute to the observed spectrum: $^{16}O(1)$–$^{16}O(2)$, $^{17}O(1)$–$^{16}O(2)$, $^{16}O(1)$–$^{17}O(2)$, and $^{17}O(1)$–$^{17}O(2)$. For 36% $^{17}O$, the relative probabilities of these four cases are calculated to be 0.41:0.23:0.23:0.13, respectively. The first-mentioned case effectively corresponds to zero isotopic enrichment; the spectrum for this case (not shown) was first computer-simulated to determine the $g$-value distributions (Stapelbroek *et al.* 1979).

Using these $g$-value distributions as given, the synthetic spectra of Figs. 3(c) and 3(d) were devised (Friebele *et al.* 1979) for the cases $^{17}O(1)$–$^{16}O(2)$ and $^{16}O(1)$–$^{17}O(2)$, respectively. Finally, these two synthetic spectra were added together in the required 1:1 ratio to achieve the simulation of Fig. 3(b), which successfully replicates all of the main $^{17}O$ hyperfine lines. (The central part of the spectrum due to the case $^{16}O(1)$–$^{16}O(2)$ is not simulated here.) The diagonal elements of the hyperfine matrices, $A_\parallel = A_{iso} + 2B$ and $A_\perp = A_{iso} - B$, were determined from this simulation for both cases. As a check, the same coupling constants were used successfully to predict the positions of the more numerous but weaker lines of the $^{17}O(1)$–$^{17}O(2)$ case (vertical bars in Fig. 3(a)). The resulting values of $A_{iso}$ and $B$ were

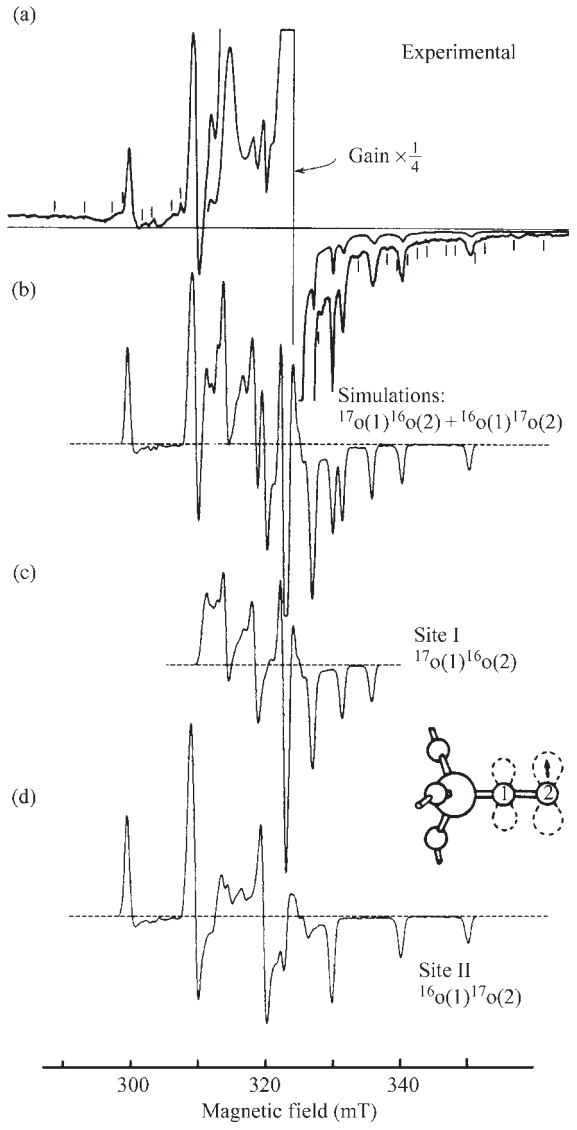

***Figure 3***
ESR spectra of peroxy radicals (PORs) in 36% $^{17}$O-enriched silica glass: (a) experimental spectrum and (b) simulation of the highly structured parts of (a) assuming a POR model with one $^{17}$O ($I=\frac{5}{2}$) and one $^{16}$O ($I=0$) per defect. Under the assumption that the two oxygen sites are chemically inequivalent (see inset), the simulation of (b) perforce comprises an equally weighted sum of the simulated component spectra (c) and (d).

then used to determine the coefficients in Eqn. (9), namely, $c_s(1) \approx c_s(2) \approx 0$, $c_p(1) = 0.26$ and $c_p(2) = 0.74$. Thus, the ground-state wavefunction of the POR in amorphous $SiO_2$ was deduced to comprise a $2p\pi$ antibonding orbital asymmetrically partitioned over two chemically inequivalent oxygen atoms. As inferred from ESR measurements of samples enriched in $^{29}$Si, the reason for this chemical inequivalence is that one of the oxygens is bonded to a single silicon atom in the glass network (c.f., Griscom 1990).

### *3.3 Transition Group Ions in Glasses*

For a single electron ($S=\frac{1}{2}$) in a *d* or *f* orbital of a transition group ion involving a nonmagnetic isotope, the resonance condition is given by Eqns. (3), (4), (5), and (7). In this event, the skew-symmetric *g*-value distributions which occur in glasses are simply calculated by assuming Gaussian distributions in the energy denominators of Eqn. (5) and effecting the transformation $\Delta \rightarrow g$ as described above (Peterson *et al.* 1974). However, in many cases where more than one electron is found in a *d* or *f* shell, details of the coordination sphere and crystal-field strengths determine not only the matrix elements of **D** but also the value of *S* (e.g., Griscom 1990, Weil *et al.* 1996). For $S > \frac{1}{2}$ the spin Hamiltonian of Eqn. (6) applies. Perturbation-theory-based resonance conditions have been derived for the cases $h\nu \gg |D|$ and $|D| \gg h\nu$. Notable is the case of $Fe^{3+}$ ions ($S=\frac{5}{2}$) in glasses, where the conditions $|D| \gg h\nu$ and $|E| \approx \frac{1}{3}|D|$ commonly prevail, leading to an isotropic absorption at an effective *g* value of $\sim 4.3$ (reviewed, e.g., in Griscom 1990). However, situations where $h\nu$ and *D* have comparable magnitudes necessitate exact matrix diagonalization of Eqn. (6).

Figure 4(b) shows the allowed transitions of an $S=\frac{5}{2}$ state determined by matrix diagonalization of Eqn. (6) for **H** parallel to each of the principal axes of **D**; these transitions are plotted here as normalized resonance fields, $g_e \beta H_{res}/h\nu$, versus the normalized fine-structure coupling constant, $|D|/h\nu$, for the special case $|E| = |D|/3$ (Griscom and Griscom 1967). This diagram pertains to $Fe^{3+}$ and (neglecting $^{55}$Mn hyperfine interactions) also to $Mn^{2+}$. ESR spectra of $Mn^{2+}$ in an alkali borate glass recorded at two separate microwave frequencies are displayed in Fig. 4(a). Note that the normalized magnetic field scale for the Ka-band spectrum ($\nu = 35$ GHz) is compressed by a factor of $\sim 4$ relative to the X-band spectrum ($\nu = 9$ GHz). Figure 4(c) represents a single Gaussian distribution in $|D|$ values plotted as $P_{|D|}(|D|/h\nu)$ for two separate values of $\nu$ (9 and 35GHz). On the basis of the correspondences indicated by the dotted lines, it has been proposed that a single bell-shaped distribution $P_{|D|}(|D|)$ might account for all details of the experimental spectra at both microwave frequencies (Griscom 1990).

In any event, the diagram of Fig. 4(b) appeared to account for the $Mn^{2+}$ spectrum in the $Li_2O \cdot 4B_2O_3$ polycrystalline compound by assuming a single discrete value of $|D|$ corresponding to $|D|/h\nu = 0.4$ at X band (Griscom and Griscom 1967). Actual computer

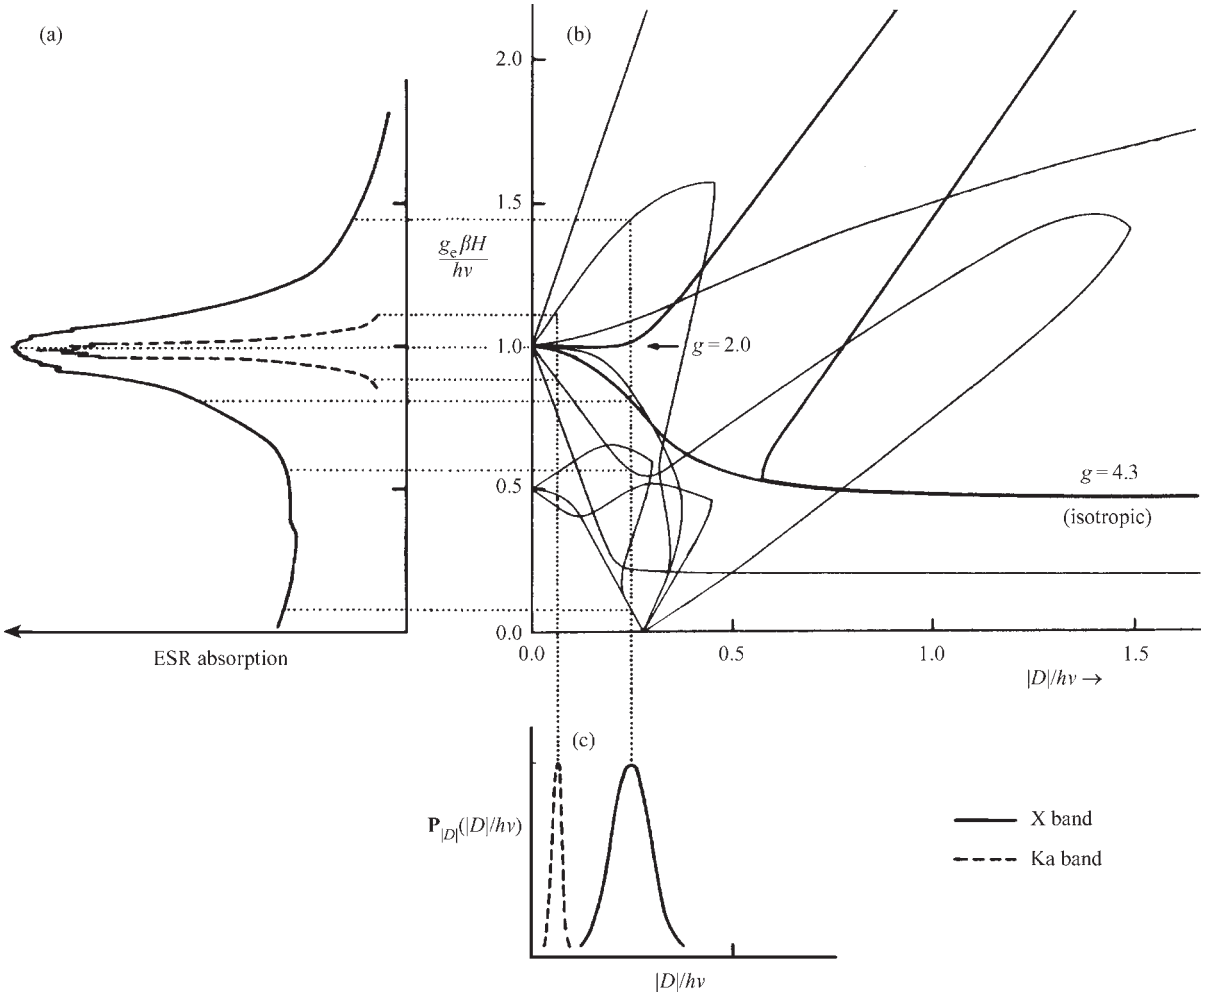

***Figure 4***
ESR of $Mn^{2+}$ in an alkali borate glass: (a) absorption spectra recorded at $\nu = 9$GHz (solid curve) and $\nu = 35$GHz (dashed curve); (b) calculated resonance conditions (neglecting $^{55}$Mn hyperfine splittings) $g_e \beta H_{res}/h\nu$ for H parallel to each of the principal axes of the tensor D (for the special condition $|E| = \frac{1}{3}|D|$) shown as functions of $|D|/h\nu$; (c) a Gaussian distribution of $|D|$ values plotted as $P_D(|D|/h\nu)$ for the two values of $\nu$ pertaining to the spectra of (a).

line-shape simulations of glassy-state ESR spectra based on matrix diagonalization in this parameter regime have been carried out by only a few workers to date (e.g., Kliava and Purāns 1980, Cugunov *et al.* 1994, Legein *et al.* 1993).

### *3.4 The Bigger Picture*

For convenience, the examples given above have pertained to a single paramagnetic species, $O_2^-$, and its occurrences as point defects in the amorphous peroxyborates (Sect. 3.1) and irradiated silica glasses (Sect. 3.2) and to a single transition group ion, $Mn^{2+}$, in an oxide glass system (Sect. 3.3). Critical reviews of the application of continuous-wave (c.w.) ESR to much broader ranges of point defects and transition group ions in oxide glasses have been given by Griscom (1980, 1990). The importance of carrying out comparative studies of both glassy and polycrystalline forms of the same material system when attempting to model paramagnetic centers in the former has been stressed in a review paper featuring point defects in the alkali borate system (Griscom 1993a).

Continuous-wave ESR of point defects in chalcogenide and multicomponent fluoride glasses have been reviewed by Griscom (1980) and (1993b), respectively. Examples of ESR investigations of

transition metal ions doped into fluoride and chalcogenide glasses can be found in Legein *et al*. (1993) and El Mkami *et al*. (1996), respectively. Street (1991) has reviewed applications of ESR to hydrogenated amorphous silicon (a-Si:H).

Continuous-wave ESR has also been employed to good advantage in the characterization of ferro- and ferrimagnetic particles precipitated in both synthetic and natural glasses (Griscom 1980, 1984). ESR studies of ferrimagnetic particles in 65-million-year-old glasses have a bearing upon the theory that an asteroidal impact triggered the extinction of the dinosaurs (Griscom *et al*. 1999).

Modern pulsed-ESR spectrometers afford several new capabilities over and above those inherent in c.w. methods. These include the possibility of separating overlapping spectra of paramagnetic centers characterized by differing spin-lattice relaxation times and the ability to resolve weak hyperfine interactions with ligand magnetic nuclei by the study of electron spin echo envelope modulation (ESEEM). ESEEM studies of defect centers in alkali borate glasses (Kordas 1997, Shkrob *et al*. 1999) appear to compel revision of some of the defect models proposed earlier on the basis of c.w. ESR results. Isoya *et al*. (1993) have used ESEEM to probe the spatial distribution of deuterium near dangling-bond defects in deuterated amorphous silicon.

Morigaki (1993) reviews the results of electron-nuclear double resonance (ENDOR) and optically detected magnetic resonance (ODMR) studies of dangling bonds in a-Si:H. Electron-hole recombination processes in a-Si:H have been investigated by a time-resolved ODMR technique (Mao and Taylor 1995). Shkrob and Trifunac (1997) comprehensively review time-resolved pulsed ESR and ODMR in radiation chemistry, including applications to amorphous silicon dioxide and a-Si:H.

## Amorphous Materials: Nuclear Magnetic Resonance, New Techniques

The elucidation of the structure and dynamics of solid or highly viscous amorphous materials represents a major challenge for techniques of characterization.

This holds, in particular, if atomistic resolution is desired. Here solid-state NMR offers unique possibilities, owing to its selectivity and versatility, in particular if multidimensional techniques are employed. This article describes advances in the field, emphasizing multidimensional exchange and double-quantum NMR. These techniques allow one, for example, to probe the *conformation* of macromolecules and their *packing* in both the solid state and the melt, as well as the *connectivity of building blocks* in inorganic glasses, and both the geometry and memory effects of complex dynamics.

## 1. Multidimensional Exchange NMR

In two-dimensional (2D) exchange NMR, information on the structure of the material is obtained by monitoring the transfer of nuclear magnetization between different building blocks, which can be distinguished in the NMR spectrum if differences in the chemical structure, conformation, or orientation of the distinct residue are reflected in different resonance frequencies. For optimum spectral resolution, magic-angle spinning (MAS) is employed, while nonrotating samples often yield better geometric information. Magnetization exchange can result from the dipole–dipole interaction between the nuclear spins; this leads to through-space spin diffusion, from which the spatial proximity and mutual orientation of molecular moieties, i.e., valuable *structural* information, can be determined.

Alternatively, magnetization exchange can result from a spatial movement of the moiety under study, thereby changing its NMR frequency, and thus providing information about *dynamics*. From the time needed for the exchange to occur, the *time scale* of the dynamic process can be directly obtained in real time. Moreover, the mutual orientation of molecular moieties before and after the move can be read from the off-diagonal exchange patterns (*geometry of dynamics*). This experiment provides information on *slow* dynamic processes on time scales between 1 ms and 100 s, which is equivalent to that available via incoherent neutron scattering on *fast* dynamics. By extending the NMR technique to three and four dimensions, *memory* effects concerning the *orientation* as well as the *rate* of molecular dynamics become experimentally accessible. For organic materials, $^{13}C$ and $^{2}H$ are widely used, while in inorganic systems, spin 1/2 nuclei such as $^{31}P$ are most popular (Schmidt-Rohr and Spiess 1994).

### 1.1 Structure

Multidimensional exchange and other solid-state NMR techniques are used to determine the *packing* of amorphous polymers in the glassy state (Klug *et al.* 1997, Tomaselli *et al.* 1997) and the *connectivity* of building blocks in inorganic glasses (Eckert 1994). Advanced approaches then combine the information provided by spectroscopy with computer simulations of the packing. Similarly, information about the conformation of macromolecules is readily available from an analysis of the observed $^{13}C$ chemical shift, making use of *ab initio* calculations of this spectroscopic parameter (Born and Spiess 1997).

### 1.2 Dynamics

The molecular dynamics is probably most complex in amorphous melts close to the glass transition. Nevertheless, applying various 2D exchange NMR techniques it has been possible to show that molecular dynamics, in both low molar mass glass-formers and synthetic polymers, consists of small-angle fluctuations causing total displacements of 2–4° and occasional jumps through 10–25° (Spiess 1997). By extension to 3D or even 4D NMR, the orientation of individual moieties can be probed at three, or even four, subsequent times, and memory effects concerning the geometry as well as the rate of the molecular dynamics in vitrifying polymer melts can be elucidated. Studies along these lines lead to the notion of *dynamic heterogeneities*, as shown schematically in Fig. 1. By combining 4D exchange NMR with spin diffusion, the length scale of these heterogeneities has been determined (Tracht *et al.* 1998).

## 2. Double-quantum Solid-state NMR

In 2D exchange NMR, direct magnetization transfer cannot readily be distinguished from transfer via a third spin or orientation. Likewise, it is difficult to distinguish transfer back to the original moiety or orientation from no transfer at all. Such problems do not occur in double-quantum (DQ) NMR, where a DQ coherence is generated within selected spin pairs. These can either be introduced by isotope labeling, in particular $^{13}C$–$^{13}C$, or separated from others by fast MAS. The latter approach even allows one to use solid-state $^{1}H$ NMR, which makes the technique widely applicable. Although mainly aimed at determining *structure*, the connectivity of functional groups provided by this technique also yields information about *dynamic* processes on mesoscopic length scales (Spiess 1997).

### 2.1 Structure

The advantages of DQ solid-state NMR have already been exploited for both inorganic and organic amorphous materials. In inorganic phosphate glasses, the connectivity between coordination polyhedrons has been elucidated with previously inaccessible detail by fast MAS DQ NMR, with motifs involving sequences of at least three polyhedrons of the same kind being

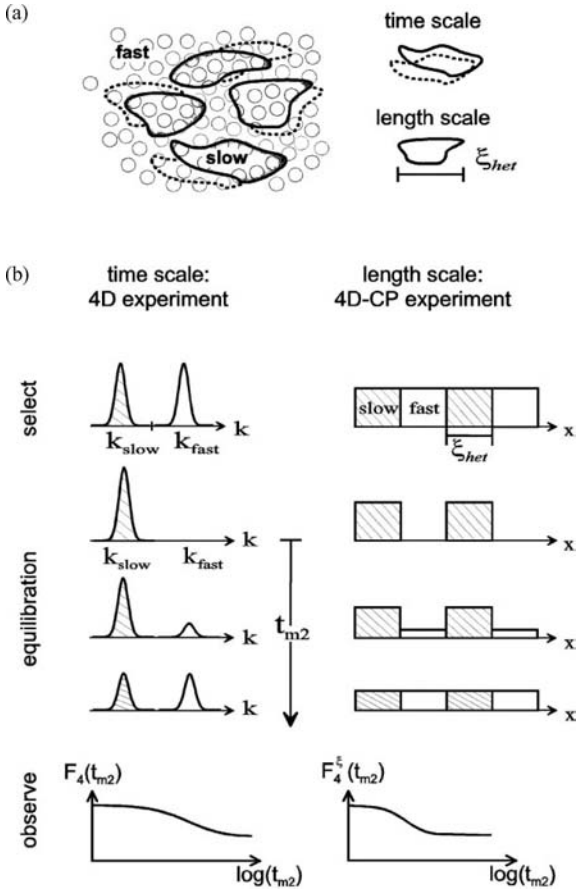

***Figure 1***
Schematic of (a) dynamic heterogeneities and (b) how their time and length scales can be measured by multidimensional NMR (after Tracht *et al*. 1998).

identified in such glasses for the first time (Feike *et al*. 1998). The conformation of organic polymers can be probed by the determination of torsional angles between nearby groups via DQ NMR on systems containing $^{13}C$–$^{13}C$ labels, and clear-cut differences between crystalline and amorphous regions have been elucidated (Schmidt-Rohr 1996). Moreover, using fast MAS DQ $^{1}H$ NMR, the structure of *hydrogen bonds* in disordered organic materials is now readily accessible. Owing to the high sensitivity of $^{1}H$ NMR, such experiments can be performed with samples of about 10 mg and measuring times as short as 30 minutes, thus seriously challenging the use of neutron scattering for this purpose (Schnell *et al*. 1998).

### 2.2 *Dynamics*

The application of DQ NMR with MAS to viscous melts even allows one to probe both the conformation of chains on mesoscopic scales as well as translational dynamics. This is due to the fact that the chain motion in entangled polymer melts is not completely isotropic, resulting in residual dipole–dipole couplings. From these residual couplings, *dynamic order parameters* can be determined, which are defined in the same way as the conventional order parameters in liquid crystals. As shown in Fig. 2, the spectral resolution of DQ MAS $^{1}H$ NMR of polymer melts is high enough to probe the order parameters for the *chain direction*. The values found are about an order of magnitude higher than anticipated from standard theory of polymer melts (Doi and Edwards 1986). From the time, molecular weight, and temperature dependence of the *dynamic order parameter*, information about *translational* chain motion as well as the length scale of the regions with partially ordered chains could be deduced (Graf *et al*. 1998).

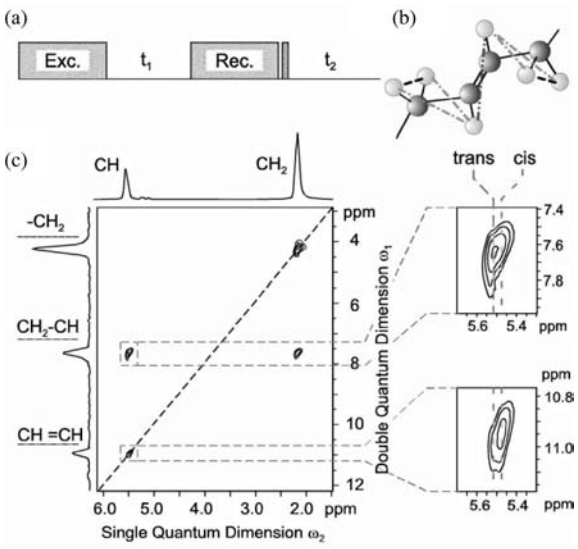

***Figure 2***
Schematic of (a) experimental scheme for measuring residual dipole–dipole couplings for selected proton–proton pairs in (b) *trans*-1,4-polybutadiene from (c) a $^{1}H$ DQ MAS NMR spectrum (after Graf *et al*. 1998).

## 3. *Conclusions*

The specific examples of advanced solid-state NMR discussed here indicate the potential of this technique. Moreover, it is possible to cover all length scales from molecular via mesoscopic to macroscopic levels (Spiess 1997). For example, the combination of spin-diffusion experiments with filters, which can discriminate between different dynamic behavior, allows one to probe the phase behavior and the interphase structure of heterogeneous polymers such as block copolymers, core-shell particles and organic–inorganic

hybrid materials, while NMR imaging can detect subtle differences in molecular dynamics resulting from nonlinear plastic deformation of solid polymers. Close analogies exist between solid-state exchange NMR and *incoherent* neutron scattering. Moreover, DQ solid-state NMR provides information even equivalent to *coherent* neutron scattering, albeit for much slower processes in the region of milliseconds. In short, advanced solid-state NMR is already an indispensable tool for the characterization of amorphous materials, and its importance is expected to increase further in the future.

## Amorphous Materials: Nuclear Spin Relaxation

Nuclear spin relaxation (NSR) techniques are widely used to investigate the dynamic properties of amorphous materials over a very wide time scale ranging from seconds to nanoseconds. Application of strong magnetic field gradients allows the measurement of tracer diffusion coefficients down to about $10^{-15}$m$^2$s$^{-1}$ on mesoscopic-length scales (Geil 1998). The techniques are extensively employed to amorphous polymers to study rotational and translational motions of molecular groups as well as glass-transition dynamics. In particular, incorporated site-specific deuterium probes yield very detailed information about molecular dynamics in polymers (Schmidt-Rohr and Spiess 1994). Until now, however, only a few NSR studies have been performed on amorphous metals. For instance, (Tang *et al*. 1998) have observed the diffusion of beryllium in a beryllium-containing metallic glass by means of $^{9}$Be NSR.

In inorganic glasses containing alkali ions, three processes are important which occur in different temperature regions. At low temperatures low-frequency transitions take place between energetically nearly equivalent positions of atomic configurations which are intrinsic to the glassy state (Dieckhöfer *et al*. 1997). At elevated temperatures, ionic diffusion becomes dominant, whereas close to the glass-transition temperature the shear viscosity decreases rapidly corresponding to fast-growing density fluctuations. The present contribution focuses on the study of ionic diffusion by NSR.

### *1. Diffusion-induced Nuclear Spin Relaxation*

Atomic diffusion gives rise to a time evolution of the nuclear magnetization in a sample towards the thermal equilibrium. The time constant (NSR time) $T_1$ of the process is given by the relation

$$1/T_1 = J(\omega_0) + 4J(2\omega_0) \tag{1}$$

where

$$J(\omega_0) = \mathrm{Re}\int_0^\infty G(t)\mathrm{e}^{-\mathrm{j}\omega_0 t}\mathrm{d}t \tag{1a}$$

denotes the spectral density of the diffusional pair correlation function

$$G(t) = \sum_{\mathrm{i}<\mathrm{j}} \langle \omega_{\mathrm{ij}}(0)\cdot\omega_{\mathrm{ij}}(t)\rangle_{\mathrm{therm.av}} \tag{1b}$$

at the applied Larmor frequency $\omega_0$ of the nuclear probes. $\omega_{\mathrm{ij}}(t)$ represents the time fluctuation of the coupling frequency between a resonant probe nucleus i and a neighboring species j (resonant or

nonresonant nuclear spin, electron spin, local charge, etc.) caused by the atomic movements.

For probe nuclei with spin $I = 1/2$ (such as $^{1}$H, $^{19}$F, $^{29}$Si, and $^{31}$P) $\omega_{ij}$ is due to mutual magnetic dipolar interactions, while for nuclei with $I > 1/2$ (alkali atoms like $^{7}$Li, $^{23}$Na, $^{85,87}$Rb, $^{11}$B, and $^{27}$Al) the coupling is dominated by the interaction between the nuclear quadrupole moment of the probe and electric field gradients at the probe site created by neighboring charges, e.g., ionic point charges. In either case $\omega_{ij}$ is related to the distance $r_{ij}$ of the particles by $\omega_{ij} \propto 1/r_{ij}^3$.

For a thermally activated diffusion of dilute particles in an ordered lattice, $G(t)$ can be expressed to a very good approximation by $G(t) \cong \langle \omega_c^2 \rangle \exp(-t/\tau)$ which corresponds to a Debye-like behavior of the diffusion-induced NSR rate $1/T_1|_{\text{Diff}}$ in accordance with $J(\omega) = \langle \omega_c^2 \rangle \tau/(1 + \omega^2\tau^2)$. Here, $1/\tau = 1/\tau_\infty \exp(-E/kT)$ is the jump rate of the moving particles with $E$ being the corresponding activation energy and

$$\langle \omega_c^2 \rangle = \frac{1}{N} \cdot \sum_{i<j}^{N} \langle \omega_{ij}^2 \rangle$$

denotes the mean-square coupling frequency.

In practice, $\langle \omega_c^2 \rangle^{1/2}$ is roughly equal to the width of the respective NMR line at sufficiently low temperatures ("rigid line width"). Moreover, one should note that the diffusive motion is observable not only by the NSR rate of the mobile particles but also by measuring the NSR rate of immobile probe nuclei. This is caused by the pair character of the coupling frequency $\omega_{ij}$ which becomes time dependent for both mobile and immobile probes whenever a hopping event occurs. Finally, as mentioned in the introduction, the measured NSR rate $1/T_1$ can be induced by different relaxation processes. If the processes are independent of each other, the related rates add up to the observed rate:

$$1/T_1 = 1/T_1|_{\text{Diff}} + \sum_{\text{other}} 1/T_1$$

## 2. *Ionic Diffusion in Glasses by Nuclear Spin Relaxation*

Ionic diffusion in glasses gives rise to a NSR rate that does not exhibit the classical Debye-like features described above. As shown as an example in Fig. 1 (diffusion-induced $^{19}$F NSR in the glassy fluorine ion conductor $27ZrF_4 \cdot 27HfF_4 \cdot 20BaF_2 \cdot 3LaF_3 \cdot 3AlF_3 \cdot 20NaF$ (ZBLAN20) (Kanert *et al.* 1996) the Arrhenius representation of $1/T_1|_{\text{Diff}}$ exhibits an asymmetric peak with remarkably different slopes on either side of the maximum. Further, the frequency dependence of $1/T_1|_{\text{Diff}}$ on the low-temperature side does not obey the $\omega^{-2}$ law proposed by the Debye relation.

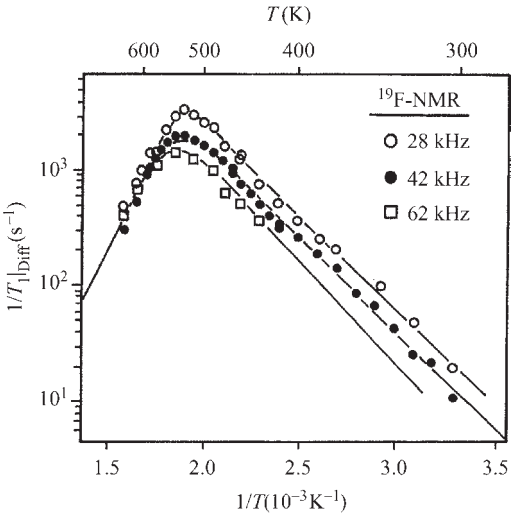

***Figure 1***
Arrhenius plot of the diffusion-induced $^{19}$F NSR rates in the glassy fluorine ion conductor ZBLAN20 observed in the rotating frame at three different frequencies (after Kanert *et al.* 1996).

Two theoretical approaches exist to interpret this unusual behavior. On the basis of the random structure of the glassy network, the correlation time $\tau$ (and correspondingly the activation energy $E$) is assumed to be distributed according to an appropriate distribution function $g(\tau)$ (Svare *et al.* 1993). Then, $G(t)$ is formed by a superposition of exponential decays according to

$$G(t) = \int_0^\infty g(\tau) e^{-t/\tau} d\ln\tau \qquad (2)$$

This approach represents the motion of a single particle in a random landscape. As discussed in detail by Beckmann (1988), a large variety of functions $g(\tau)$ can be used to fit properly the experimental data to the model.

There is strong evidence, however, that $G(t)$ decays inherently nonexponentially due both to the Coulomb interaction between the mobile ions and to their interactions with the glass skeleton. There exist different theoretical approaches dealing with the complex coupled motion of charged particles in a random matrix—e.g., Monte Carlo simulations (Maass *et al.* 1995), an analytical jump relaxation model (Funke 1993), a diffusion-controlled relaxation model (Elliott and Owens 1991), and a phenomenological coupling model (Ngai 1993)—which all result in a nonexponential time evolution of $G(t)$. So far, the models do not take into account the real structure of the glasses, i.e., a quantitative agreement cannot be expected between the experimental data and such calculations. In

future, molecular dynamics simulations will offer more realistic results of ionic diffusion-induced NSR in vitreous solids.

However, from the different models the following general features can be extracted: above a lower cross-over time $t_c(\sim 10^{-11}\text{s})$ the complexity of the ionic motion enhances the initial ionic jump time $\tau = \tau_{0,\infty}\exp(V/kT)$ to the apparent jump time

$$\tau(t) = f(t_c, n)\cdot \tau_0^{1/(1-n)} = \tau_\infty \exp\left(\frac{V}{(1-n)kT}\right) \quad (3)$$

where $V$ is the microscopic barrier height for the hopping ion and $n$ denotes the so-called coupling coefficient where $0 \leqslant n \leqslant 1$. Instead of $n$, often the coefficient $\beta = 1-n$ is used in the literature. In consequence, the mean-square displacement $\langle r^2(t)\rangle$ of a moving ion becomes sublinear in time between $t_c$ and $\tau(T)$ $(\langle r^2(t)\rangle \propto t^{1-n})$ which corresponds to a frequency dispersion of the apparent diffusion coefficient (Funke 1993) and gives rise to the non-Debye behavior of the NSR rate. For $t > \tau(T)$ the ion enters the Gaussian region where $\langle r^2(t)\rangle \propto t$. Here one observes the d.c. activation energy $E$ which is related to the barrier height $V$ *by* $E = V/(1-n)$.

The corresponding correlation function $G(t)$ can be expressed to a good approximation by a stretched exponential function in the relevant time regime $10^{-3} \leqslant t/\tau \leqslant 10^2$:

$$G(t) = \langle \omega_c^2 \rangle \exp[-(t/\tau)^{1-n}] \quad (4)$$

The diffusion-induced NSR rate is given by Eqns. (1), (1a), and (4), where for arbitrary exponents $1-n$ the Fourier transformation has to be performed numerically. The following analytical relation, however, represents a good approximation to the numerical results (Maass *et al.* 1995):

$$1/T_1|_{\text{Diff}} = \langle \omega_c^2 \rangle \left(\frac{\tau}{1+(\omega_0\tau)^{2-n}} + \frac{4\tau}{1+(2\omega_0\tau)^{2-n}}\right) \quad (5)$$

Applying this relation to Fig. 1 one obtains from the slopes $E = 1.15\,\text{eV}$ and $V = 0.34\,\text{eV}$, i.e., $n = 0.70$. The data confirm also the $\omega^{n-2}$-dependence of $1/T_1$ as proposed by Eqn. (5) for $\omega_0\tau \gg 1$. Moreover, the temperature dependence of the NSR rate maxima, which is given by the condition $\omega\tau \cong 0.6$, leads to a temperature-dependent correlation time $\tau = 10^{-16}\text{s}.\exp(E/kT)$ with $E = 1.15$ eV equal to $V/(1-n)$ in accord with Eqn. (3).

Approaching the glass-transition temperature $T_g$, the shear viscosity $\eta$ and, therefore, the related correlation time $\tau_\eta$ of the glass both decrease rapidly. The question whether the diffusion-induced NSR rate is affected by the process in the vicinity of $T_g$ is answered by the actual magnitude of the decoupling coefficient $R = \tau_\eta/\tau$. For $R \gg 1$ the glass structure is rigid on the time scale of the ionic hops, i.e., the observed NSR rate is dominated by the diffusion.

By use of site-selective spin excitation, NSR is able to detect the ionic diffusion separately in different environments. Kim *et al.* (1997) observed the motion of lithium ions in $Li_2S\cdot B_2S_3$ glasses near 3($BS_3$)- and 4($BS_4^-$)-coordinated boron atoms by measuring the temperature dependence of the $^{11}$B NSR rate of different parts of the $^{11}$B NMR spectrum belonging to $BS_3$ and $BS_4^-$ units, respectively. They obtained two well-separated NSR rate peaks. From the position of the maxima they drew the conclusion that the lithium ions move much faster close to the 3-coordinated boron than to the 4-coordinated boron. Such site-selective NSR experiments should also be applied to highly-resolved magic angle spinning (MAS)-NMR spectra (Eckert 1992) of glasses, opening new insights into the ionic motion at different sites of the glassy network.

With increasing temperature, the correlation time $\tau$ reaches the magnitude of the inverse NMR line width, and the width starts to decrease. Such motional line-width narrowing offers a simple possibility to distinguish diffusing from immobile probe nuclei: while for mobile probes the line width approaches zero for sufficiently high temperatures, the corresponding width of the immobile probes remains finite (Kanert *et al.* 1996).

## 3. Comparison Between Nuclear Spin Relaxation and Ionic Conductivity

It is very instructive to compare the results of diffusion-induced NSR with those obtained from complex ionic conductivity ($\tilde{\sigma}$) measurements. Though both $1/T_1(\omega,T)$ and $\tilde{\sigma}(\omega,T)$ measurements are probing the same physical process, in practice the results can differ due to the different structure of the underlying correlation functions $G(t)$ and $G_\sigma(t)$. While $G(t)$ is a pair correlation function of the coupling frequencies $\omega_{ij}$, $G_\sigma$ is a particle autocorrelation function of the ionic velocities $v_i$ (Ngai 1993). In practice, however, the results of NSR and ionic conductivity agree fairly well, i.e., both the correlation functions can be approximated by a stretched exponential (Eqn. (4)) with the same coupling coefficient $n$ but different time constants $\tau$ and $\tau_\sigma$.

This is due to the fact that $\tau$ is the mean waiting time (correlation time) of an ion between consecutive hops, while $\tau_\sigma$ denotes the relaxation time of the decaying electric field under constant dielectric displacement. According to Funke (1993), $\tau$ and $\tau_\sigma$ are related by

$$\tau = \frac{nq^2x_0^2}{6\varepsilon_0\varepsilon_\infty kT}\tau_\sigma = C\cdot\tau_\sigma \quad (6)$$

where $n$ is the density and $q$ the charge of the ions, and $x_0$ denotes the mean jump distance of a hopping

ion. Using appropriate values for the different quantities (see below) one finds $C \cong 5 \div 100$, i.e., $\tau \gg \tau_\sigma$ in qualitative accord with experimental findings (Kanert *et al.* 1996).

For a uniform correlation function $G(t/\tau)$ for both NSR and conductivity differing only with regard to the time constant $\tau$ (i.e., $\tau_\infty \neq \tau_{\sigma,\infty}$), the NSR rate $1/T_1$ can be linked to the imaginary part of the electric modulus, $M''$, by the following general expression (Funke 1993)

$$1/T_1(\omega_0\tau(T)) \propto [M''(\omega_0\tau_\sigma) + 2M''(2\omega_0\tau_\sigma)]/\varpi_0 \quad (7)$$

This relation turns out to be very useful for comparative NSR and conductivity experiments on ionic transport in glasses.

Unfortunately, until now only a limited number of investigations exists on ionic diffusion in inorganic glasses comparing in detail NSR and conductivity data. Blache *et al.* (1998) performed an extended study on a series of lithium silicophosphate glasses measuring the temperature dependence of $Li^+$ diffusion by NMR and electrical conductivity for different glass compositions. Part of the results are shown in Fig. 2 exhibiting the dependence of the activation energy $E$ and barrier height $V$ on the concentration $c$(Li) of the lithium ions for a fixed ratio of the network formers $SiO_2$ and $P_2O_5$. The data were obtained from electrical conductivity, $^7$Li and $^{31}$P NSR, and $^7$Li tracer diffusion $D_T(T)$ using the NMR field-gradient technique (Geil 1998). As expected for the diffusion of a single species of charged carriers, $D_T(T)$ was found to be in accord with the diffusion constant $D_\sigma(T)$ calculated from the dc conductivity $\sigma_{dc}$ by

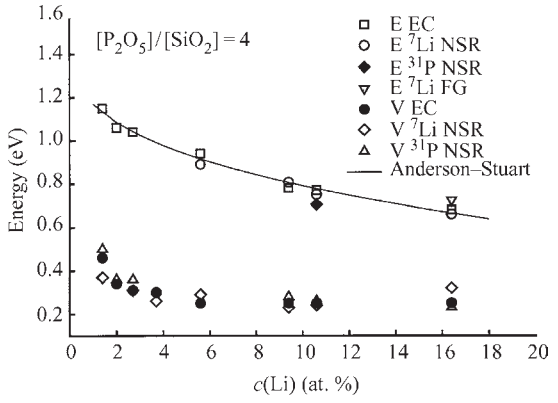

***Figure 2***
Dependence of the activation energy $E$ and barrier height $V$ of lithium diffusion on the amount of lithium in the glassy lithium ion conductor $Li_2O \cdot SiO_2 \cdot P_2O_5$ observed by different methods (see text). Solid curve is a fit by the Anderson–Stuart model (after Blache *et al.* 1998).

$D_\sigma = k/(q^2 n) \cdot \sigma_{dc} \cdot T$, i.e., the Haven ratio $D_T/D_\sigma$ is about 1.

The figure demonstrates that the corresponding quantities $V$ and $E$ obtained from the different experiments agree well, resulting in a uniform coupling coefficient $n = 0.67$ for $c \geqslant 2$ at.%. For $c \leqslant 2$ at.% the data indicate a slight decrease of $n$ as proposed by the coupling model (Ngai 1993). The observed monotonic decrease of the activation energy $E$ with increasing amount of lithium ions could be interpreted fairly well by the simplified Anderson–Stuart relation (Patel and Martin 1992) $E = E_1 + E_2 \cdot c(\mathrm{Li})^{1/3}$ using $E_1 = 1.5\,\mathrm{eV}$ and $E_2 = 1.52\,\mathrm{eV}\ (\mathrm{at.\%})^{-1/3}$ as best-fit parameters.

Moreover, the authors measured the dependence of $\tau$ and $\tau_\sigma$ on temperature and on the concentration of lithium ions. Evaluation of the data revealed that the following relation is approximately valid:

$$\tau \cong 10\tau_\sigma = 5 \times 10^{-14}\mathrm{s} \exp\left(\frac{E(c(\mathrm{Li}))}{kT}\right)$$

for $c$(Li) $\geqslant 5$ at.%. This result seems to confirm Eqn. (6): using the suitable values $\langle n \rangle \cong 0.8 \times 10^{28}\mathrm{m}^{-3}$ ($\triangleq$ 10at.% Li), $\langle T \rangle = 500\mathrm{K}$, $\varepsilon_\infty = 3$, $x_0 = 2.4\mathrm{\AA}$, one obtains $C \cong 10$ in accord with the experimental findings. It has to be noted, however, that in some glassy ionic conductors the activation energy $E$ observed by NSR was found to be somewhat larger than the corresponding energy $E_\sigma$ measured by dc conductivity, i.e., $n > n_\sigma$ using the relation $E = V/(1 - n)$ (Kanert *et al.* 1996). Such deviations were proposed also by Monte Carlo simulations (Maass *et al.* 1995). At present, however, a final decision whether Eqn. (6) is correct and $E$ equals $E_\sigma$ cannot be made because of a lack of sufficient experimental data.

## Amorphous Superconductors

Amorphous superconductors are a class of superconducting materials that lack long-range, translational ordering in their atomic arrangement. Since the discovery of superconductivity in amorphous bismuth and gallium (a-Bi, a-Ga) by Bückel and Hilsch in the 1950s, noncrystalline superconductors have been the subject of numerous experimental and theoretical studies. Recently, interest in this field has been focused on amorphous transition-metal (TM) superconductors as opposed to the amorphous nontransition-metal (non-TM) superconductors investigated earlier.

The techniques used to synthesize amorphous superconducting materials include quenching from the vapor (obtained by evaporation or sputtering), particle irradiation, ion mixing or ion implantation, and liquid quenching. The technique of quenching from the melt is capable of producing large quantities of metallic glasses in the form of ribbons, flakes or powder suitable for large-scale engineering applications. Vapor deposition and particle bombardment methods are used to prepare thin films amenable to small-scale electronic device applications.

In general, the Cooper pairs in superconductors are formed from time-reversed electron states, no matter how complicated these states are in real space as a result of scattering from various disorders. Hence, the basic mechanism of superconductivity is not expected to be different in disordered or crystalline materials. There are, however, several interesting differences between amorphous superconducting materials and their crystalline counterparts; these differences will be discussed.

### 1. Systematics of the Transition Temperature

#### 1.1 Nontransition Metals

Amorphous non-TM superconductors usually show an enhancement in transition temperature $T_c$ over that of corresponding crystalline phases. For example, a-Bi thin films become superconducting at about 6 K, whereas the crystalline phase, a semimetal, remains normal down to 0.05 K. The value of $T_c$ for a-Ga is found to be 8.4 K, significantly higher than the $T_c$ of the crystalline phases ($T_c = 1.08$ K for $\alpha$-Ga and 6 K for $\beta$-Ga). A more complete listing of the $T_c$ values of amorphous superconductors and their crystalline counterparts is given in Table 1. It is

***Table 1***
The $T_c$ of some amorphous (or highly disordered) superconductors and their crystalline counterparts.

| Metals | Amorphous or highly disordered (K) | Crystalline (K) |
|---|---|---|
| Nontransition metals | | |
| Pb | 7.16 | 7.2 |
| $Pb_{50}Bi_{50}$ | 6.99 | 8.1 |
| Ga | 8.4 | 6($\beta$-Ga)<br>1.08 ($\alpha$-Ga) |
| Bi | 6.1 | $<0.05$ |
| Be[a] | 10 | 0.026 |
| Al[a] | 6 | 1.18 |
| Transition metals | | |
| Nb | 5.7 | 9.2 |
| Mo | 8–9 | 0.9 |
| $Nb_3Ge$ | 3.6 | 23 |
| $Nb_3Si$ | 3.9 | 18 |
| $Nb_3Sn$ | 3 | 18 |
| $V_3Si$ | 1.5 | 17 |
| $Mo_3Si$ | 7.5 | 1.4 |

a Extrapolated values.

noted that $T_c$ for amorphous non-TM superconductors tends to increase with valence and with atomic number for a given valence (Johnson 1981; Bergmann 1976).

### *1.2 Transition Metals*

A systematic study by Collver and Hammond (1973) on amorphous 4*d* and 5*d* TM elements and alloys thereof indicates that the well-known Matthias rule for crystalline superconductors (see *Superconducting Materials, Types of*) is significantly altered for the amorphous state. The variation of $T_c$ as a function of $e/a$ (the average valence electrons–atom ratio) shows a sharp peak at $e/a = 6.4$, corresponding to a half-filled *d* shell (see Fig. 1). More recent work has revealed that $T_c$ as a function of $e/a$ is more symmetric than the original Collver–Hammond curve and similar systematics are also observed in some liquid-quenched TM-metalloid metallic glasses. The $T_c$ of amorphous TM alloys made from elements widely separated in the periodic table is always significantly lower than that of the original Collver–Hammond alloys composed of nearest 4*d* or 5*d* elements. The $T_c$ of alloys mixing the 4*d* and 5*d* elements shows an even more intriguing behavior. For example, whereas the values of $T_c$ for a-MoRe alloys are slightly higher than those for the a-MoRu alloys, lower $T_c$ values have been found for all the a-MoRh alloys in the same range of $e/a$. The $T_c$ values for a-NbIr, a-NbRh, a-TaRh and a-TaIr alloys are considerably lower than those for corresponding amorphous near-neighbor TM alloys and show essentially no variation of $e/a$. These data along with others are plotted in Fig. 1. (Recent $T_c$ data on amorphous alloy systems containing 3*d* elements and noble metals, for example a-ZrCu, a-ZrFe and a-ZrNi, are not included in this plot and should be treated separately.) It is clear from Fig. 1 that there is no universal curve of $T_c$ as a function of $e/a$ for all amorphous TM alloys. It has been suggested that the effects of spin fluctuations and charge transfer may be responsible for this.

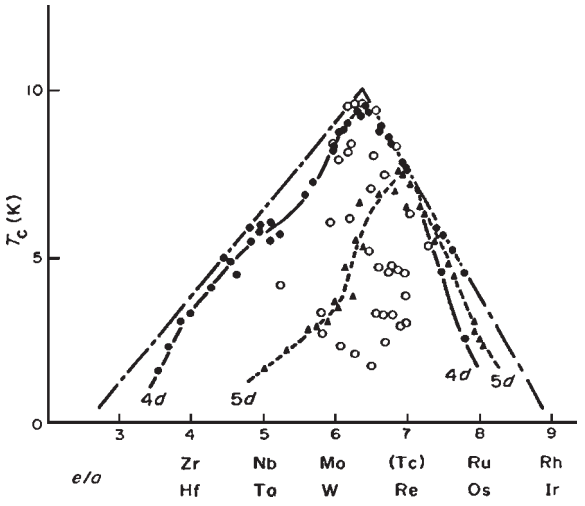

***Figure 1***
The $T_c$ of amorphous TM elements and alloys as a function of $e/a$. The original Collver–Hammond curves for amorphous TM superconductors are shown for (•) 4*d* and (▲) 5*d* metals; also shown are (○) the $T_c$ values of various amorphous TM alloys made from elements widely separated in the periodic table and from mixing the 4*d* and 5*d* metals. For a given $e/a$, there is an upper limit of $T_c$ as outlined by the triangular peak (– · – · )

At present, there is no satisfactory interpretation for all the systematics of $T_c$ previously described. The data shown in Fig. 1 do suggest, however, that there is an upper limit of $T_c$ for a given $e/a$ in amorphous 4*d* and 5*d* TM alloys as roughly outlined by the modified Collver–Hammond curve. The fact that the peak of this upper-bound curve coincides with half-filled *d* shells suggests that there is an atomic parameter characterizing the $e/a$ dependence of $T_c$. This point can be qualitatively discussed with the aid of the well-known McMillan formula:

$$T_c(\theta_D/1.45)\exp\left[\frac{-1.04(1+\lambda)}{\lambda-\mu^*(1+0.62\lambda)}\right] \qquad (1)$$

where $\lambda$ is the dimensionless electron–phonon coupling parameter, $\mu^*$ is the effective electron–electron Coulomb pseudopotential and $\theta_D$ is the Debye temperature. The parameter $\lambda$ can be expressed as

$$\lambda = N(E_F)\langle I^2\rangle / M\langle\omega^2\rangle \qquad (2)$$

where $N(E_F)$ is the bare electronic density of states at the Fermi level, $\langle\omega^2\rangle$ is an average square phonon frequency and $\langle I^2\rangle$ is the Fermi-surface average of the electron–phonon interaction strength.

In terms of tight-binding models, it has been suggested that the Collver–Hammond curve essentially reflects the $e/a$ dependence of $N(E_F)$ and that the ratio $\langle I^2\rangle/\langle\omega^2\rangle$ is a constant throughout the 4*d* series. A systematic study of the low-temperature specific heat of some of the more stable Collver–Hammond alloy films is crucial in determining $N(E_F)$ quantitatively as a function of $e/a$. It should be pointed out that the empirical and calculated values of $\langle I^2\rangle$ for the 4*d* transition metals (Butler 1977) are insensitive to structural change and their $e/a$ variation closely mimics the $T_c$ upper limit shown in Fig. 1.

## *2. Strength of the Electron–Phonon Interaction*

The coupling between electrons and phonons is fundamentally important to the occurrence of superconductivity and is of particular interest in the case of amorphous superconductors in view of possible

enhancement of the coupling strength through structural disorder as suggested by several theories. The strength of the electron–phonon interaction can be estimated from (a) the ratio of Bardeen–Cooper–Schrieffer (BCS) energy gap to transition temperature, $2\,\Delta(0)/k_B T_c$, and (b) the parameter $\lambda$ (see *Superconducting Materials*: *BCS and Phenomenological Theories*). The BCS gap can be measured directly by superconductive tunnelling experiments or estimated indirectly from calorimetric measurements. The parameter $\lambda$ can be determined using either the McMillan formula for $T_c$ or the technique of superconductive tunnelling spectroscopy through

$$\lambda = 2\int_0^\infty d\omega\, \omega^{-1}\alpha^2(\omega)F(\omega) \tag{3}$$

where $\alpha^2(\omega)F(\omega)$ is the Eliashberg electron–phonon spectral function.

The results accumulated so far clearly lead to three conclusions.

First, amorphous non-TM superconductors are all characterized by a very strong electron–phonon coupling (i.e., $2\,\Delta(0)/k_B T_c \sim 4$–5 and $\lambda > 2$), as are their crystalline counterparts.

Second, amorphous TM or TM-based superconductors are found to be in the BCS weak-coupling limit. In particular, the electron–phonon coupling strength of several strong-coupled A15 superconductors is found to be reduced to the BCS limit in the amorphous state. These experimental findings suggest that structural disorder alone does not necessarily give rise to a significantly enhanced electron–phonon interaction.

Third, a detailed analysis of the tunnelling data for various amorphous non-TM superconductors has revealed that the Eliashberg function is enhanced and varies linearly with $\omega$ in the low-frequency region as predicted by various theories. There is no significant low-frequency enhancement found in $\alpha^2F(\omega)$ for amorphous nitrogen-stabilized niobium and molybdenum films. The function $\alpha^2F(\omega)$, in fact, follows the phonon density of states $F(\omega)$ based on a structural model of dense random packing of hard spheres. From this finding, it is concluded that the observed low-frequency enhancement in $\alpha^2F(\omega)$ for amorphous non-TM superconductors is essentially a manifestation of an increase in the electron–phonon interaction caused by structural disorder. The lack of such enhancement in amorphous TM superconductors is attributed to the "nearly localized" nature of *d* electrons, which are relatively insensitive to structural disorder.

In a more general perspective, this result can also be understood by noting the difference between the TM and non-TM amorphous superconductors in the effectiveness of the phonon modes in contributing to the electron–phonon coupling. Unlike amorphous TM superconductors, the phonon density of states in non-TM superconductors (crystalline and amorphous) is distributed over a range from 0 to approximately 10 meV and is most efficient in achieving a strong electron–phonon interaction (Tsuei 1981).

## 3. Critical Fields

Amorphous superconductors are all characterized by relatively large upper critical fields $H_{c2}$ in view of their generally low $T_c$ values. This is mainly a manifestation of a short electron mean free path ($l \lesssim 1$ nm) leading to a short zero-temperature coherence length $\xi(0)$ (see *Coherence Length, Proximity Effect and Fluctuations*). The upper critical field at 0 K is related to $\xi(0)$ by

$$H_{c2}(0) = \Phi_0/2\pi\xi^2(0) \tag{4}$$

where $\Phi_0 = h/2e$ is the flux quantum. Typical values of $\mu_0 H_{c2}(0)$ are about 2–5 T (20–50 kG) for amorphous non-TM superconductors and are in the range 10–40 T (100–400 kG) for the noncrystalline TM or TM-based superconductors. The lower critical field $H_{c1}(T)$ for several metallic glasses has been measured; $\mu_0 H_{c1}(0)$ values are typically of the order of 1–10 mT (10–100 G). Both $H_{c2}(T)$ and $H_{c1}(T)$ are found to vary linearly with temperature over a wide range of temperatures below $T_c (\sim 0.5 T_c$ to $T_c)$. Examples of $dH_{c2}/dT$ near $T_c$ are about $-2\,\mathrm{T\,K^{-1}}$ to $-3\,\mathrm{T\,K^{-1}}$ for amorphous TM superconductors and about $-0.5\,\mathrm{T\,K^{-1}}$ for amorphous simple metals. The values of $dH_{c1}/dT$ are about $1\,\mathrm{mT\,K^{-1}}$.

From critical-field measurements, values for $\xi(0)$ and the Ginzburg–Landau parameter $\kappa$ can be estimated; the values are of the order of 5 nm and 60, respectively. Such large values of $\kappa$ represent a true indication of the extreme type II, or "dirty limit," behavior expected for amorphous superconductors. Detailed studies of the temperature dependence of $H_{c2}(T)$ for several amorphous TM alloys indicate that $H_{c2}$ is enhanced at low temperatures by the effect of weak localization as predicated by the FEM theory (Fukuyama *et al.* 1984). The amount of the $H_{c2}$ enhancement depends on the alloy system and can be as large as 20% (Poon 1985a,b). It should be mentioned that the quantum correction effects of weak localization and interaction also manifest themselves in suppressing $T_c$ (Fukuyama *et al.* 1984) and reducing the temperature coefficient of the normal-state resistivity.

## 4. Flux Pinning Phenomena

The pinning of the flux line lattice (FLL) in superconductors can be studied by measuring the critical current density $J_c(T, H)$ as a function of temperature and applied field. Results of critical-current measurements on amorphous superconductors show that $J_c$ at $H = 0$ is in general relatively low ($\sim 10^7$–$10^8\,\mathrm{A\,m^{-2}}$)

and that it decreases rapidly with increasing field. Such a weak FLL pinning can probably be attributed to the homogeneity and isotropy, on a scale of $\xi(0)$, intrinsic in all amorphous materials. It is exactly this characteristic property which makes direct use of amorphous superconductors in high-field applications less attractive. A possible solution to this problem is to incorporate, by appropriate heat treatments, some second-phase precipitates in an amorphous superconducting matrix (Johnson 1981). Homogeneous amorphous superconductors, however, are ideal for studying flux pinning phenomena in terms of existing theory (see *Electrodynamics of Superconductors: Flux Properties*). The fact that amorphous TM or TM-based superconductors are weak coupled and in the extreme type II limit simplifies the analysis of the experimental data considerably, because theoretical expressions in the dirty limit are highly developed. Furthermore, pinning behavior in these materials (in the form of carefully prepared thin films) is expected to be insensitive to complications arising from pinning by surface irregularities, edge dislocations and buckling of the flux lines.

A recent fundamental study of flux pinning in amorphous films of $Nb_3Ge$ and $Nb_3Si$ (Kes and Tsuei 1981) led to the following results.

(a) Owing to the large $\kappa$ and low $J_c$, the FLL in amorphous thin-film superconductors is essentially two dimensional.

(b) The pinning force density $F_p(=J_cB$, where $B$ is flux density) as a function of perpendicular field and temperature is found to be in good agreement with the theory of collective pinning.

(c) A sharp peak in $F_p$ is observed near $H_{c2}$. A pinning-mediated renormalization of the shear modulus of the FLL is probably responsible for this peak effect.

(d) The $F_p$ for samples with relatively large $J_c$ shows a domelike behavior characteristic of strong pinning. By annealing, $J_c$ decreases by up to two orders of magnitude and both two-dimensional collective pinning and the peak effect are recovered, supporting the view that weak pinning is an essential requirement to observe the collective behavior. It has also been demonstrated that the flux pinning can serve as a sensitive probe to study structural relaxation in amorphous metals.

The concept of collective flux pinning along with the consideration of the thermal fluctuation effects has been used to understand the flux-creep-related phenomena in high-$T_c$ cuprate superconductors (Feigel'man and Vinokur 1990). It is interesting to note that both amorphous superconductors and high-$T_c$ copper oxides are characterized by short coherence length and relatively high normal-state resistivity except that there is a large difference in $T_c$ and temperature scale.

## 5. Potential Applications

Most amorphous non-TM superconductors are structurally stable only at very low temperatures. For example, a-Bi films are found to crystallize at 20 K and the amorphous phase of gallium films transforms into a crystalline state ($\beta$-Ga, $T_c = 6.4$ K) at about 15 K. Further annealing at 60 K results in the room-temperature stable phase $\alpha$-Ga with a $T_c$ of 1.08 K. In sharp contrast, many TM or TM-based superconducting alloys can resist crystallization at temperatures up to more than 1000 K. In addition to this phase stability, these materials are ductile, flexible and possess extremely high mechanical strength, comparable with that of single crystals. Potential areas for using amorphous superconductive materials include high-field magnets, especially for use in an environment of high-level radiation, and possibly some specialized vortex memory devices for computer applications.

## Boltzmann Equation and Scattering Mechanisms

When an external force is applied to the conduction electron system of a solid, a drift velocity results. Random scattering effects tend to restore a dynamical balance between the acceleration caused by the external forces and restoring forces due to scattering processes.

In general we expect currents $J_i$ to develop as a response of the system to generalized external forces $X_k$. If these responses can be considered to be linear the relation between the forces $X_k$ and the currents $J_i$ can be written as

$$J_i = \sum_{k=1}^{n} L_{ik} X_k \tag{1}$$

The coefficients $L_{ik}$ are called the linear transport coefficients. Their physical nature depends on which current is connected to which force. If the forces and the currents are properly selected so that the internal entropy production per unit time is

$$\frac{\mathrm{d}S_i}{\mathrm{d}t} = \sum_{i=1}^{n} J_i X_i \tag{2}$$

then they are canonically conjugated in the sense of irreversible thermodynamics. In this case Onsager's theorem provides the symmetry relation

$$L_{ik}(\vec{B}) = L_{ki}(-\vec{B}) \tag{3}$$

for these transport coefficients, where $\vec{B}$ is an external magnetic field.

In principle two different kinds of force can induce a current $J_i$. The first and the more familiar type is an electric field acting on the electron system. The second type of force has its origin in statistics; it is not a "force" in the usual sense but arises from concentration and temperature gradients. It should be noted that an external magnetic field is influencing the transport phenomena but does not contribute to a current in the sense discussed above.

In order to give a theoretical description of the transport phenomena (electrical and thermal resistivity, thermopower, Peltier effect, etc.) the Boltzmann formalism may be used as one among a number of different other theoretical concepts.

### 1. Distribution Function

The Boltzmann formalism is based on the assumption that a distribution function in phase space $(\vec{r}, \vec{k})$ can be defined. Since we are dealing with a strongly interacting quantum mechanical system it is by no means clear that such a function can be defined because of the Heisenberg uncertainity principle. In many cases, however, one considers the distribution function to be a function of $\vec{k}$ only; the Heisenberg uncertainity principle does not preclude the use of this distribution. When an $\vec{r}$-dependence is considered at all, the position in real space usually occurs through the dependence of the distribution function on external position dependent parameters, such as the $\vec{r}$-dependence of the temperature in the case of an applied temperature gradient. This expression makes sense if the electrons can be localized over macroscopic distances. This can be done by using wave-packets which contain a small number of wave-numbers. In this limited sense one can use a distribution function which is a function of both $\vec{k}$ and $\vec{r}$ (Butcher 1973).

#### 1.1 Bloch Electrons

For an electron interacting with a periodic potential

$$V(\vec{r} + \vec{R}_l) = V(\vec{r}), \quad \vec{R}_l \text{ lattice vector} \tag{4}$$

the stationary eigenstates are given by the solutions of the Schrödinger equation

$$\left(-\frac{\hbar^2}{2m}\Delta + V(\vec{r})\right)\psi_{n\sigma\vec{k}}(\vec{r}) = E_{n\sigma}(\vec{k})\psi_{n\sigma\vec{k}}(\vec{r}) \tag{5}$$

where $n$, $\sigma$, and $\vec{k}$ denote the band index, the spin, and the wave-vector of the conduction electrons, respectively.

The eigenstates are usually written as Bloch functions

$$\psi_{n\sigma\vec{k}}(\vec{r}) = \frac{1}{\sqrt{N}} e^{i\vec{k}\cdot\vec{r}} u_{n\sigma\vec{k}}(\vec{r}) \tag{5a}$$

with the periodic amplitude

$$u_{n\sigma\vec{k}}(\vec{r} + \vec{R}_l) = u_{n\sigma\vec{k}}(\vec{r}) \tag{5b}$$

where $N$ is the number of the unit cells of the crystal. The eigenvalues $E_{n\sigma}(\vec{k})$ of Eqn. (5) are functions of the wave-vector $\vec{k}$. From Kramer's degeneracy

$$E_{n,-\sigma}(-\vec{k}) = E_{n,\sigma}(\vec{k}) \tag{5c}$$

it follows that the electrical (and the thermal) currents for a thermodynamical equilibrium state are zero.

### *1.2 Semiclassical Motion of Wave-packets*

In order to describe the movement of an electron through the periodic array of the ions in the lattice, the electrons are represented by wave-packets. Constructing a wave-packet from Bloch states in the vicinity of a wave vector $\vec{k}$ in the energy band $n\sigma$, we can consider the time dependence of the shape of this wave-packet in real space as well as in reciprocal space corresponding to a classical particle with position $\vec{r}$ and momentum $\vec{p}$.

The corresponding semiclassical equations describing the movement of a wave-packet are:

$$\vec{v} = \frac{\mathrm{d}\vec{r}}{\mathrm{d}t} = \frac{1}{\hbar}\vec{\nabla}_k E_{n\sigma}(\vec{k}) \tag{6a}$$

$$\frac{\mathrm{d}\vec{k}}{\mathrm{d}t} = \frac{1}{\hbar}\vec{F} \tag{6b}$$

$\vec{F}$ is an external force acting on the electron (for an electromagnetic field this force is the Lorentz force). The mechanical momentum $\vec{p}$ is connected in the usual way with the wave vector: $\vec{p} = \hbar\, k$.

### *1.3 Electrical and Heat Current*

Using Eqns. (6a) and (6b) each electron in an energy band $n\sigma$ gives a trajectory in the 6-dimensional phase space $(\vec{k}, \vec{r})$. We therefore define (in analogy to classical statistical mechanics) a distribution function $f(n, \sigma, \vec{k}, \vec{r}, t)$ with the following properties

$$\frac{1}{(2\pi)^3}\Delta^3 k \Delta^3 r \times f(n,\ \sigma,\ \vec{k},\ \vec{r},\ t) = \begin{cases} \text{number of electrons} \\ \text{in the energy band } n\sigma \\ \text{within the phase space} \\ \text{volume } \Delta^3 k \Delta^3 r \end{cases} \tag{7}$$

The factor $1/(2\pi)^3$ ensures, that the distribution function $f(n, \sigma, \vec{k}, \vec{r}, t)$ for a local thermodynamical equilibrium state (characterized by the local temperature $T(\vec{r})$ and the local chemical potential $\mu(\vec{r})$) is identical with the local Fermi distribution function

$$f(n,\ \sigma,\ \vec{k};\ T(\vec{r}),\ \mu(\vec{r})) = f_0\left(\frac{E_{n\sigma\vec{k}} - \mu(\vec{r})}{k_B T(\vec{r})}\right) \tag{8}$$

whereby

$$f_0(x) = \frac{1}{e^x + 1}$$

Using the distribution function we are able to calculate the mean values of all single electron properties.

In the following the abbreviation $\gamma$ is used for all three quantum numbers $n$, $\sigma$, and $\vec{k}$ ($\gamma \equiv n, \sigma, \vec{k}$) in order to characterize the Bloch states. Furthermore we use the notation

$$\sum_\gamma \cdots = \sum_{n,\sigma} \frac{Vol}{(2\pi)^3} \int_{1.\mathrm{BZ}} \mathrm{d}^3 k \ldots \tag{9}$$

where the integral is over the 1st Brillouin zone. The local electron density can now be written as

$$n(\vec{r},\ t) = \frac{1}{Vol}\sum_\gamma f(\gamma,\ \vec{r},\ t) \tag{10}$$

with the total number of electrons $N_e$

$$N_e = \int \mathrm{d}^3 r n(\vec{r},\ t) \tag{11}$$

It then follows that the electrical current density, $\vec{I}$, may be expressed as

$$\vec{I}(\vec{r},\ t) = \frac{1}{Vol}\sum_\gamma f(\gamma,\ \vec{r},\ t)(-e\,\vec{v}_\gamma) \tag{12}$$

whereby $e = |q_e|$ is the absolute value of the electric charge of an electron.

A similar expression may be derived for the thermal heat current density $\vec{J}$,

$$\vec{J}(\vec{r},\ t) = \frac{1}{Vol}\sum_\gamma f(\gamma,\ \vec{r},\ t)(E_\gamma - \mu)\,\vec{v}_\gamma \tag{13}$$

The energy is measured relative to the chemical potential $\mu$; this is the correct heat-current for a statistical force caused by a temperature gradient. Then we obtain the usual relation between the thermopower $S$ and the Peltier coefficient $\Pi$: $\Pi = TS$.

## *2. Boltzmann Equation*

For the calculation of the current densities $\vec{I}$ and $\vec{J}$ the distribution function $f$ is needed (see Eqns. (12) and (13)). This distribution function is a solution of the Boltzmann equation in presence of external forces $\vec{F}$. The Boltzmann equation describes the time development of the distribution function and can be written in the form

$$\frac{\partial f(\gamma,\ \vec{r},\ t)}{\partial t} + \frac{1}{\hbar}\vec{F}\cdot\vec{\nabla}_k f(\gamma,\ \vec{r},\ t) + \vec{v}\cdot\vec{\nabla}_r f(\gamma,\ \vec{r},\ t) = \left(\frac{\partial f}{\partial t}\right)_C \tag{14}$$

The left hand side describes the time development of the distribution function caused by the semiclassical equations of motion (see Eqns. (6a) and (6b)). These terms are called drift terms. The right hand side is the

collision term. It takes into account the changes of the distribution function due to scattering processes.

### 2.1 Collision Term

The change of $f(\gamma, \vec{r}, t)$ caused by scattering processes may be subdivided as follows:

Scattering processes from electron state $\gamma'$ to electron state $\gamma$ result in an increase of $f(\gamma, \vec{r}, t)$:

$$f(\gamma')[1-f(\gamma)]P_{\gamma'\to\gamma} \tag{15a}$$

Scattering processes from electron state $\gamma$ to electron state $\gamma'$ result in a decrease of $f(\gamma, \vec{r}, t)$:

$$f(\gamma)[1-f(\gamma')]P_{\gamma\to\gamma'} \tag{15b}$$

The factor $f$ gives the probability that the initial state is occupied whereas the factor $(1-f)$ ensures that the final state is empty. $P_{\gamma\to\gamma'}$ is the quantum mechanical probability per unit time for the transition from the state $\gamma$ to the state $\gamma'$. It is expressed using first order perturbation theory by Fermi's golden rule

$$P_{\gamma\to\gamma'} = \frac{2\pi}{\hbar}\sum_{\psi\psi'} g_\psi |\langle\gamma\psi|H_{\text{int}}|\gamma'\psi'\rangle|^2 \delta(E_{\gamma\psi} - E_{\gamma'\psi'}) \tag{16}$$

In this equation $H_{\text{int}}$ is the interaction Hamiltonian between the Bloch electrons and the system (rest of the solid) characterized by quantum states $\psi$ and $\psi'$. $g_\psi$ is the probability that one finds the system in the state $\psi$. If a thermodynamical description of the system is possible, this factor corresponds to the Boltzmann factor

$$g_\psi = \frac{e^{-\beta E_\psi}}{\sum\limits_\psi e^{-\beta E_\psi}} \tag{17}$$

whereby $\beta$ is proportional to the inverse temperature: $\beta = 1/(k_B T)$ ($k_B$ is the Boltzmann constant, $T$ is the temperature). The collision term is now the sum over all possible scattering processes which contribute to a change of the distribution function at $\gamma$:

$$\left(\frac{\partial f(\gamma)}{\partial t}\right)_C = \sum_{\gamma'}\{f(\gamma')[1-f(\gamma)]P_{\gamma'\to\gamma} - f(\gamma)[1-f(\gamma')]P_{\gamma\to\gamma'}\} \tag{18}$$

### 2.2 Thermal Equilibrium

The thermal equilibrium distribution function $f_0$ is characterized by a vanishing collision term:

$$\left(\frac{\partial f}{\partial t}\right)_{C0} = \sum_{\gamma'}\{f_0(\gamma')[1-f_0(\gamma)]P_{\gamma'\to\gamma} - f_0(\gamma)[1-f_0(\gamma')]P_{\gamma\to\gamma'}\} = 0 \tag{19}$$

Because this equilibrium condition must be fulfilled for any interaction, it follows that each term of this sum is zero and hence:

$$f_0(\gamma')[1-f_0(\gamma)]P_{\gamma'\to\gamma} = f_0(\gamma)[1-f_0(\gamma')]P_{\gamma\to\gamma'} \tag{20}$$

This equation allows the definition of a symmetric equilibrium transition rate

$$W_{\gamma'\gamma} = f_0(\gamma')[1-f_0(\gamma)]P_{\gamma'\to\gamma} = f_0(\gamma)[1-f_0(\gamma')]P_{\gamma\to\gamma'} = W_{\gamma\gamma'} \tag{21}$$

which will be used in the treatment of the linearized Boltzmann equation.

The thermal equilibrium distribution function $f_0$ is the Fermi–Dirac function

$$f_0(\beta(E_\gamma - \mu)) = \frac{1}{e^{\beta(E_\gamma-\mu)}+1} \tag{22}$$

characterized by a temperature $T$ and a chemical potential $\mu$. With this function we obtain from Eqn. (20) the relation

$$e^{\beta E_\gamma} P_{\gamma'\to\gamma} = e^{\beta E_{\gamma'}} P_{\gamma\to\gamma'} \tag{23}$$

which has to be fulfilled by the transition probabilities $P_{\gamma\to\gamma'}$ for any scattering process.

## 3. Linearized Boltzmann Equation

Assuming that there is simultaneously a time-independent electric and magnetic field applied to the system of conduction electrons we can make use of the Lorentz force

$$\vec{F} = -e\left(\frac{1}{c}\,\vec{v}\times\vec{B} + \vec{E}\right) \tag{24}$$

For this time-independent force we can look for a time-independent distribution function $f(\gamma, \vec{r})$ which fulfils the Boltzmann equation (Eqn. (14))

$$-\frac{e}{\hbar c}(\vec{v}_\gamma \times \vec{B})\cdot\vec{\nabla}_k f(\gamma, \vec{r}) - \frac{e}{\hbar}\vec{E}\cdot\vec{\nabla}_k f(\gamma, \vec{r}) + \vec{v}_\gamma\cdot\vec{\nabla}_r f(\gamma, \vec{r}) = \left(\frac{\partial f}{\partial t}\right)_C \tag{25}$$

As it is shown in Eqn. (18) the collision term depends also on the distribution function.

### 3.1 Linearization of the Boltzmann Equation

Due to the external forces the local thermodynamical equilibrium distribution function $f_0(\gamma, T(\vec{r}), \mu(\vec{r}))$ is disturbed. Assuming this distortion to be small we can use

$$f(\gamma, \vec{r}) = f_0(\gamma, T(\vec{r}), \mu(\vec{r})) + f_1(\gamma, \vec{r}) \tag{26}$$

The Boltzmann equation thus splits into equations of zero, first, and higher order. Terms of higher than first order will not be included in the further discussion.

The zero order equation reads:

$$-\frac{e}{\hbar c}(\vec{v}_\gamma \times \vec{B}) \cdot \vec{\nabla}_k f_0(\gamma, \vec{r}) = \left(\frac{\partial f}{\partial t}\right)_{C0} \tag{27}$$

with the zero order collision term given in Eqn. (19). A thermodynamic state characterized by a local temperature distribution $T(\vec{r})$ and a local chemical potential $\mu(\vec{r})$ has the undisturbed distribution function

$$f_0(\gamma, \vec{r}) = \frac{1}{e^{\beta(\vec{r})[E_\gamma - \mu(\vec{r})]} + 1} \tag{28}$$

and therefore Eqn. (27) is fulfilled since both sides are zero.

The first order equation reads:

$$\begin{aligned} &-\frac{e}{\hbar}\vec{E} \cdot \vec{\nabla}_k f_0(\gamma, \vec{r}) + \vec{v}_\gamma \cdot \vec{\nabla}_r f_0(\gamma, \vec{r}) \\ &= \left(\frac{\partial f}{\partial t}\right)_{C1} + \frac{e}{\hbar c}[\vec{v}_\gamma \times \vec{B}] \cdot \vec{\nabla}_k f_1(\gamma, \vec{r}) \end{aligned} \tag{29}$$

with the first-order collision term

$$\begin{aligned} \left(\frac{\partial f}{\partial t}\right)_{C1} = \sum_{\gamma'} \{ & f_1(\gamma')[1 - f_0(\gamma)] P_{\gamma' \to \gamma} - f_0(\gamma') f_1(\gamma) P_{\gamma' \to \gamma} \\ & - f_1(\gamma)[1 - f_0(\gamma')] P_{\gamma \to \gamma'} + f_0(\gamma) f_1(\gamma') P_{\gamma \to \gamma'} \} \end{aligned} \tag{30}$$

Equation (29) is frequently called linearized Boltzmann equation and it is used to calculate the linear transport coefficients.

Using the symmetric equilibrium transition rate from Eqn. (21) the linear collision term can be written as:

$$\left(\frac{\partial f}{\partial t}\right)_{C1} = \sum_{\gamma'} \left\{ \frac{f_1(\gamma')}{f_0(\gamma')[1 - f_0(\gamma')]} - \frac{f_1(\gamma)}{f_0(\gamma)[1 - f_0(\gamma)]} \right\} W_{\gamma\gamma'} \tag{31}$$

Using for $f_0$ the local thermodynamic distribution function given by Eqn. (28) we can calculate the gradient of this function. The linearized Boltzmann equation is then given by:

$$\begin{aligned} &-\frac{\partial f_0(\gamma, \vec{r})}{\partial E_\gamma} \vec{v}_\gamma \cdot \left( \underbrace{e\vec{E} + \vec{\nabla}_r \mu}_{e\vec{E}'} + \frac{E_\gamma - \mu}{T} \vec{\nabla}_r T \right) \\ &= \left(\frac{\partial f}{\partial t}\right)_{C1} + \frac{e}{\hbar c}(\vec{v}_\gamma \times \vec{B}) \cdot \vec{\nabla}_k f_1(\gamma, \vec{r}) \end{aligned} \tag{32}$$

We have assumed that a spatial variation of the temperature $T(\vec{r})$ and the chemical potential $\mu(\vec{r})$ are represented by first-order terms.

### *3.2 Operator Formalism*

Instead of describing the distortion of the distribution function by $f_1$ we use a function $\phi$, which is connected to $f_1$ through the relation

$$\begin{aligned} f_1(\gamma, \vec{r}) &:= -\frac{\partial f_0(\gamma, \vec{r})}{\partial E_\gamma} \phi(\gamma, \vec{r}) \\ &= \beta f_0(\gamma, \vec{r})[1 - f_0(\gamma, \vec{r})] \phi(\gamma, \vec{r}) \end{aligned} \tag{33}$$

Equation (31) is now used to define the linear collision operator $C$

$$\begin{aligned} C\phi(\gamma, \vec{r}) &:= \left(\frac{\partial f}{\partial t}\right)_{C1} \\ &= \beta \sum_{\gamma'} W_{\gamma\gamma'}[\phi(\gamma', \vec{r}) - \phi(\gamma, \vec{r})] \end{aligned} \tag{34}$$

The second term on the right hand side of Eqn. (32) is used in an analogous fashion to define a magnetic operator $\Omega$:

$$\begin{aligned} \Omega\phi(\gamma, \vec{r}) := & \beta f_0(\gamma, \vec{r})[1 - f_0(\gamma, \vec{r})] \\ & + \frac{e}{\hbar c}(\vec{v}_\gamma \times \vec{B}) \cdot \vec{\nabla}_k \phi(\gamma, \vec{r}) \end{aligned} \tag{35}$$

With these two operators the linearized Boltzmann Eqn. (32) can be written in the short notation

$$(C + \Omega)\phi(\gamma, \vec{r}) = -\frac{\partial f_0(\gamma, \vec{r})}{\partial \varepsilon_\gamma} \vec{v}_\gamma \cdot \vec{X} \tag{36}$$

with the general force $\vec{X}$ defined as

$$\vec{X} = e\vec{E}' + \frac{\varepsilon_\gamma}{T} \vec{\nabla}_r T \tag{37}$$

and a modified electron energy

$$\varepsilon_\gamma = E_\gamma - \mu \tag{38}$$

## *4. Linear Transport Coefficients*

Using Eqn. (26) we can calculate the stationary electrical current density $\vec{I}$ and the stationary heat current density $\vec{J}$ according to Eqns. (12) and (13)

$$\vec{I}(\vec{r}) = -\frac{e}{Vol} \sum_\gamma [f_0(\gamma, \vec{r}) + f_1(\gamma, \vec{r})] \vec{v}_\gamma \tag{39a}$$

$$\vec{J}(\vec{r}) = \frac{1}{Vol} \sum_\gamma [f_0(\gamma, \vec{r}) + f_1(\gamma, \vec{r})][E_\gamma - \mu] \vec{v}_\gamma \tag{39b}$$

There is no contribution to both current densities due to $f_0$. Using the function $\phi$ (see Eqn. (33)) the

expressions for the current densities are

$$\vec{I}(\vec{r}) = +\frac{e}{Vol}\sum_{\gamma}\frac{\partial f_0(\gamma,\ \vec{r})}{\partial\varepsilon_\gamma}\ \vec{v}_\gamma\phi(\gamma,\ \ \vec{r}) \quad (40a)$$

$$\vec{J}(\vec{r}) = -\frac{1}{Vol}\sum_{\gamma}\frac{\partial f_0(\gamma,\ \vec{r})}{\partial\varepsilon_\gamma}\,\varepsilon_\gamma\ \vec{v}_\gamma\phi(\gamma,\ \ \vec{r}) \quad (40b)$$

For the calculation of the heat current the modified electron energy $\varepsilon_\gamma$ is used according to Eqn. (38). The function $\phi$ obtained as a solution of the linearized Boltzmannn equation (Eqn. (36)) can be written formally as:

$$\phi(\gamma,\ \vec{r}\,) = -(C+\Omega)^{-1}\ \frac{\partial f_0(\gamma,\ \vec{r}\,)}{\partial\varepsilon_\gamma}\ \vec{v}_\gamma\cdot\vec{X} \quad (41)$$

The current densities thus obtained are given by:

$$\vec{I}(\vec{r}) = -\frac{e}{Vol}\sum_{\gamma}\frac{\partial f_0(\gamma,\ \vec{r}\,)}{\partial\varepsilon_\gamma}\ \vec{v}_\gamma(C+\Omega)^{-1}\frac{\partial f_0(\gamma,\vec{r}\,)}{\partial\varepsilon_\gamma}\,\vec{v}_\gamma\cdot\vec{X} \quad (42a)$$

$$\vec{J}(\vec{r}) = +\frac{1}{Vol}\sum_{\gamma}\frac{\partial f_0(\gamma,\ \vec{r}\,)}{\partial\varepsilon_\gamma}\,\varepsilon_\gamma\ \vec{v}_\gamma(C+\Omega)^{-1} \times\frac{\partial f_0(\gamma,\ \vec{r}\,)}{\partial\varepsilon_\gamma}\ \vec{v}_\gamma\cdot\vec{X} \quad (42b)$$

### *4.1 Phenomenological Transport Coefficients*

Using the expression for the general force $\vec{X}$ (see Eqn. (37)) these current densities are linear functions of the general electric field strength $\vec{E}'$ and the temperature gradient $\vec{\nabla}_r T$:

$$\vec{I}(\vec{r}) = e^2\,\overleftrightarrow{\mathbf{K}}_{00}\cdot\vec{E} + ek_{\mathrm{B}}\,\overleftrightarrow{\mathbf{K}}_{01}\cdot\vec{\nabla}_r T \quad (43a)$$

$$\vec{J}(\vec{r}) = -ek_{\mathrm{B}}T\,\overleftrightarrow{\mathbf{K}}_{10}\cdot\vec{E} - k_{\mathrm{B}}^2 2T\,\overleftrightarrow{\mathbf{K}}_{11}\cdot\vec{\nabla}_r T \quad (43b)$$

It is important to note that the coefficients $\overleftrightarrow{\boldsymbol{K}}_{ij}$ represent tensors which are functions of the external magnetic field:

$$\overleftrightarrow{\mathbf{K}}_{ij}(\vec{B}) := -\frac{1}{Vol}\sum_{\gamma}\left(\frac{\varepsilon_\gamma}{k_{\mathrm{B}}T}\right)^i\frac{\partial f_0(\gamma,\ \vec{r}\,)}{\partial\varepsilon_\gamma}\ \vec{v}_\gamma\circ(C+\Omega)^{-1} \times\frac{\partial f_0(\gamma,\ \vec{r}\,)}{\partial\varepsilon_\gamma}\ \vec{v}_\gamma\left(\frac{\varepsilon_\gamma}{k_{\mathrm{B}}T}\right)^j \quad (44)$$

Equations (43a) and (43b) are now compared with the phenomenological transport equations as obtained in the scope of irreversible thermodynamics

$$\vec{E} = \overleftrightarrow{\rho}\cdot\vec{I} + \overleftrightarrow{\boldsymbol{S}}\cdot\vec{\nabla}_r T \quad (45b)$$

$$\vec{J} = \overleftrightarrow{\Pi}\cdot\vec{I} - \overleftrightarrow{\lambda}\cdot\vec{\nabla}_r T \quad (45b)$$

The different transport tensors: electrical resistivity $\overleftrightarrow{\rho}$, thermopower $\overleftrightarrow{\boldsymbol{S}}$, Peltier coefficient $\overleftrightarrow{\Pi}$, and thermal conductivity $\overleftrightarrow{\lambda}$ can now be written as:

$$\overleftrightarrow{\rho}(\vec{B}) = \frac{1}{e^2}(\overleftrightarrow{\mathbf{K}}_{00}(\vec{B}))^{-1} \quad (46a)$$

$$\overleftrightarrow{\mathbf{S}}(\vec{B}) = -\frac{k_{\mathrm{B}}}{e}(\overleftrightarrow{\mathbf{K}}_{00}(\vec{B}))^{-1}\cdot\overleftrightarrow{\mathbf{K}}_{01}(\vec{B}) \quad (46b)$$

$$\overleftrightarrow{\Pi}(\vec{B}) = -\frac{k_{\mathrm{B}}T}{e}\,\overleftrightarrow{\mathbf{K}}_{10}(\vec{B})\cdot(\overleftrightarrow{\mathbf{K}}_{00}(\vec{B}))^{-1} \quad (46c)$$

$$\overleftrightarrow{\lambda}(\vec{B}) = k_{\mathrm{B}}^2 T[\overleftrightarrow{\mathbf{K}}_{11}(\vec{B}) - \overleftrightarrow{\mathbf{K}}_{10}(\vec{B})\cdot(\overleftrightarrow{\mathbf{K}}_{00}(\vec{B}))^{-1}\cdot\overleftrightarrow{\mathbf{K}}_{01}(\vec{B})] \quad (46d)$$

In the following we consider homogeneous materials and therefore there is no $r$-dependence.

### *4.2 Relaxation Time Approximation*

If we use for the collision term the relaxation time approximation

$$\left(\frac{\partial f}{\partial t}\right)_{\mathrm{C}} = -\frac{f_1}{\tau_\gamma} \quad (47)$$

we see, that in this approximation the collision operator $C$ reduces to a factor:

$$C = \frac{\partial f_0}{\partial\varepsilon_\gamma}\frac{1}{\tau_\gamma} \quad (48)$$

Without a magnetic field the coefficients $\overleftrightarrow{\mathbf{K}}_{ij}$ are then:

$$\overleftrightarrow{\mathbf{K}}_{ij} = -\frac{1}{Vol}\sum_{\gamma}\left(\frac{\varepsilon_\gamma}{k_{\mathrm{B}}T}\right)^{i+j}\frac{\partial f_0(\gamma)}{\partial\varepsilon_\gamma}\ \vec{v}_\gamma\circ\vec{v}_\gamma\tau_\gamma \quad (49)$$

For an isotropic material (or a material with cubic symmetry) these tensor coefficients are proportional to the unit tensor

$$\overleftrightarrow{\mathbf{K}}_{ij} = K_{ij}\,\overleftrightarrow{\boldsymbol{I}} \text{ with } K_{ij} = \tfrac{1}{3}\mathrm{Tr}\,\overleftrightarrow{\mathbf{K}}_{ij} \quad (50)$$

where

$$K_{00} = -\frac{1}{3Vol} \sum_{\gamma} \frac{\partial f_0(\gamma)}{\partial \varepsilon_\gamma} \vec{v}_\gamma^{\,2} \tau_\gamma = -\frac{1}{e^2} \int \mathrm{d}\varepsilon \, \frac{\partial f_0}{\partial \varepsilon} \, \sigma(\varepsilon) \tag{51a}$$

$$K_{01} = K_{10} = -\frac{1}{3Vol} \sum_{\gamma} \frac{\varepsilon_\gamma}{k_\mathrm{B} T} \frac{\partial f_0(\gamma)}{\partial \varepsilon_\gamma} \vec{v}_\gamma^{\,2} \tau_\gamma = -\frac{1}{e^2} \int \mathrm{d}\varepsilon \, \frac{\varepsilon}{k_\mathrm{B} T} \frac{\partial f_0}{\partial \varepsilon} \, \sigma(\varepsilon) \tag{51b}$$

$$K_{11} = -\frac{1}{3Vol} \sum_{\gamma} \left( \frac{\varepsilon_\gamma}{k_\mathrm{B} T} \right)^2 \frac{\partial f_0(\gamma)}{\partial \varepsilon_\gamma} \vec{v}_\gamma^{\,2} \tau_\gamma = -\frac{1}{e^2} \int \mathrm{d}\varepsilon \left( \frac{\varepsilon_\gamma}{k_\mathrm{B} T} \right)^2 \frac{\partial f_0}{\partial \varepsilon} \, \sigma(\varepsilon) \tag{51c}$$

$\sigma(\varepsilon)$ is a short notation for the energy-dependent electrical conductivity defined by:

$$\sigma(\varepsilon) := \frac{e^2}{3Vol} \sum_{\gamma} \delta(\varepsilon - \varepsilon_\gamma) \vec{v}_\gamma^{\,2} \tau_\gamma = \frac{e^2}{3} \underbrace{\frac{1}{Vol} \sum_{\gamma} \delta(\varepsilon - \varepsilon_\gamma)}_{N(\varepsilon)} \underbrace{\frac{\sum_{\gamma} \delta(\varepsilon - \varepsilon_\gamma) \vec{v}_\gamma^{\,2} \tau_\gamma}{\sum_{\gamma} \delta(\varepsilon - \varepsilon_\gamma)}}_{\langle v^2 \tau \rangle_\varepsilon} \tag{52}$$

The energy dependence of $\sigma(\varepsilon)$ derives principally from the energy dependence of the density of states $N(\varepsilon)$, whereas the mean value of $v^2\tau$ shows little variation with energy.

Applying a series expansion

$$\sigma(\varepsilon) = \sigma(0) + \sigma'(0)\varepsilon + \cdots \tag{53}$$

and taking into account only the leading terms it follows that

electrical conductivity:

$$\sigma = -\int \mathrm{d}\varepsilon \, \frac{\partial f_0}{\partial \varepsilon} \, \sigma(\varepsilon) = \sigma(0) \tag{54a}$$

thermopower:

$$S = -\frac{\pi^2}{3e} k_\mathrm{B}^2 T \, \frac{\sigma'(0)}{\sigma} \tag{54b}$$

thermal conductivity:

$$\lambda = \frac{\pi^2 k_\mathrm{B}^2 T}{3e^2} \, \sigma(0) \tag{54c}$$

In the expression for $\lambda$ the second term in the square bracket of Eqn. (46d) has been neglected. From Eqns. (54a) and (54c) the Wiedemann–Franz law follows:

$$\lambda = \frac{\pi^2 k_\mathrm{B}^2}{3e^2} \, T\sigma = L_0 T \sigma \tag{55}$$

with $L_0$, the Lorenz–number

$$L_0 = \frac{\pi^2 k_\mathrm{B}^2}{3e^2} = 2.45 \times 10^{-8} \, \frac{\mathrm{V}^2}{\mathrm{K}^2} = 24.5 \, \frac{\mathrm{mW}}{\mathrm{cm\ K}} \cdot \mu\Omega\mathrm{cm} \cdot \frac{1}{K} \tag{56}$$

### *4.3 Variational Principle*

For the diagonal elements of the electrical conductivity and the thermal conductivity tensor it is possible to formulate a variational principle. If a finite set of basis functions $\phi_s(\gamma)$ $(s = 0, 1, \ldots, r-1)$ has been selected one can determine the distribution function using this variational principle. The result can formally be written as (Gratz *et al.* 1987)

$$[C + \Omega]^{-1} h(\gamma) := \sum_{s=0}^{r-1} \sum_{t=0}^{r-1} \phi_s(\gamma) ([\hat{C} + \hat{\Omega}]^{-1})_{st} = \frac{1}{Vol} \sum_{\gamma'} \phi_t(\gamma') h(\gamma') \tag{57}$$

where $h(\gamma)$ denotes an arbitrary function. Note: $[\hat{C} + \Omega]^{-1}$ is the inverse of the matrix $\hat{C} + \Omega$ with the matrix elements

$$(\hat{C} + \hat{\Omega})_{st} := \frac{1}{Vol} \sum_{\gamma} \phi_s(\gamma) [C + \Omega] \phi_t(\gamma) \tag{58}$$

This matrix describes the effect of the sum of the collision operator $C$ and the magnetic operator $\Omega$ on the selected set of basis functions. Using Eqn. (57) for the calculation of the coefficients $\vec{\vec{\mathbf{K}}}_{ij}$ (see Eqn. (44)) allows to calculate the transport coefficients (see Eqns. (46a)–(46d)).

*(a) Scalar transport coefficients*

For a material with cubic symmetry or a polycrystalline sample the transport coefficients in zero magnetic field are scalars (see Eqn. (50)). Therefore the tensor component $(\vec{\vec{\mathbf{K}}}_{ij})_{xx}$ corresponds to the scalar coefficient $K_{ij}$, which can be written as:

$$K_{ij} = -\sum_{s,t} h_s^i (\hat{C}^{-1})_{st} h_t^j \tag{59a}$$

with

$$h_s^i := -\frac{1}{Vol} \sum_{\gamma} \left( \frac{\varepsilon_\gamma}{k_\mathrm{B} T} \right)^i \frac{\partial f_0(\gamma)}{\partial \varepsilon_\gamma} \, v_x(\gamma) \phi_s(\gamma) \tag{59b}$$

The transport coefficients which then follow from Eqns. (46a)–(46d) are:

electrical conductivity:

$$\sigma = e^2 K_{00} \tag{60a}$$

thermopower:

$$S = -\frac{k_B}{e}\frac{K_{01}}{K_{00}} \tag{60b}$$

Peltier coefficient:

$$\Pi = -\frac{k_B T}{e}\frac{K_{10}}{K_{00}} \tag{60c}$$

thermal conductivity:

$$\lambda = k_B^2 T\left(K_{11} - \frac{K_{10}K_{01}}{K_{00}}\right) \tag{60d}$$

*(b) The simplest variational approach*

From the relaxation time approximation (Eqn. (48)) it can be seen, that the function $\phi$ (Eqn. (41)) is proportional to $v_x(\gamma)$ or $v_x(\gamma)\varepsilon_\gamma$ depending on which external force is acting in the $x$-direction. If we operate in a two-dimensional variation space with the two basis functions

$$\phi_0(\gamma) = v_x(\gamma),\ \phi_1(\gamma) = v_x(\gamma)\varepsilon_\gamma \tag{61}$$

the simplest result within the scope of the variational approximation is obtained:

$$\text{electrical conductivity: } \sigma = e^2 K_{00} = -e^2 h_0^0 \frac{1}{\hat{C}_{00}} h_0^0 \tag{62a}$$

$$\text{thermal conductivity: } \lambda = k_B^2 T K_{11} = -k_B^2 T h_1^1 \frac{1}{\hat{C}_{11}} h_1^1 \tag{62b}$$

$$\text{thermopower: } S = -\frac{k_B}{e}\frac{K_{01}}{K_{00}} = \frac{k_B}{e}\frac{h_1^1}{h_0^0}\frac{\hat{C}_{01}}{\hat{C}_{11}} \tag{62c}$$

where the inequalities

$$\hat{C}_{00}\hat{C}_{11} \gg \hat{C}_{10}\hat{C}_{01},\ h_0^0,\ h_1^1 \gg h_0^1,\ h_1^0 \tag{63}$$

have been used.

The electrical and the thermal resistivity are then expressed by:

$$\text{electrical resistivity: } \rho = -\frac{1}{e^2}\frac{1}{h_0^0 h_0^0}\hat{C}_{00} \tag{64a}$$

$$\text{thermal resistivity: } W = -\frac{1}{k_B^2 T}\frac{1}{h_1^1 h_1^1}\hat{C}_{11} \tag{64b}$$

$\rho$ and $W$ are proportional to only one matrix element of the collision operator $C$ whereas in the expression for the thermopower two matrix elements $\hat{C}_{01}$, $\hat{C}_{11}$ enter (see Eqn. (62c)). However, when multiplying $W$ and $S$, the product contains only one matrix element

$$WS = -\frac{1}{ek_B T}\frac{1}{h_0^0 h_1^1}\hat{C}_{01} \tag{65}$$

### *4.4 Sum Rules*

If there are two or more independent scattering mechanisms (e.g., A and B) for the Bloch electrons then the transition probabilities can be added. In terms of the collision operator this can be written as:

$$C^{AB} = C^A + C^B \tag{66}$$

For the relaxation time approximation it follows from Eqn. (48) that:

$$\frac{1}{\tau^{AB}} = \frac{1}{\tau^A} + \frac{1}{\tau^B} \tag{67}$$

where $\tau^{AB}$ denotes the total relaxation time.

Since the electrical and the thermal resistivity (Eqns. (64a) and (64b)) are proportional to the collision operator, the sum rules for $\rho$ and $W$ are:

$$\rho^{AB}(T) = \rho^A(T) + \rho^B(T) \tag{68a}$$

$$W^{AB}(T) = W^A(T) + W^B(T) \tag{68b}$$

or

$$\frac{1}{\lambda^{AB}(T)} = \frac{1}{\lambda^A(T)} + \frac{1}{\lambda^B(T)}$$

Equations (68a) and (68b) are known as Matthiessen's rules. Even if more than two scattering mechanisms exist Matthiessen's rule is applicable, provided the different scattering processes are independent.

For the thermopower no such simple relation exists, however from Eqn. (65) it can be seen, that for the thermopower $S$ multiplied by thermal resistivity $W$ a similar rule follows:

$$W^{AB}(T)S^{AB}(T) = W^A(T)S^A(T) + W^B(T)S^B(T) \tag{69}$$

Inserting Eqn. (68b) than gives the Kohler rule for the thermopower:

$$S^{AB}(T) = \frac{W^A(T)}{W^A(T) + W^B(T)}S^A(T) + \frac{W^B(T)}{W^A(T) + W^B(T)}S^B(T) \tag{70}$$

It follows from this equation that the thermopower $S^{AB}$ in the presence of two independent scattering

processes lies between the thermopowers $S^{\mathrm{A}}$ and $S^{\mathrm{B}}$. The weighting factors depend on the respective thermal resistivities. The thermal conductivity is frequently not known, and there is the additional problem in determining the contribution of the lattice thermal conductivity. However, it is possible to replace the thermal resistivities in Eqn. (70) by the electrical resistivities using the Wiedemann–Franz law (Eqn. (55)):

$$S^{\mathrm{AB}}(T) = \frac{\rho^{\mathrm{A}}(T)}{\rho^{\mathrm{A}}(T) + \rho^{\mathrm{B}}(T)}\, S^{\mathrm{A}}(T) + \frac{\rho^{\mathrm{B}}(T)}{\rho^{\mathrm{A}}(T) + \rho^{\mathrm{B}}(T)}\, S^{\mathrm{B}}(T) \tag{71}$$

This is the well-known Nordheim–Gorter rule.

## 5. *Scattering Mechanism*

Three of the most important scattering mechanism will be considered in the following: elastic potential scattering, inelastic phonon scattering, and magnetic scattering.

### 5.1 *Potential Scattering*

Since these scattering processes are elastic, no energy transfer from the conduction-electron system to the scatterer takes place. Such scattering may occur from dislocations, foreign atoms and grain boundaries. However, if the material includes magnetic moment carrying atoms also, a disorder in the static moment arrangement will contribute to these scattering mechanism.

The transport coefficients due to this kind of interaction are given by

$$\rho_0(T) = C_0^{\rho} \tag{72a}$$

$$W_0(T) = C_0^{w}/T \tag{72b}$$

$$S_0(T) = -C_0^{s} T \tag{72c}$$

where the different constants $C_0$ are temperature independent (the subscript 0 characterize potential scattering and the suffices $\rho$, $w$, and $s$ the type of the corresponding transport coefficient). The constants $C_0^{\rho}$ and $C_0^{w}$ are proportional to the interaction strength (this means the electrical and thermal resistivity becomes lower for a smaller interaction strength). This is not the case for the constant $C_0^{s}$ of the thermopower (the thermopower must not become lower if the interaction strength decreases). The simplest approximation for this constant is given by

$$C_0^{s} = \frac{\pi^2 k_{\mathrm{B}}}{3|e|}\, \frac{\mathrm{d}}{\mathrm{d}\varepsilon} \ln v^2(\varepsilon) \tag{73}$$

whereby the energy dependence of the square of the electron velocity is given analogous to Eqn. (52) by the equation

$$v^2(\varepsilon) = \frac{\sum\limits_{\gamma} \delta(\varepsilon - \varepsilon_\gamma)\, \vec{v}_\gamma^{\,2}}{\sum\limits_{\gamma} \delta(\varepsilon - \varepsilon_\gamma)} \tag{74}$$

In the schematic pictures shown below the temperature variation of $\rho_0$, $W_0$ and $S_0$ is depicted together with $\rho_p$, $W_p$, $S_p$ and $\rho_m$, $W_m$, $S_m$, the subscripts $p$ and $m$ referring to phonon and magnetic scattering.

### 5.2 *Phonon Scattering*

Using the Debye model to describe the lattice dynamics, the simplest results (Gratz and Nowotny 1985) for the transport coefficients are (in what follows the subscript $p$ denotes phonon scattering)

$$\rho_p(T) = C_p^{\rho} T F_p^{\rho}(\Theta_{\mathrm{D}}/T) \tag{75a}$$

$$W_p(T) = C_p^{w} F_p^{w}(\Theta_{\mathrm{D}}/T) \tag{75b}$$

$$S_p(T) = -T(C_p^{sf} F_p^{s}(\Theta_{\mathrm{D}}/T) + C_p^{sg} G_p^{s}(\Theta_{\mathrm{D}}/T)) \tag{75c}$$

where the different constants $C_p$ are again temperature independent (because the formula for the thermopower consists now of two terms, the suffix $s$ is extended to $sf$ or $sg$, corresponding to the function $F$ or $G$). The functions $F_p$ and $G_p$ are given by

$$F_p^{\rho}(x) = J_5(x) \tag{76a}$$

$$F_p^{w}(x) = J_5(x) + \frac{3}{4\pi^2}\, x^2 \left( J_5(x) - \frac{4}{9} J_7(x) \right) \tag{76b}$$

$$F_p^{s}(x) = \frac{1}{F_p^{w}(x)} \left( F_p^{\rho}(x) + F_p^{w}(x) - \frac{3}{8\pi^2}\, x^2 J_5(x) - F(x) \right) \tag{76c}$$

$$G_p^{s}(x) = \frac{1}{F_p^{w}(x)}\, (F_p^{\rho}(x) + F_p^{w}(x) - 2F(x)) \tag{76d}$$

where the generalized Debye integrals $J_n(x)$ are

$$J_n(x) = \frac{n-1}{x^{n-1}} \int_0^x \mathrm{d}\omega\, \frac{\omega^n}{(e^{\omega} - 1)(1 - e^{-\omega})} \tag{77a}$$

and the function $F(x)$ is

$$F(x) = \left( 1 + \frac{1}{4\pi^2}\, x^2 \right) \frac{x^2}{(e^x - 1)(1 - e^{-x})} \tag{77b}$$

The functions $F_p^{\rho}$, $F_p^{w}$ and $F_p^{s}$ are normalized, having the limit one for very high temperatures, whereas $G_p^{s}$ vanishes in the high temperature region (see insert in Fig. 3).

The temperature dependence of the electrical resistivity $\rho_p$ given in Eqn. (75a) corresponds to the well known Bloch–Grüneisen law. The constant $C_p^{\rho}$ includes the electron–phonon coupling constant, the atomic masses of the different types of atoms and the characteristic temperature $\Theta_D$ for the phonons. From Eqn. (75a) (together with Eqns. (76a) and (77a)) it follows for the low and the high temperature region

$$\rho_{ph}(T) \propto C_p^{\rho} T^5 \text{ for } T \ll \Theta_D \tag{78a}$$

$$\rho_{ph}(T) = C_p^{\rho} T \text{ for } T \geqslant \Theta_D \tag{78b}$$

The derivation of these equations is based on the assumptions that the Boltzmann formalism is applicable. Basically this means that the scattering events are separated spatially by a sufficient numbers of wavelengths of the conduction electrons so that an electron recovers from a previous collision before experiencing the next one. Another important simplification is the assumption that the Debye model for the description of the phonon dynamics is valid. Therefore one of the parameters in the theoretical model calculation is the Debye temperature $\Theta_D$, which can most easily be obtained from a fit of the Bloch–Grüneisen law to the resistivity data (for examples see *Intermetallic Compounds: Electrical Resistivity*).

The thermal resistivity due to the electron–phonon scattering given in Eqn. (75b) corresponds mainly to a formula obtained by Wilson (see e.g., Ziman 1962). For the low and high temperature ranges the thermal resistivity follows simple relations:

$$W_p(T) \propto C_p^{w} T^2 \text{ for } T \ll \Theta_D \tag{79a}$$

$$W_p(T) = C_p^{w} \text{ for } T \geqslant \Theta_D \tag{79b}$$

For the high temperature region the Wiedemann – Franz law follows from these equations.

The temperature variation of the thermopower its not as simple as for the electrical and thermal resistivity even for simple nonmagnetic compounds, since the thermopower can take positive or negative signs depending on temperature. This is because its sign is determined by the conduction electron properties at the Fermi level. The parameters $C_p^{sf}$ and $C_p^{sg}$ are proportional to the energy derivative of the velocity and the density of states of the conduction electrons at the Fermi level:

$$C_p^{sf} \propto \frac{\mathrm{d}}{\mathrm{d}\varepsilon} \ln v^2(\varepsilon), C_p^{sg} \propto \frac{\mathrm{d}}{\mathrm{d}\varepsilon} \ln N(\varepsilon) \tag{80}$$

The calculation of $S_p(T)$ requires the knowledge of these two model parameters (Durczewski and Ausloos 1996).

### 5.3 Spin-dependent Scattering Mechanism

For a magnetic RE-compound the existence of scattering processes of the conduction electrons on the localized 4f spins of the RE-ions has to be taken into consideration. We will describe a ferromagnetic system of localized 4f-moments by a Heisenberg-Hamiltonian in the molecular field approximation and the magnetic scattering processes between the conduction electrons and the localized 4f moments by a s-f interaction Hamiltonian. When neglecting a possible influence of the crystal field or short range correlations, one obtains after some simplifications the following magnetic contributions to the electrical resistivity, the thermal resistivity, and the thermopower (the subscript $m$ denotes magnetic scattering):

$$\rho_m(T) = C_m^{\rho} F_m^{\rho}(T/T_c) \tag{81a}$$

$$W_m(T) = C_m^{w} F_m^{w}(T/T_c)/T \tag{81b}$$

$$S_m(T) = -T(C_m^{sf} F_m^{s}(T/T_c) + C_m^{sg} G_m^{s}(T/T_c)) \tag{81c}$$

$T_c$ represents the ferromagnetic ordering temperature (Curie temperature). Above $T_c$ the function $G_m^{s}$ vanishes and the functions $F_m^{r}$, $F_m^{w}$ and $F_m^{s}$ are equal to one (see inset of Fig. 3). Within this paramagnetic region ($T > T_c$) the magnetic scattering processes are called spin–disorder scattering. The results for this spin–disorder scattering are similar to those for potential scattering because of the elastic nature of these interactions:

$$\rho_{spd}(T) = C_m^{\rho} \tag{82a}$$

$$W_{spd}(T) = C_m^{w}/T \tag{82b}$$

$$S_{spd}(T) = -C_m^{sf} T \tag{82c}$$

In the ferromagnetic region ($T < T_c$) the magnetization $M(T/T_c)$ mostly determines the temperature dependence of the transport coefficients. This magnetization is proportional to the average value of $J_z$ given in the molecular field theory by

$$\langle J_z \rangle = J B_J(2J\eta) \tag{83a}$$

where $B_J$ is the Brillouin function for localized spins with the fixed total momentum $J$

$$B_J(x) = \frac{2J+1}{2J} \coth \frac{2J+1}{2J} x - \frac{1}{2J} \coth \frac{1}{2J} x \tag{83b}$$

and $\eta$ is a function of the reduced temperature $T/T_c$ determined by

$$B_J(2J\eta) = \frac{2(J+1)}{3}\frac{T}{T_c}\eta \tag{83c}$$

The functions $F_m^{\rho}$, $F_m^{w}$, $F_m^{sf}$ and $F_m^{sg}$ are given by:

$$F_m^{\rho}(T/T_c) = R_J^0(T/T_c) \tag{84a}$$

$$F_m^{w}(T/T_c) = R_J^0(T/T_c) + R_J^2(T/T_c) \tag{84b}$$

$$F_m^{s}(T/T_c) = \frac{R_J^0(T/T_c)}{R_J^0(T/T_c) + R_J^2(T/T_c)} \tag{84c}$$

$$G_m^{s}(T/T_c) = \frac{R_J^2(T/T_c)}{R_J^0(T/T_c) + R_J^2(T/T_c)} \tag{84d}$$

with the abbreviations

$$R_J^0(T/T_c) = \frac{1}{J(J+1)}\left(\langle J_z^2\rangle - \langle J_z\rangle^2 + \frac{\eta\langle J_z\rangle}{\sinh^2\eta}\right) \tag{85a}$$

$$R_J^2(T/T_c) = \frac{4}{\pi^2}\frac{1}{J(J+1)}\frac{\eta^3\langle J_z\rangle}{\sinh^2\eta} \tag{85b}$$

whereby $\langle J_z\rangle$ is given by Eqn. (83a), $\eta$ has to be determined from Eqn. (83c) and $\langle J_z^2\rangle$ is given by

$$\langle J_z^2\rangle = J(J+1) - \langle J_z\rangle\coth\eta \tag{85c}$$

The parameters $C_m^{sf}$ and $C_m^{sg}$ are again proportional to the energy derivative of the velocity and the density of states at the Fermi level (see Eqn. (80)). Below $T_c$, $S_m(T)$ can show a maximum, whereby the magnitude of the maximum strongly depends on the ratio of the parameters $C_m^{sf}$ and $C_m^{sg}$ (see Fig. 3). It should be noted, that such a maximum (or minimum) observed below $T_c$ in magnetically ordered materials is caused by the inelastic spin flip scattering of the conduction electrons. Such a behavior has sometimes been interpreted to be a drag effect (magnon drag, phonon drag; hereby magnons and/or phonons are taken along with the conduction electrons). Such drag effects may have some influence at very low temperatures, but each maximum (or minimum) in the temperature dependence of the thermopower is not an indication of a drag effect.

The contribution to the total electrical or thermal resistivity depends strongly on whether the material is magnetically ordered or is in the paramagnetic state. If the magnetically ordered state is not ferromagnetic no general rules can be given for the electrical resistivity or for those of $W$ and $S$ since the magnetic order in general can show a complex non collinear arrangement of the spins (see also *Localized 4f and 5f Moments: Magnetism*). Mainly at low temperatures the temperature variation is sensitively dependent on the spin dynamic which itself might be very complex in an antiferromagnetic ordered state (this spin wave scattering also occurs in ferromagnetic material and is not included in the formulas given above).

In the following figures the temperature dependencies for the different contributions to electrical resistivity, thermal resistivity and thermopower are sketched.

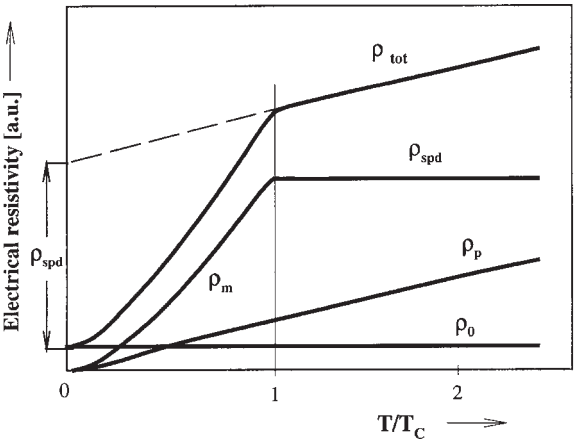

***Figure 1***
The calculated temperature dependence of the electrical resistivity for a magnetic compound is shown assuming that the total resistivity is the sum of the residual, the phonon, and the magnetic resistivity.

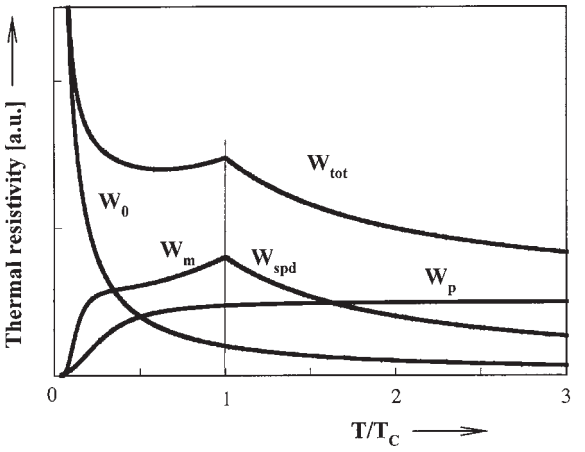

***Figure 2***
The calculated temperature dependence of the electronic thermal resistivity $W$ due to impurity, phonon and magnetic scattering (schematic). The total electronic part of the thermal resistivity is the sum of the residual, the phonon, and the magnetic thermal resistivity.

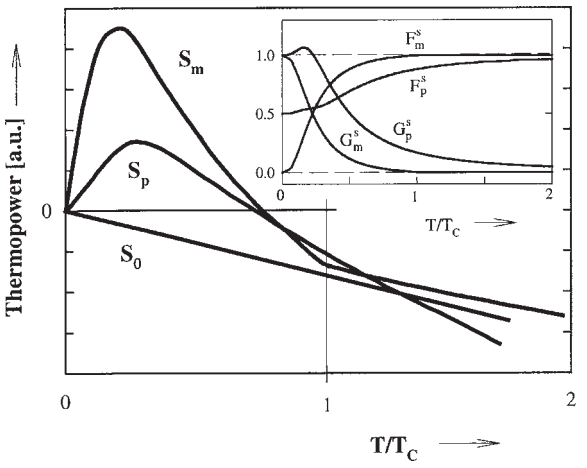

***Figure 3***
The calculated temperature variation of the thermopower $S$ for a ferromagnetic compound due to impurity, phonon, and magnetic scattering (the inset shows the functions $F_m^s$, $F_p^s$, $G_p^s$, and $G_m^s$.

Fig. 1 shows schematically the temperature variation of the electrical resistivity due to potential scattering ($\rho_0$), phonon scattering ($\rho_p$) and magnetic scattering ($\rho_m$ and $\rho_{spd}$). The total resistivity $\rho_{total}$ is the sum of the residual, the phonon and the magnetic resistivity. That means we assume that Matthiessen's rule holds.

Fig. 2 shows in an analogous way to Fig. 1 the temperature variation of the thermal resistivities $W$ due to impurity, phonon and magnetic scattering. The total thermal resistivity $W_{total}$ is again the sum of these three thermal resistivities (Matthiessen's rule).

In Fig. 3 the temperature variation of the thermopower due to potential scattering ($S_0$), phonon scattering ($S_p$) and magnetic scattering ($S_m$) are sketched. The inset shows the functions $F_m^s$, $F_p^s$, $G_p^s$ and $G_m^s$.

## 6. Conclusion

In this section the electronic transport coefficients ($\rho$, $W$, $S$ and $\Pi$) have been considered in the scope of the linearized Boltzmann equation. To use this classical formalism it is necessary that

(i) the conduction electrons can be described by Bloch wave-packets (characterized by $\gamma = k, n, \sigma$)

(ii) scattering processes can be described as transitions from a state $\gamma$ into a state $\gamma'$

(iii) the time in between two successive scattering processes has to be long enough in order to establish the formation of a wave packet.

From the latter point it follows that the mean free path of a conduction electron has to be much longer than the interatomic distances. This means that only a limited number of collisions per unit time can be experienced by an electron (for a normal metal this gives an upper limit for the electrical resistivity of about 200–300 $\mu\Omega$ cm). If these conditions are not fulfilled the classical treatment of transport phenomena fails and a quantum mechanical consideration is necessary (Kubo 1959). For an example, see $YMn_2$ in *Intermetallic Compounds: Electrical Resistivity*. In the scope of the Boltzmann formalism the external fields change the distribution function which is used in order to calculate the corresponding current densities (see Eqns. (39a) and (39b)).

The linear relations between these current densities and the external fields determine the linear transport coefficients (see Eqns. (46a)–(46d)). The necessary distribution functions were calculated as a solution of the linearized Boltzmann equation. In this section, two of the most simplest solution methods for the Boltzmann equation have been discussed

(i) Relaxation time approximation

(ii) Variational method (however with only two trial functions)

An important result of these simple approximations are the sum rules, since these rules are very helpful for the analysis of experimental data (see also *Intermetallic Compounds: Electrical Resistivity*, *Kondo Systems and Heavy Fermions: Transport Phenomena*). As independent scattering mechanisms, the potential scattering, the phonon scattering and spin dependent scattering are considered and the corresponding temperature dependence of $\rho$, $W$ and $S$ are outlined. In the figures these temperature dependencies are schematically shown according to Eqns. (72a)–(72c) (potential scattering), Eqns. (75a)–(75c) (phonon scattering) and Eqns. (81a)–(81c) (magnetic scattering).

# Bulk Magnetic Materials: Low-dimensional Systems

The magnetism in space dimension $D$ reduced to one or two shows very interesting and nontrivial features which result essentially from the enhancement of both the thermal and quantum fluctuations. The ground and excited states of low-dimensional magnetic systems appear more exotic as the spin dimension, $n$, increases ($n=1$, 2, or 3) and the spin value, $S$, decreases ($S=\frac{1}{2}$, 1 ...). Thus, the largest effect is expected for the one-dimensional (1D) $S=\frac{1}{2}$ Heisenberg ($n=3$) system. The nature of the ground state also depends strongly on the type of spin–spin couplings which are involved (see *Magnetism in Solids: General Introduction*): ferromagnetic, antiferromagnetic, or frustrating, at short or long range. The most interesting cases are predicted (and observed) for exchange interactions favoring antiferromagnetic or frustrated spin configurations, this resulting from the enhancement of quantum effects at low dimension. As a direct consequence of the strengths of both the thermal and quantum fluctuations in one or two dimensions, in most cases the spin system can no longer develop a long-range ordering at finite temperature and thus remains disordered down to $T=0\,\mathrm{K}$.

This article outlines the main features of magnetism at low dimension, emphasizing in particular the role played by quantum fluctuations, frustration, and doping.

## 1. Generalities and Definitions

A one-dimensional magnetic system is one in which the spin interactions are strong only along a well-defined direction in space, thus defining a quasi-isolated chain of spins. When the spin interactions are large along two directions in space and weak along the third one, the spin system can be viewed as a stacking of quasi-isolated magnetic layers. Figure 1 gives examples of 1D, 2D, and "intermediate" antiferromagnetic lattices. Figure 2 shows an example of a spin-ladder spin-chain system ($Sr_{14}Cu_{24}O_{41}$). Following the general theory of phase transitions (Domb and Green 1972, 1976; Domb and Lebowitz 1983, 1988), a spin system at a given temperature $T$ is characterized by an order parameter which is generally defined as the thermal expectation value of the spin $\boldsymbol{S}_i$ at site $i$, $|\langle \boldsymbol{S}_i \rangle_T|$. The magnetic system exhibits a phase transition towards long-range ordering if the order parameter becomes nonzero below some characteristic temperature $T_C$ called the critical temperature.

Generally, the spin fluctuations are characterized by the space- and time-dependent spin–spin correlation functions:

$$G_{ij}^{\alpha\beta}(t) = \langle \mathbf{S}_i^{\alpha}(R_i,0) \cdot \mathbf{S}_j^{\beta}(R_j,t) \rangle_T \qquad (1)$$

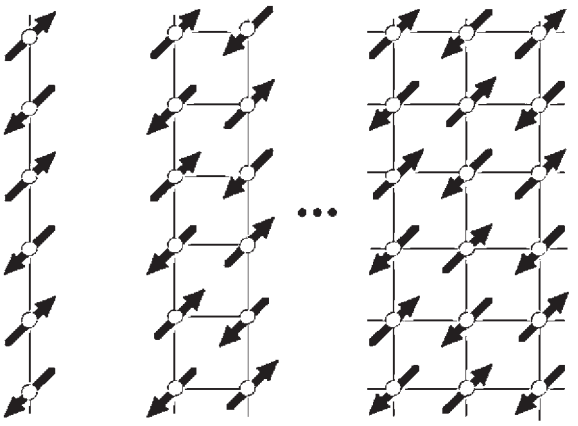

*Figure 1*
The $n$-leg antiferromagnetic spin-ladder system: the 1D–2D crossover.

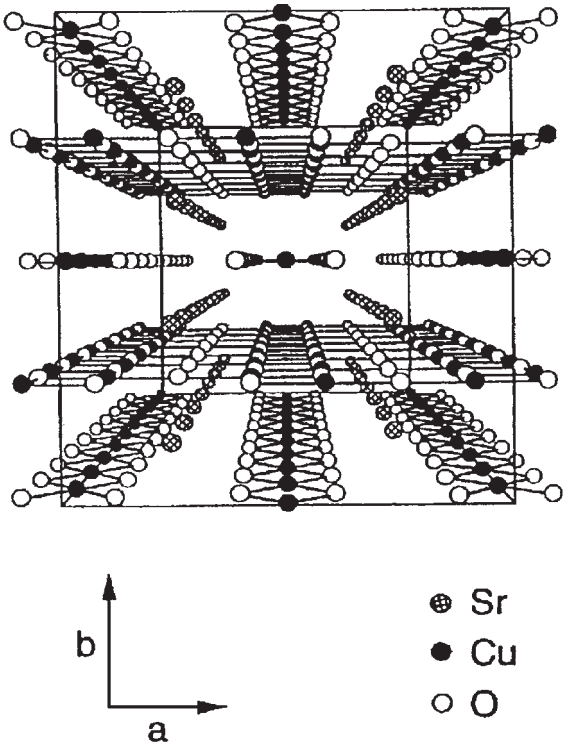

*Figure 2*
An example of a low-dimensional system: crystallographic structure of the spin-ladder dimer-chain compound $Sr_{14}Cu_{24}O_{41}$.

where $\alpha$ and $\beta$ label the various spin components. Some experimental techniques such as NMR (Slichter 1990) or inelastic neutron scattering (INS) (Lovesey 1987) probe more or less completely the various

dynamical structure factors $S^{\alpha\beta}(\mathbf{q}, \omega)$ which are nothing else than the Fourier transforms of the spin–spin correlation functions $G_{ij}^{\alpha\beta}(t)$. The quantities $S^{\alpha\beta}(\mathbf{q}, \omega)$ contain all the physics of spin fluctuations and spin excitations. They are related to the wave vector and energy-dependent generalized susceptibilities $\chi^{\alpha\beta}(\mathbf{q}, \omega)$ through the well-known fluctuation–dissipation theorem:

$$\chi^{\alpha\beta}(\mathbf{q}, \omega) = \frac{1}{\pi}(1 - \exp(-\hbar\omega/kT))S^{\alpha\beta}(\mathbf{q}, \omega) \qquad (2)$$

Information on $\chi^{\alpha\beta}(\mathbf{q}, \omega)$ can be obtained from various techniques such as susceptibility ($\chi^{\alpha\alpha}(\mathbf{q}=0, T)$), magnetization ($M^{\alpha}(H, T)$), specific heat ($C(T)$), and ESR measurements (Abragam and Bleaney 1970). In the absence of long-range ordering, the spin system is characterized in the direction $v$ by a length scale $\xi_v(T)$ (the correlation length), defined as the average distance over which two spins are correlated. $\xi_v(T)$ can be determined from INS studies of the $q$-dependencies of the energy-integrated structure factors:

$$S_v(\mathbf{q}) = \int S_v(\mathbf{q}, \omega)\mathrm{d}\omega \qquad (3)$$

In the vicinity of a "classical" critical point (when it exists), the quantities $|\langle \mathbf{S}_i \rangle_T|$, $\xi(T)$, and $\chi(T)$ are expected to exhibit power-law dependencies of $T_C - T$:

$$|\langle \mathbf{S}_i \rangle_T| \propto (T_C - T)^{\beta} \qquad (4)$$

$$\xi(T) \propto (T_C - T)^{-\nu} \qquad (5)$$

$$\chi(T) \propto (T_C - T)^{-\gamma} \qquad (6)$$

allowing one to define critical exponents $\beta$, $\nu$, and $\gamma$, whereas at $T_C$ the "instantaneous" correlation function $\langle \mathbf{S}_0 \bullet \mathbf{S}_r \rangle$ should behave at large distance as $1/r^n$.

## 2. Critical Phenomena in Low-dimensional Classical Systems

It is now accepted that the existence of a magnetic phase transition at finite temperature depends in a crucial way on both the space dimension ($D$) and spin dimension ($n$). Following the usual terminology, $n = 1$, 2, and 3 correspond, respectively, to the so-called "Ising," "XY," and "Heisenberg" models (see *Magnetism in Solids: General Introduction*).

In the space dimension $D = 2$, there exists a true phase transition only for the Ising model (de Jongh and Miedema 1974, de Jongh 1990). The general characteristics of this phase transition depend only weakly on the type of lattice under consideration, even in the presence of "frustration" (as in the case of the antiferromagnetic triangular lattice (see *Magnetic Systems: Lattice Geometry-originated Frustration*)). Owing to the Ising character, the spin excitation spectrum displays a gap $\Delta_I \approx 2zJS^2$ ($z$ being the number of adjacent spins), whereas both the longitudinal susceptibility and the specific heat follow thermal activation laws ($\sim \exp(-\Delta_I/kT)$). Theoretical predictions for the critical exponents of the 2D Ising model for a square lattice ($\beta = 1/8$, $\nu = 1$, $\gamma = 7/4$, and $\eta = 1/4$) have been quantitatively verified by quasi-elastic neutron scattering experiments on the prototype compound $K_2CoF_4$ (Ikeda and Hirakawa 1974). Figure 3 shows, for example, that the sublattice magnetization closely obeys the well-known Onsager formula established for that model:

$$\frac{M_S(T)}{M_S(0)} \approx \left(1 - \sinh^{-4}\left(\frac{2JS^2}{kT}\right)\right)^{1/8} \qquad (7)$$

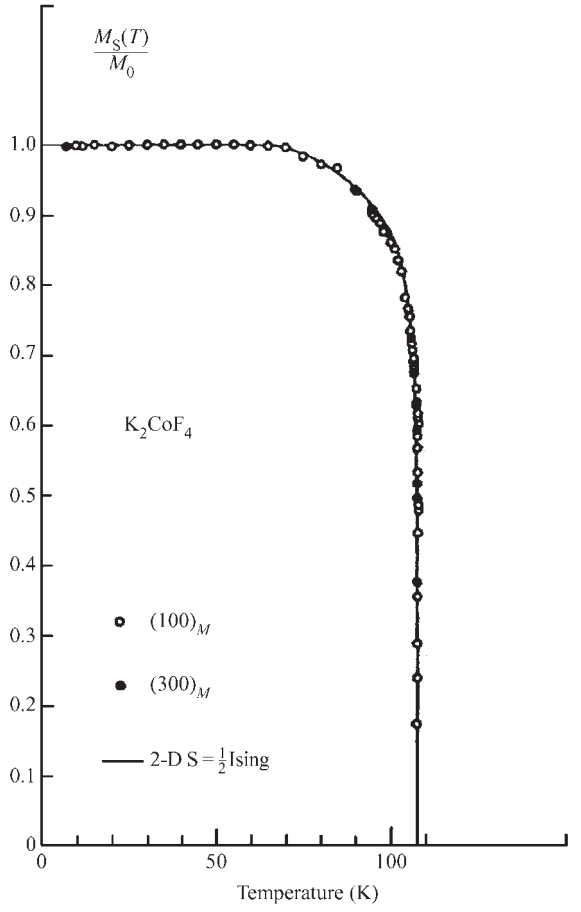

***Figure 3***
Temperature dependence of the normalized magnetic intensities in the two-dimensional Ising material $K_2CoF_4$.

For such a system, the magnetization $M_S(T)$ vanishes at $kT_C \approx 1.8JS^2$. For the frustrated antiferromagnetic triangular lattice, $kT_C \approx 1.5JS^2$ is smaller, reflecting closely the change of nearest-neighbor number $z$.

For $D=2$, $n=2$ and $D=2$, $n=3$, no phase transition towards long-range ordering can exist, owing to the increase of thermally activated spin fluctuations: $|\langle \mathbf{S}_i \rangle_T| = 0$. For $n=3$, the correlation length diverges exponentially as $T \to 0$, according to the relationship:

$$\xi(T) \propto \exp(cJS^2/kT) \tag{8}$$

where $c$ is a constant of the order of $2\pi$. The spin excitation spectrum of the 2D Heisenberg model is gapless, and linear or quadratic in $q$, respectively, for antiferromagnetic or ferromagnetic couplings. At wave vectors $q$ smaller than some cut-off value $q_c$ (roughly corresponding to the relationship $\hbar\omega(q_c) \approx kT$), the spin dynamics become of the diffusive type. The case $D=2$, $n=2$ is quite pathologic.

For the 2D XY model, there exists a very peculiar phase transition (the so-called Kosterlitz–Thouless (KT) transition) below some finite temperature $T_{KT}$ towards a new "topological" order (Kosterlitz and Thouless 1973). The low-temperature phase is characterized by the absence of long-range ordering together with a divergence of the spin susceptibility ($\chi(T)$ remains infinite down to $T=0$K). The instantaneous correlation function decays following a power-law relationship:

$$\langle \mathbf{S}_0 \bullet \mathbf{S}_r \rangle \propto 1/r^{\eta(T)} \tag{9}$$

where $\eta(T_{KT}) = kT/2\pi JS^2$ (indeed defining a line of critical points with $\eta(T_{KT}) = 1/4$ and $T_{KT} = \pi JS^2/2$). The physical origin of this nonconventional behavior has been attributed to the existence in the low-temperature phase of "topological" vortex–antivortex pairs melting at the KT transition.

This gives rise to a very special temperature dependence of the correlation length which behaves exponentially according to the well-known relationship:

$$\xi(T) \propto \exp\left(\frac{b}{\sqrt{\frac{T}{T_C} - 1}}\right) \tag{10}$$

where $b = \pi/\sqrt{2}$. At $T \approx 0$K, the low-energy magnetic excitation spectrum of the 2D XY model is gapless, as expected for any quasi-isotropic system. It is, moreover, linear in $q$ at small $q$ (even for the ferromagnetic case), giving rise to a $T^2$ term in the specific heat. There are no good experimental realizations of the classical $D=2$, $n=2$ and $D=2$, $n=3$ systems (de Jongh and Miedema 1974, de Jongh 1990). For the former case, this situation is mainly ascribed to the fact that the KT ground state is marginal and easily destroyed by any small corrective term (interlayer coupling or axial anisotropy), which should be inherent to all real materials. Both tend to induce a long-range ordering when the temperature becomes sufficiently low.

Experimental investigations exist for the quasi-2D planar compounds $K_2CuF_4$, $Rb_2CrCl_4$, $BaNi_2(PO_4)_2$, or $BaCo_2(AsO_4)_2$ (de Jongh 1990), which give some evidences for the exponential behavior of the correlation length above $T_{KT}$. Concerning the 2D Heisenberg model, prototype systems like $Rb_2MnCl_4$ or $K_2MnF_4$ exist (de Jongh 1990). Unfortunately, they all order at finite temperature owing to non-negligible interlayer couplings and to the presence of a small axial single-ion anisotropy term, preventing the observation of the true 2D behavior.

In the space dimension $D=1$, the strength of spin fluctuations increases so much that no spontaneous magnetization can appear down to $T=0$K, even for the Ising system (Steiner *et al.* 1976). For $D=1$, $n=1$, the correlation length obeys the quasi-exponential relationship:

$$\xi(T) = \frac{a}{|\ln(\tanh(JS^2/kT))|} \tag{11}$$

where $a$ is the intrachain spin–spin spacing. The excitation spectrum has a spin gap, implying an exponential decay of both the longitudinal susceptibility $\chi(T)$ and the specific heat $C(T)$ at low temperature. For $D=1$, $n=2$ and $D=1$, $n=3$, the correlation length behaves linearly in $T$ according to the simple relationship:

$$\xi(T) = \xi_0 JS(S+1)/kT \tag{12}$$

where prefactors $\xi_0 = 2$ and 1, respectively. The excitation spectrum is gapless ($\hbar\omega(q) \propto q$ at small $q$) for both systems, a result again in agreement with the isotropic character of this spin system. As for the 2D case, there exists a cut-off wave vector $q_c \approx \xi^{-1}(T)$ separating the diffusive regime from the quasi-propagating spin wave regime. The specific heat $C(T)$ is linear in $T$ and $\chi(T)$ remains finite at low temperature.

One of the best prototypes of the classical Heisenberg chain is probably the manganese-based ($S=5/2$) chain compound $((C_2H_3)_4NH_4)NMnCl_3$ (TMMC), which exhibits magnetic properties in very quantitative agreement with the theoretical predictions of that model. In particular the relevance of nonlinear excitations (also known as solitons) in the thermal properties (Mikeska 1980) has been clearly demonstrated in TMMC by very comprehensive NMR and INS studies as functions of temperature and field (Regnault *et al.* 1982).

Indeed, in real materials there always exists either a small interchain coupling (quasi-1D system) or a small interlayer coupling $J'$ (quasi-2D system) which

finally leads to the occurrence of a phase transition towards a true long-range ordering at finite temperature. Qualitatively, the critical temperature $T_C$ can be determined from the implicit relationship:

$$2J'S^2\xi^D(T_C) \approx kT_C \tag{13}$$

which means that the phase transition takes place as soon as the thermal energy is comparable to the exchange energy of adjacent correlated segments. For the quasi-1D isotropic chain, this relationship gives:

$$kT_C \approx 2S^2\sqrt{JJ'} \tag{14}$$

For the quasi-2D Heisenberg system this implies a logarithmic dependence on the ratio $J'/J$:

$$kT_C \approx \frac{4\pi JS^2}{|\ln(J'/J)|} \tag{15}$$

The latter relationship explains why very good prototypes of the ideal 2D Heisenberg and XY systems are lacking (de Jongh 1990).

## 3. *Effects of Quantum Fluctuations*

Quantum fluctuations are expected to become stronger as the spin value, $S$, decreases from infinity (classical limit) to $\frac{1}{2}$ (strongly quantum limit). However, the space dimension, $D$, the number of adjacent spins, and the sign of the intrachain or intralayer couplings, $J$, also play an important role. Qualitatively, one finds that the smaller $D$, the larger the quantum effects. Antiferromagnetic interactions are particularly suitable for the existence of strong quantum fluctuations, the more so if they are frustrating the spin system. This is especially the case in the antiferromagnetic triangular lattice, for the $J_1$–$J_2$ antiferromagnetic model of the square lattice, or in the $J_1$–$J_2$ $S=\frac{1}{2}$ antiferromagnetic chain.

### 3.1 *The Two-dimensional Case*

In space dimension $D=2$, for evident topology arguments the predictions are not much different from the classical case. The thermal behavior is qualitatively the same as to some renormalization of coefficients or prefactors. Thus, the 2D Ising model exhibits a phase transition at finite temperature, whereas the 2D XY model exhibits again the topological phase transition. For the 2D Heisenberg model, the ground and excited states correspond to the so-called ''spin-liquid'' state, as far as the frustration is absent from the problem. The predictions are qualitatively the same for both the ferromagnetic and the antiferromagnetic system. Basically, the quantum antiferromagnetic system exhibits no phase transition at finite temperature and remains short-range ordered down to $T=0\,\mathrm{K}$. The temperature dependence of the in-plane correlation length is again exponential, given by an expression similar to that predicted for the classical model (as to some renormalization of the prefactors).

The excitation spectrum at $T=0\,\mathrm{K}$ is gapless and behaves linearly at small wave vector, $\hbar\omega_q \approx cq$, with a spin wave velocity, $c$, only slightly renormalized with respect to its classical value. The best realizations of the 2D $S=\frac{1}{2}$ Heisenberg antiferromagnetic system are the two layered compounds $La_2CuO_4$ ($T_N \approx 320\,\mathrm{K}$, $J \approx 1500\,\mathrm{K}$) and $YBa_2Cu_3O_6$ ($T_N \approx 410\,\mathrm{K}$, $J \approx 1300\,\mathrm{K}$), well known for their very good high $T_C$ superconducting properties appearing upon hole doping. In both materials, comprehensive INS studies (Furrer 1998) have allowed an accurate determination of magnetic excitation spectra and a quantitative comparison with the main predictions of the $S=\frac{1}{2}$ antiferromagnetic square lattice (in particular $\xi(T)$).

### 3.2 *The One-dimensional Case*

In space dimension $D=1$, the strength of quantum fluctuations is considerably enhanced. The magnetic behavior depends not only on the sign of the spin–spin couplings, but also on the parity of the quantity $2S+1$. The case of the antiferromagnetic Heisenberg chain is the most interesting because in that case the magnetic properties are found to be very different for $2S+1$ even ($S=\frac{1}{2}, \frac{3}{2}\ldots$) or $2S+1$ odd ($S=1, 2\ldots$).

#### *(a) The $S=\frac{1}{2}$ antiferromagnetic chain*

The main difference in comparison with the classical system is seen in the excitation spectrum. As shown from analytical as well as numerical calculations (Steiner *et al.* 1976, Schulz 1986), the spin excitation spectrum of the $S=\frac{1}{2}$ Heisenberg antiferromagnetic chain consists of a continuum of triplet ($S=1$) excitations limited on the low-energy side by the threshold energy:

$$\hbar\omega_1(q_c) = \frac{\pi}{2}J\sin(2\pi q_c a) \tag{16}$$

and on the high-energy side by the threshold energy:

$$\hbar\omega_2(q_c) = \pi J\sin(\pi q_c a) \tag{17}$$

The excitation spectrum (unbound spinon continuum (Schulz 1986)) is gapless and the ground state is not ordered, even at $T=0\,\mathrm{K}$. The equal-time spin–spin correlation function behaves according to the algebraic relationship $\langle \mathbf{S}_0\mathbf{S}_n \rangle \propto (-)^n \ln(n)/n$, whereas the magnetic susceptibility at very low temperature remains finite and the magnetic specific heat is linear in $T$. The most important predictions of the $S=\frac{1}{2}$ Heisenberg antiferromagnetic chain have been quantitatively verified in the two prototype materials $CuCl_2 \cdot 2N(C_5H_5)$ (CPC) (Endo *et al.* 1974) and

$KCuF_3$ (Tennant *et al.* 1993). Figure 4 shows, for example, the dispersion relationship along the chain axis and the wave vector dependence of the energy-integrated intensity in CPC, both found to be in good quantitative agreement with the corresponding theoretical predictions.

The $S=\frac{1}{2}$ Heisenberg antiferromagnetic chain in the presence of non-negligible spin–lattice interactions shows a quite different behavior. As shown by Pytte (1974), the strong 1D spin fluctuations induce a lattice instability (indeed a dimerization) below a well-defined temperature, $T_{SP}$, called the spin-Peierls transition temperature. As a consequence of the presence of alternating couplings induced by the dimerization, the ground state of the spin-Peierls system is a nonmagnetic singlet ($S=0$) state. It is well separated from the first excited triplet ($S=1$) states by a gap energy of $\Delta_{SP} \approx 1.75\, kT_{SP}$, directly related to $T_{SP}$ through a Bardeen–Cooper–Schrieffer (BCS)-type relationship, as in phonon-mediated superconductivity. Under an applied magnetic field, the triplet excited states are linearly split by the Zeeman effect into three components of energy $\Delta_v \approx \Delta_{SP} + v g \mu_B H$, with $v=-1, 0, 1$.

Above a critical field $H_c \approx 0.84 \Delta_{SP}/g\mu_B$, the spin-Peierls system undergoes a first-order phase transition towards a new incommensurate magnetic phase which can be viewed as a regular stacking of undistorted regions magnetized along the field direction and distorted nonmagnetic regions (defining the so-called soliton lattice structure). The period, $L$, of the soliton lattice is directly controlled by the homogeneous magnetization, $M$, according to $M \approx \mu_B a/L$. This relationship means that each soliton bears a total spin $\frac{1}{2}$. The major predictions of the standard spin-Peierls model (lattice distortion, singlet ground state, gap in the excitation, high-field incommensurate phase, etc.) have been quantitatively verified in several good prototype compounds such as TTF–Cu–BDT ($T_{SP} \approx 12$ K) (Bray *et al.* 1975) or $CuGeO_3$ ($T_{SP} \approx 14$ K) (Hase *et al.* 1993, Boucher and Regnault 1996). As an example, Fig. 5 shows the temperature dependence of the static susceptibility in $CuGeO_3$, which confirms the spin-Peierls scenario.

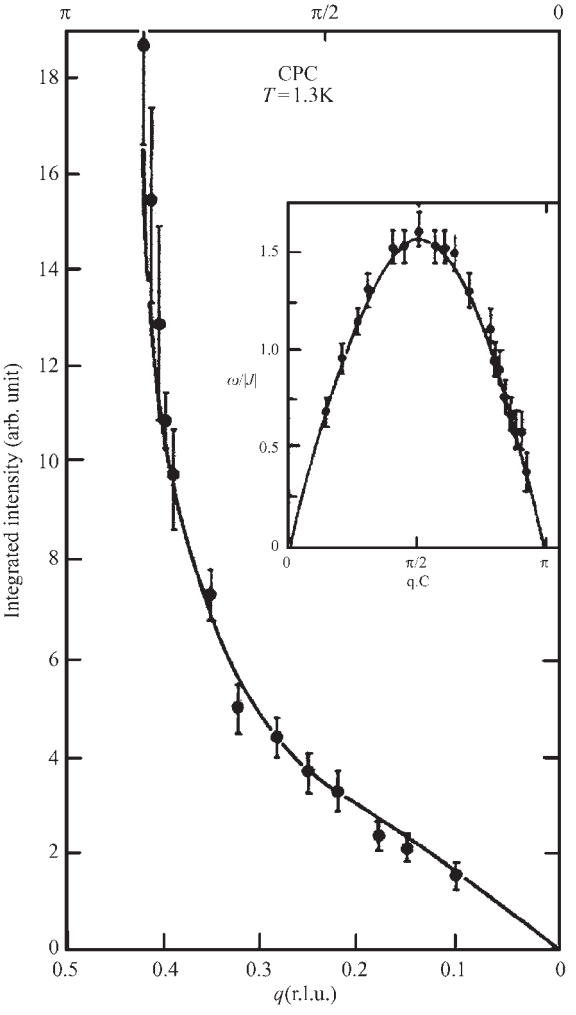

*Figure 4*
Wave vector dependence of the energy-integrated intensity in CPC. Comparison with the theoretical prediction for the $S=\frac{1}{2}$ Heisenberg antiferromagnetic chain.

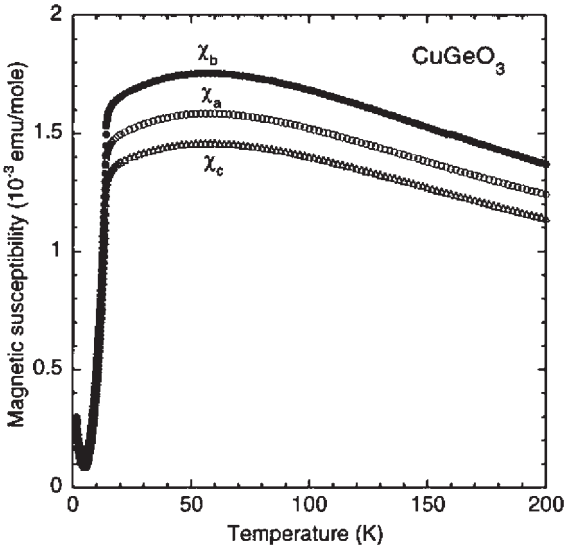

*Figure 5*
Temperature dependence of the magnetic susceptibility along the crystalline directions $a$, $b$, and $c$ (chain axis) in the $S=\frac{1}{2}$ spin-Peierls compound $CuGeO_3$.

*(b) The $S=1$ antiferromagnetic chain*

The spin $S=1$ Heisenberg antiferromagnetic chain displays quite different magnetic properties. As shown by Haldane (1983) and Affleck (1990), for a spin $S=1$ the ground state is a nonmagnetic singlet ground state well separated from the first excited triplet states by a large energy gap $\Delta \approx 0.41J$, where $J$ is the intrachain coupling constant. Contrary to the $S=\frac{1}{2}$ Heisenberg antiferromagnetic case, the spin–spin correlation function behaves exponentially:

$$\langle \mathbf{S}_{0i}\mathbf{S}_n \rangle \propto (-)^n \frac{\exp(-na/\xi)}{\sqrt{n}} \tag{18}$$

with a correlation length $\xi$ which is directly related to the gap energy $\Delta$ by the relationship $\xi \approx c/\Delta$, with $c \approx 2.7Ja$ ($c$ being the spin wave velocity for the model). As a consequence of the spin-gap opening, both the susceptibility and the magnetic specific heat vanish exponentially at low temperature, according to:

$$\chi(T) \propto \frac{\exp(-\Delta/kT)}{\sqrt{T}} \tag{19}$$

and

$$C(T) \propto T\exp(-\Delta/kT) \tag{20}$$

In agreement with numerical calculations, the correlation length of the $S=1$ chain remains finite at $T=0\,\mathrm{K}$ ($\xi \approx 6.5a$). Under an applied field the Haldane ground state disappears at a critical field $H_c \approx \Delta/g\mu_B$, above which a more conventional magnetic phase is recovered. Experimentally, the nickel-based organic compound $Ni(C_2H_8N_2)_2NO_2ClO_4$ (NENP) is probably the best and most studied prototype of the Haldane gap system. In this material, the large Haldane triplet is split into three components by the presence of an intrinsic orthorhombic single-ion anisotropy. Macroscopic as well as microscopic measurements have clearly demonstrated the existence at low temperature of a Haldane phase and the opening of three quantum gaps (Renard *et al.* 1987). Figure 6 shows, for example, the disappearance of the static magnetic susceptibility along the three main crystallographic directions in NENP, a clear signature of the existence of both a singlet ground state and a spin gap at low temperature.

For a larger spin value $S$, the Haldane gap vanishes exponentially according to the semiclassical relation $\Delta \approx 2JS\exp(-\pi S)$ (Haldane 1983, Affleck 1990) and the quantum fluctuations are not strong enough to prevent the interchain couplings from inducing a 3D long-range order.

### 3.3 The Spin-ladder System

At the crossing between chain and plane (see Fig. 1), the $n$-leg $S=\frac{1}{2}$ ladder system displays quite interesting magnetic properties, depending drastically on the parity of $n$, the number of legs. As in the purely 1D case, the most pronounced effects are expected when the spin couplings are antiferromagnetic, both along the legs and the rungs. For $n$ odd, the spin system behaves like the $S=\frac{1}{2}$ chain: gapless magnetic ground state and power-law decay of spin–spin correlation functions. For $n$ even, the spin system exhibits a nonmagnetic singlet ground state separated from the first triplet states by a gap energy $\Delta \propto J\exp(-n)$ and behaves like a Haldane system (Dagotto and Rice 1996). The largest quantum effect is predicted for the two-leg ($n=2$) antiferromagnetic ladder with a gap energy amounting to about $0.53J$. Basically, the singlet ground state results from the formation of strongly coupled $S=0$ dimers along the rungs. The main interest of the two-leg spin-ladder system is in the very interesting conducting properties supposed to appear upon charge doping (e.g., hole doping). As shown theoretically (Dagotto and Rice 1996), if the antiferromagnetic couplings along the legs and the rungs are strong enough to cancel the Coulomb repulsion, the charge carriers tend to be confined to the rungs, leading to an anisotropic pairing mechanism of charge carriers of d-wave symmetry, very reminiscent of that existing in high $T_C$ superconductors.

Experimentally, the $n$-parity effect has been unambiguously observed from susceptibility measurements in the series $Sr_{n-1}Cu_{n+1}O_{2n}$ (Azuma *et al.* 1994). In agreement with theoretical studies, $SrCu_2O_3$ (a two-leg ladder compound) exhibits a susceptibility vanishing exponentially at low temperature, characteristic of a spin-gap opening. In contrast, $Sr_2Cu_3O_5$ (a three-leg ladder compound) displays a finite

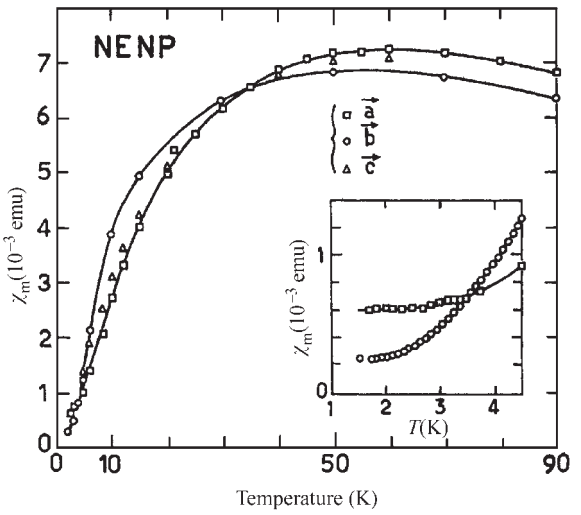

***Figure 6***
Temperature dependence of the magnetic susceptibility along $a$, $b$ (chain), and $c$ axes in the quasi-1D $S=1$ antiferromagnetic chain compound NENP.

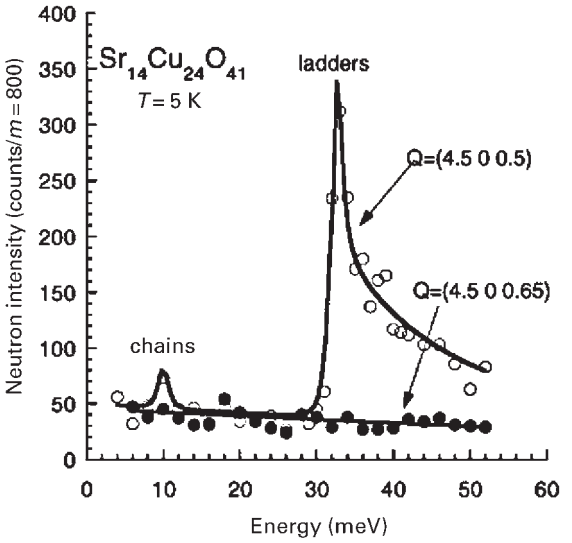

*Figure 7*

susceptibility at $T=0\,K$, characteristic of a gapless system. The existence of the singlet ground state and the spin gap has been seen in the insulating ladder cuprate $Sr_{14}Cu_{24}O_{41}$ from comprehensive NMR (Kumagai *et al*. 1997) and INS studies (Eccleston *et al*. 1998). This compound is very interesting because its crystallographic structure (see Fig. 2) can be described as a stacking of magnetically inert $Cu_2O_3$ two-leg ladder layers and $CuO_2$ chain layers, separated by strontium layers (forming a so-called "composite" structure).

Figure 7 shows a typical INS experimental result obtained for a single-crystalline sample, demonstrating clearly the presence in this material of a forbidden energy window below 33 meV. Interestingly, the chain subsystem contains a large amount of intrinsic quasi-ordered holes ($\sim 0.6$/Cu) and plays the role of charge reservoir. When substituting calcium for strontium, a part of these holes is released to the $Cu_2O_3$ ladders, and the new material (of chemical formula $Sr_{14-x}Ca_xCu_{24}O_{41}$) undergoes an insulator–metal transition at ambient pressure and finally a nonconventional superconductivity is induced under pressure. For calcium content of $x \approx 13.6$, the superconducting transition temperature $T_C$ reaches a maximum value of 10 K at 30 kbar (Uehara *et al*. 1996, Mayaffre *et al*. 1998).

## 4. Effects of Impurities

Chemical substitution takes on different aspects depending on the substituted element. In the most frequent case, a part of the magnetic ions in the parent material is replaced by magnetic or nonmagnetic elements of the same chemical nature (e.g., substitution of zinc for copper or nickel for copper). The magnetic properties of the doped system will depend on several factors, among which is the nature of the ground state (long-range ordered or quantum disordered), the space dimension of the lattice ($D=1$ or $D=2$), and the nature of the impurity itself (valence state, spin). In some cases, the substitution leads to a real charge doping and the formerly insulating material acquires a metallic character and superconductivity can even occur.

### 4.1 Dilution by Magnetic or Nonmagnetic Impurities

The introduction of randomly distributed impurities breaks the regular network of exchange links coupling the magnetic ions. The effect is particularly dramatic for a 1D system because the impurity cuts a chain more or less completely, depending on its spin value. Obviously, the topology of the parent lattice plays a large role. The size of the region disturbed around the impurity will also depend on the strength of quantum fluctuations. The strongest effects are again expected for the $S=\frac{1}{2}$ spin-Peierls system or the $S=\frac{1}{2}$ alternating antiferromagnetic chain, two systems exhibiting a singlet ground state and a spin gap. In the gapless quasi-1D or quasi-2D systems, the main effect of impurities is to reduce the correlation length (and thus the 3D ordering temperature) and to bring an additional $1/T$ contribution to the susceptibility (assuming noninteracting impurities, which is the case if the impurity density, $n_i$, is small). This is easily understandable by assuming that the impurity is "dressed" by a magnetic defect of finite size.

Within this picture, the correlation length at low temperature is mainly controlled by the impurity–impurity distance $d_i$. This distance is directly related to $n_i$ by the geometrical relationship $d_i \approx a/n^{1/D}$. At finite temperature, both the impurity and temperature effects are at first order additive: $\xi^{-1}(n_i, T) \approx d_i^{-1} + \xi_{int}^{-1}(T)$. Both the magnetic defects created around each impurity and the intradefect correlated segments contribute to the spin dynamics. At low temperature, quasi-propagating damped spin wave modes exist for wave vectors larger than a cutoff value $q_c \approx 2\pi/d_i$, whereas at low $q$ a diffusive quasi-elastic mode appears. This classical behavior has been quantitatively observed in the $S=5/2$ Heisenberg antiferromagnetic chain compound TMMC slightly substituted with copper for manganese (Dupas and Renard 1978).

The case of strongly quantum antiferromagnetic chain systems displaying a spin gap $\Delta$ is less intuitive. Basically, in such systems the correlation length of spin fluctuations is strongly reduced by the quantum fluctuations and remains finite at $T=0\,K$ ($\xi \approx c/\Delta$,

where $c$ is the spin wave velocity, i.e., typically $\xi \approx (3-7)a$ depending on the particular system). The main role of impurities is to suppress the quantum fluctuations and thus the doped system recovers a more conventional magnetic behavior, with spin excitations appearing in the gap. In some cases, simultaneously with the destruction of the singlet ground state, a true long-range ordered antiferromagnetic phase occurs, coexisting with the singlet phase. This puzzling result (order by disorder!) is attributed to the fact that around each impurity a magnetic defect is formed (a soliton in this case) developing a staggered magnetization $S(\mathbf{R}_i)$ and extending over a characteristic length scale of the order of the quantum correlation length $\xi$.

Each soliton bears a total spin $\frac{1}{2}$ which can be detected, for example, by susceptibility or ESR measurements. Such a scenario has been observed in the $S=1$ Heisenberg antiferromagnetic chain compound NENP doped with a small amount of copper or cadmium. The case of the spin-Peierls compound $CuGeO_3$ is even more interesting. For this system, the substitution of a small amount $x$ of silicon for germanium or $y$ of zinc for copper is enough to considerably reduce $T_{SP}$ ($\Delta T_{SP}/T_{SP} \approx -35x$ for silicon doping), meaning that the coherence length of the dimerization associated with the spin-Peierls transition decreases strongly, even at small doping. Neutron diffraction measurements reveal the presence of a true long-range ordered antiferromagnetic phase coexisting with the short-range dimerized phase (Fukuyama *et al*. 1996, and references therein). An explanation has been proposed for such a coexistence based on the solitonic model (Fukuyama *et al*. 1996). Doping by zinc or silicon has qualitatively the same effect: that of modifying locally the magnetic couplings, either by breaking completely the exchange links (zinc doping) or by changing the value and/or the sign of $J$ (silicon doping).

Topological solitons bearing a total spin $\frac{1}{2}$ are created around each impurity. These objects are associated with weakly distorted regions extending over a length scale $\xi$ and cut the nonmagnetic distorted chain segments of characteristic length $\sim a/x$ (this value corresponding roughly to the average soliton–soliton distance). For $x$ large enough, the solitons overlap and the phase can propagate, giving rise to the nonzero staggered magnetization detected by neutron diffraction. Such coexistence is indeed a general feature of low-dimensional systems. It has also been observed in doped spin-ladder materials.

### 4.2 Charge Doping

In the doping mechanism previously considered, the substitution between chemical elements having the same valence states (e.g., $Zn^{2+}$ for $Cu^{2+}$) does not change the global charge balance. In most cases the material remains electrically inert. However, there are systems for which the substitution of elements of different valence states generates charge carriers in the material. This is, for example, the case when substituting $Sr^{2+}$ for $La^{3+}$ in the "high $T_C$" material $La_2CuO_4$, for which holes are created in the $CuO_2$ planes. In some other cases, the host material contains intrinsically an amount of charge carriers (holes or electrons) confined to crystallographic entities playing the role of a charge reservoir. This is the case in the quasi-2D material $YBa_2Cu_3O_{6+x}$ (YBCO) or, as previously seen, in the spin-ladder compound $Sr_{14}Cu_{24}O_{41}$, for which the charge carriers (indeed holes) are confined to the CuO chain layers. The change in oxygen content for the former or the substitution of calcium for strontium for the latter induces a charge transfer and some holes are released, respectively, in the $CuO_2$ planes and in the $Cu_2O_3$ ladders, which become metallic. The superconductivity can occur either at ambient pressure (as in YBCO) or under strong pressure (as in the ladder compound). The presence of holes in the $CuO_2$ or $Cu_2O_3$ layers not only affects the exchange links but also distorts the surrounding lattice, thus creating magnetoelastic defects (usually called polarons). As in the previous case, the magnetic coherence length should reflect directly the hole–hole distance, $\sim a/\sqrt{n_h}$, where $n_h$ is the hole density, whereas the spin dynamics should be analogous to that of the diluted system (assuming $n_h$ is sufficiently small).

The presence of such large-size magnetic defects is the origin of the strong decrease of $T_N$ which is observed in the high $T_C$ cuprates upon doping, just before entering the metallic regime. As shown from comprehensive neutron scattering investigations in LSCO and YBCO, the antiferromagnetic long-range ordering disappears for a hole density as small as 2–2.5% hole $Cu^{-1}$. Above this critical value, the previously gapless excitation spectrum starts to develop a spin gap directly related to the superconducting order parameter. In this nontrivial regime, a clear non-Fermi liquid behavior is observed which originates from the existence of strong antiferromagnetic (more or less incommensurate) correlations persisting in the superconducting state (Furrer 1998).

## 5. Conclusion and Perspectives

The magnetism in low-dimensional systems often shows quite nonconventional features resulting in a large part from an increase in both the thermal and quantum fluctuations. The general properties of a given material depend on the subtle balance between several factors: the spin fluctuations and magnetic correlations, the (more or less dynamical) charge ordering, and the spin–lattice or electron–lattice couplings. Depending on their relative strengths, quite different ground states can be realized (e.g., insulating

long-range ordered, nonmagnetic singlet, spin-liquid, Lüttinger-liquid, and superconducting ground states). In most cases, the magnetic behavior can be well described by considering spin Hamiltonians involving only the spin degrees of freedom. However, there is a tendency to reconsider the role played by the orbital degrees of freedom in the strongly correlated electron systems. Techniques probing directly both the spin and orbit correlations (such as spherical neutron polarimetry or polarized x-ray resonant magnetic diffraction) should bring particularly relevant information for the understanding of the roles played by the spin and orbital ordering.

## Coercivity Mechanisms

Since the early days of the commercial use of permanent magnets (PMs) the coercive field has been a topic of theoretical discussion concerning its quantitative interpretation (Becker and Döring 1939, Kersten 1942). With the development of the theory of micromagnetism in the 1930s and 1940s the basic concepts became available for a quantitative treatment of magnetization processes and of the hysteresis loop. At the beginning of the twentieth century the application of magnetic materials was mainly based on iron, cobalt, nickel, carbon steels, and natural iron oxides such as magnetite ($Fe_3O_4$). As a consequence of the quantum theoretical interpretation of spin order by Heisenberg, Bloch, and Néel, combined with the development of the theory of micromagnetism by Landau and Lifshitz (1935), Becker and Döring (1939), and Brown (1945), a more systematic tailoring of magnetic materials became possible. The characterization of the constitution and of the microstructure allowed an analysis of the microstructure–property relationships. The development of high-permeability, high-coercivity, high-remanence, giant-magnetoresistive, and giant-magnetostrictive materials combined with suitable electrical and mechanical properties has influenced the whole field of magnetic devices ranging from the energy technique to high-density recording systems.

The hysteresis loops of these high-quality magnetic materials are characterized by three main parameters: coercive field, $H_c$, remanence, $J_r$, and initial susceptibility, $\chi_0$ (see *Magnetic Hysteresis*). In particular, nanocrystalline alloys have become the leading material for high-technology applications. These applications, the applied experimental techniques, and the underlying physical effects are summarized in Table 1. In all these materials the coercive field is the basic property that should be either very large for permanent magnets or extremely small for high-permeability or sensor materials. For high-density recording systems $H_c$ values of 100–200 $kA\,m^{-1}$ are used. The characteristic parameters of the hysteresis loop depend on the main intrinsic material parameters, such as the spontaneous polarization, $J_s = \mu_0 M_s$ ($M_s$ = magnetization, $\mu_0 = 4\pi \times 10^{-7}\,V\,s\,A^{-1}\,m^{-1}$), the magnetocrystalline constants, $K_1$ and $K_2$ (see *Magnetic Anisotropy*), and the magnetostriction, $\lambda$. Furthermore, the microstructure has a strong influence on $H_c$ and $\chi_0$. The important role of the anisotropy constant $K_1$ is demonstrated by Fig. 1 where the dependence of $H_c$ of different prominent material groups is presented schematically as a function of $K_1$. Here the coercive field varies over eight orders of magnitude from $10^{-1}\,A\,m^{-1}$ up to $10^{7}\,A\,m^{-1}$. This very large range of variation is due to the large variations of $K_1$ and the microstructures with length scales varying from nano- to centimeters. The main mechanisms governing the coercive field are nucleation and domain wall pinning processes. Sometimes also combinations of rotation and nucleation processes exist. In the following the micromagnetic backgrounds of nucleation and pinning in inhomogeneous regions are reviewed.

### *1. Brown's Paradox on and the Role of Microstructures*

The ideal coercive field of an ellipsoidal, single-domain uniaxial particle for a uniform rotation process (Brown 1963) is given by the so-called nucleation field:

$$\mu_0 H_N = \mu_0 H_c = \frac{2K_1}{M_s} - (N_\parallel - N_\perp) J_s \qquad (1)$$

According to Eqn. (1), $H_c$ is independent of the size of particles but depends only on the shape via the

***Table 1***
Nanocrystalline, high-quality magnetic materials.

| Application | Experimental technique | Physical phenomena |
|---|---|---|
| High-coercivity–high-remanence magnets: $H_c > 1.5\,T$; $J_r > 1\,T$ | Nanocrystalline melt-spinning Mechanical alloying | High anisotropy Intergrain exchange coupling |
| High-permeability–high-remanence magnets: $J_r > 1\,T$; $\mu > 10^5$ | Nanocrystalline melt-spinning Amorphous crystallization | Low anisotropy Random anisotropy effect |
| Giant-magnetostrictive alloys $\lambda > 10^{-4}$ | Ion d.c. sputtering | Single ion anisotropies of 4f electrons |
| Giant-magnetoresistive alloys $\Delta R/R > 50\%$ | Laser ablation | Double exchange Magnetic phase transition |
| High-density recording: $> 1\,Gb\,cm^{-2}$ | Multilayers Ion d.c. sputtering Self-organization of substrates and particles on substrates | Single-domain granular systems Perpendicular anisotropy |

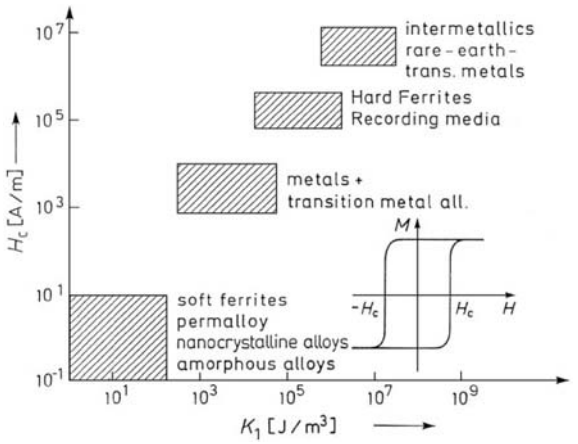

*Figure 1*

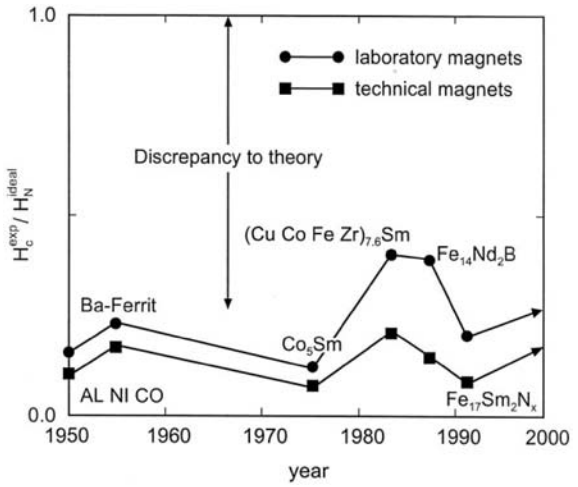

*Figure 2*
Ratio $H_c^{exp}/H_N$ of permanent magnets developed since the 1950s.

demagnetization factors $N_{\parallel}$ and $N_{\perp}$ parallel and perpendicular to the easy axis. The coercive fields predicted by Eqn. (1) so far have not been realized for technical materials. Only in the case of elongated iron whiskers could the theoretical values of the curling mode be approached (Luborsky and Morelock 1964). According to Fig. 2, for the most prominent PMs only 20–30% of the theoretically predicted coercive field could be realized for many years. It is now generally accepted that this discrepancy has to be attributed to magnetic imperfections that lead locally to a drastic reduction of the ideal nucleation field. The main sources of this phenomenon, originally known as Brown's paradoxon (Brown 1945), are the following: (i) reduced anisotropy constant at grain surfaces, (ii) misaligned grains that are exchange coupled with neighboring grains, and (iii) enhanced local demagnetization fields at sharp edges and corners of polyhedral grains.

A relationship that has been shown to be very useful in describing the role of the microstructure and the temperature dependence of $H_c$ is a modification of Eqn. (1) (Kronmüller 1987, Kronmüller *et al.* 1988, Sagawa and Hirosawa 1988):

$$\mu_0 H_c = \frac{2K_1}{M_s}\alpha - N_{eff} J_s \qquad (2)$$

where two microstructural parameters, $\alpha$ and $N_{eff}$, have been introduced. Here $\alpha < 1$ describes the reduction of the ideal crystal field $2K_1/M_s$ owing to lattice imperfections and atomic disorder at grain surfaces. The effective demagnetization factor takes care of the enhanced stray fields at edges and corners of polyhedral grains. Equation (2) not only applies to nucleation-hardened PMs but also describes $H_c$ of thin films and multilayers and the coercive field of the pinning hardened $Sm_2Co_{17}$-based PMs. The parameter $\alpha$ subsumes the above described microstructural effects and is composed of three subparameters (Kronmüller *et al.* 1987, Bauer *et al.* 1996):

$$\alpha = \alpha_K \alpha_\psi \alpha_{ex} \qquad (3)$$

where $\alpha_K$, $\alpha_\psi$, and $\alpha_{ex}$ describe the effect of a reduced anisotropy constant, of misaligned grains, and of exchange coupling between grains. An explicit determination of $\alpha$ is based on solutions of the micromagnetic equations for special models of microstructures.

## 2. Nucleation Field in Regions of Reduced Anisotropy Constants

Nucleation fields are usually derived as the eigenvalues of the linearized micromagnetic equations. For example, the nucleation field for uniform rotation has been obtained for constant material constants $J_s$, $K_1$, and $A$ ($A$ = exchange constant). Similarly the curling and the buckling mode have been determined for constant material parameters (Aharoni 1962). In magnetically inhomogeneous regions in general all three material parameters vary spatially. However, $K_1$ is much more sensitive with respect to atomic disorder than $J_s$ and $A$, as known from amorphous alloys. To a first approximation $J_s$ and $A$ therefore may be considered to be constant and only variations of $K_1$ are taken into account. In the case of a planar grain boundary or a deteriorated surface, the main parameters characterizing the magnetic defect are the half width, $r_0$, and the change, $\Delta K$, of the anisotropy

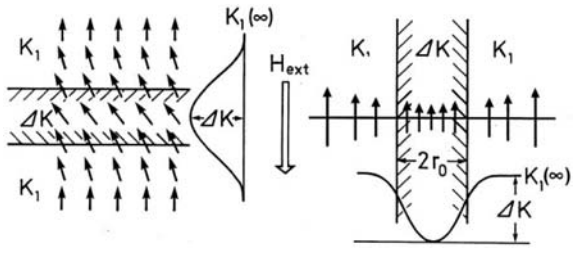

*Figure 3*
Nucleation of a reversed domain within a planar intergranular phase of reduced anisotropy. Left: perpendicular stripe; right: parallel stripe.

constant. A suitable one-dimensional equation for the position dependence of $K_1(z)$ allowing a quantitative solution of the nucleation problem is given by (Kronmüller 1987).

$$K_1(z) = K_1(\infty) - \Delta K/ch^2(z/r_0) \tag{4}$$

In the case of a one-dimensional problem, e.g., a planar grain boundary as shown in Fig. 3, the linearized micromagnetic equation is then

$$2A\frac{\mathrm{d}^2\varphi}{\mathrm{d}z^2} - \left\{2\left[K_1(\infty) - \frac{\Delta K}{ch^2(z/r_0)}\right] - J_s(H_{\mathrm{ext}} + N_{\mathrm{eff}}M_s)\right\}\varphi = 0 \tag{5}$$

where $\varphi$ is the angle between $\underline{J}_s$ and the easy axis. The solution of Eqn. (5) leads to hypergeometric functions and the parameter $\alpha_K$ follows from the lowest eigenvalue of possible solutions:

$$\alpha_K = 1 - \frac{1}{4\pi^2}\frac{\delta_B^2}{r_0^2}\left(1 - \sqrt{1 + \frac{4\pi^2 r_0^2}{\delta_B'^2}}\right)^2 \tag{6}$$

where $\delta_B = \pi\sqrt{A/K_1(\infty)}>$ denotes the wall width of the perfect crystal and $\delta_B' = \pi\sqrt{A/\Delta K}$ corresponds to a fictitious wall width of a material with anisotropy $\Delta K$. The parameter $\alpha_K$ is presented in Fig. 4 as a function of $\delta_B/r_0$ and for $\Delta K$ as a parameter. From Eqn. (6), three interesting limiting cases can be derived:

$$\begin{aligned}
&1.\quad 2\pi r_0 < \delta_B;\ \alpha_K = 1 - \pi^2\frac{\delta_B^2}{\delta_B'^4}r_0^2\\
&2.\quad 2\pi r_0 \geqslant \delta_B;\ \alpha_K = \frac{1}{\pi}\frac{\delta_B^2}{\delta_B'}\frac{1}{r_0} + \frac{K_1 - \Delta K}{K_1}\\
&3.\quad 2\pi r_0 \gg \delta_B;\ \alpha_K = \frac{K_1 - \Delta K}{K_1}
\end{aligned} \tag{7}$$

In the case where $\Delta K = K_1$, $\alpha_K$ in the three limits is $\alpha_K = 1 - \pi^2 r_0^2/\delta_B^2$, $\alpha_K = (1/\pi)(\delta_B/r_0)$, and $\alpha_K = 0$. Inserting

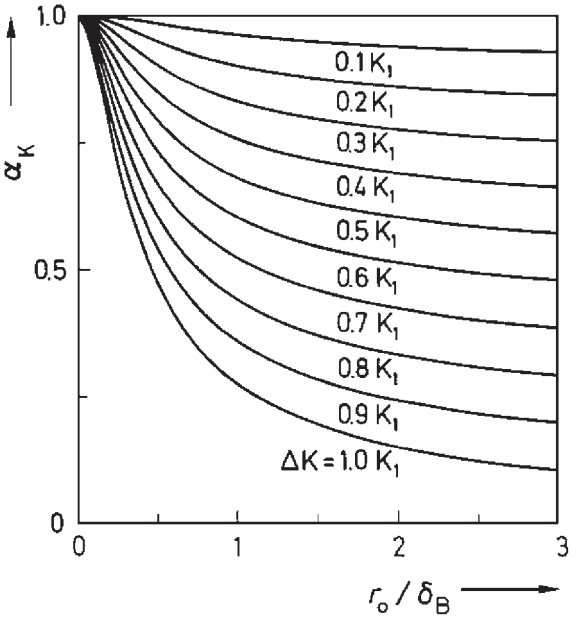

*Figure 4*
Variation of $\alpha_K$ as a function of $r_0/\delta_B$ for various $\Delta K$.

$\alpha_K$ of the second limit into Eqn. (2) gives

$$H_N = H_c = \frac{2K_1}{J_s}\frac{\delta_B}{\pi r_0} - N_{\mathrm{eff}}M_s = \frac{\gamma_B}{2J_s}\frac{1}{r_0} - N_{\mathrm{eff}}M_s \tag{8}$$

where $\gamma_B = 4\sqrt{AK_1}$ denotes the wall energy per unit area.

## 3. Nucleation Field of Misaligned Grains

The nucleation field is reduced by a factor $\alpha_\psi$ if the field is applied under an angle $\psi_0$ with respect to the negative $c$-axis. Stoner and Wohlfarth (1948) have determined $\alpha_\psi$ for a uniaxial particle and the anisotropy constant $K_1$. An expansion of the Stoner–Wohlfarth result including the second anisotropy constant $K_2$ is given by (Kronmüller *et al.* 1987)

$$\alpha_\psi = \frac{1}{[(\cos\psi_0)^{2/3} + (\sin\psi_0)^{2/3}]^{3/2}} \times \left[1 + \frac{2K_2}{K_1 + K_d}\frac{(\tan\psi_0)^{2/3}}{1 + (\tan\psi_0)^{2/3}}\right] \tag{9}$$

The angle $\varphi_N$ by which $\underline{J}_s$ is rotated before spontaneous nucleation takes place is given by

$$\varphi_N = \tan^{-1}\sqrt[3]{\tan\psi_0} + \frac{2}{3}\frac{K_2}{K_1 + K_d} \tag{10}$$

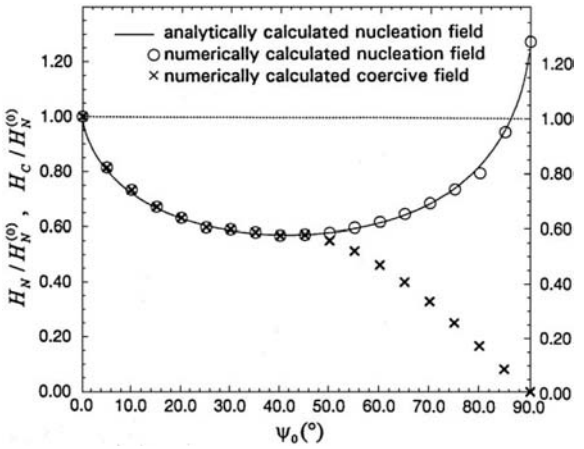

***Figure 5***
Angular dependence of the nucleation and the coercive field of a $Nd_2Fe_{14}B$ sphere in reduced units ($\alpha_\psi = H_N/H_N^{(0)}$).

where $K_d = (1/2)\mu_0(N_\perp - N_\parallel)M_s^2$. The parameter $\alpha_\psi$, defined as $\alpha_\psi = H_N(\psi)/H_N(0)$, is shown in Fig. 5 for the extended theory with $K_2 \neq 0$ for the case of $Nd_2Fe_{14}B$ and $K_d = 0$ (sphere). Also shown in Fig. 5 are the coercive fields which for $\psi_0 < \pi/4$ coincide with the nucleation fields, but decrease for $\psi_0 > \pi/4$, because nucleation takes place in the third quadrant.

## 4. *Coercive Fields of Assemblies of Grains*

In the case of assemblies of grains three types of permanent magnets have to be distinguished that are characterized by special microstructures, as shown schematically in Fig. 6 and leading to hysteresis loops presented in Fig. 7:

(i) High-coercivity PMs where the grains are magnetically decoupled by a paramagnetic intergranular film. In the case of $R_2Fe_{14}B$-based magnets, this microstructure is realized by an overstoichiometry of R and suitable additives such as gallium and niobium (Kronmüller *et al.* 1996) (see *Magnets: Sintered*). There still exists a long-range dipolar interaction between the grains, which, however, becomes rather small in the case of nanograins (Rieger *et al.* 1999).

(ii) High-remanence–high-coercivity PMs are obtained if nanograins are magnetically coupled by exchange interactions (Kneller and Hawig 1991, Kronmüller *et al.* 1996). These types of PMs are realized by highly stoichiometric alloys.

(iii) Composite high-remanence PMs (Coehoorn *et al.* 1988, Bauer *et al.* 1996, Goll *et al.* 1998, Neu *et al.* 1996) are obtained by melt-spinning of alloys with overstoichiometric content of α-Fe. In this case, in addition to the effect of exchange coupling between the grains, the large magnetization of α-Fe also enhances the remanence (see *Magnets: Remanence-enhanced*).

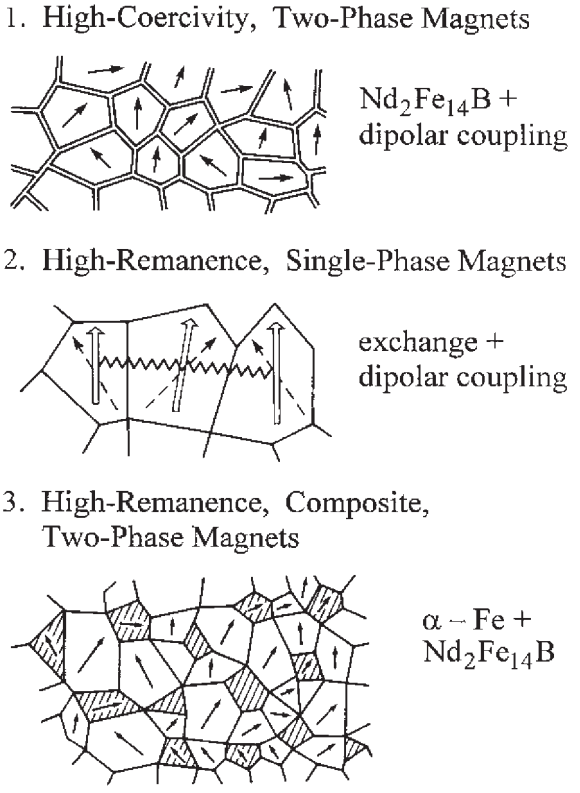

***Figure 6***
Schematic microstructures of nanocrystalline melt-spun permanent magnets.

### 4.1 *Isotropic Distribution of Decoupled Grains*

In the case of decoupled grains, $\alpha_\psi$ has to be replaced by an effective value, $\alpha^{eff}$, which takes care of the fact that the demagnetization process takes place by irreversible nucleation processes and also by reversible rotational processes. Owing to the angular dependence of $\alpha_\psi$ all those grains oriented symmetrically around $\psi_0 = \pi/4$ reorient their magnetization first. Neglecting the reversible rotations in the remaining grains the demagnetization to zero polarization is performed by those grains with misalignment angles in the range $30° < \psi < 60°$. In this range the average, $\langle \alpha_\psi \rangle$, is of the order of 0.53, i.e., this value is very near to the minimum value $\alpha_\psi^{min} = 0.5$ at $\psi_0 = \pi/4$. The value of 0.53 is even lowered if the contributions of the reversible rotations are taken into account. Consequently, in the case of an isotropic distribution of

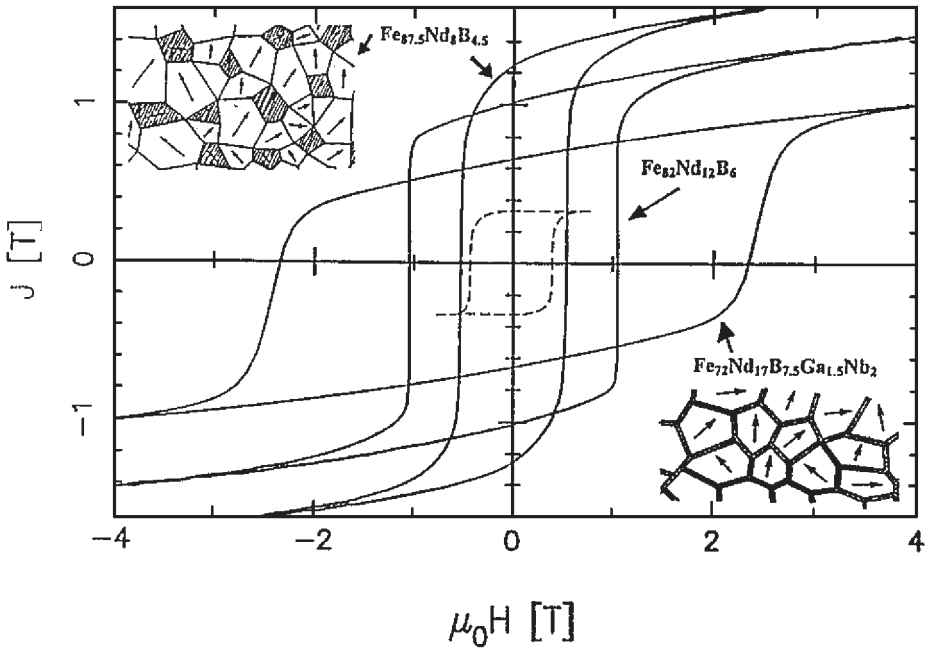

*Figure 7*
Hysteresis loops of nanocrystalline PMs with the microstructures of Fig. 6. The broken curve represents the conventional (Ba, Sr)-based ferrite. The intermediate loop results from the stoichiometric $Nd_2Fe_{14}B$.

easy axes, it is a reasonable approximation to use for $\alpha_\psi$ the minimum value $\alpha_\psi^{\min}$, given by (Kronmüller 1990)

$$\alpha_\psi^{\min} = \frac{K_1 + K_2}{2K_1} \cong \frac{1}{2} \tag{11}$$

### 4.2 Isotropic Distribution of Exchange-coupled Grains

In nanocrystalline PMs with exchange coupling between the grains the coercive field is in general smaller as compared to exchange-decoupled grains. Several sources may contribute to this decrease of $H_c$. The random anisotropy effect (Herzer 1990) leads to a reduction of the effective anisotropy constant if the grain sizes are smaller than the wall width. In the case of hard magnetic materials, $\delta_B < 5$ nm holds whereas in most nanocrystalline PMs $D$ is larger than $\delta_B$ (10–20 nm) and therefore the random anisotropy effect becomes ineffective. Another source of reduced coercive fields are grains with misalignment angles $\psi_0 > \pi/4$. According to Fig. 5 the coercive field of these grains decreases to zero for $\psi_0 = \pi/2$ where $H_N > H_c$, i.e., they contribute to the demagnetization process only by reversible rotations.

Owing to the exchange coupling these strongly misaligned grains increase the rotation of $J_s$ within the neighboring grains which leads to an enhancement of the reversal of magnetization in these neighboring grains because the critical angle, $\varphi_N$, is achieved at lower fields. The demagnetization process of exchange-coupled grains therefore is a collective process where a cluster of grains becomes reversed by the grain of largest misalignment. It can therefore be assumed that the demagnetization process in assemblies of exchange-coupled grains is governed by the grains with misalignment angles $\pi/4 < \psi < \pi/2$. The average coercive field of these grains is of the order of $(1/4)(2K_1/J_s)$, i.e., $\alpha_{ex} \sim 1/2$.

## 5. Analysis of Temperature Dependence

### 5.1 The Nucleation Model

The analysis of hardening mechanisms and of the temperature dependence of $H_c$ starts from Eqn. (2). In general it is assumed that the grains with the smallest $H_c$ values determine the global $H_c$, i.e., the grains that are characterized by $\alpha_\psi^{\min}$ of Eqn. (11). A precise value of $\alpha_\psi^{\min}$ including $K_2$ has been determined by Martinek and Kronmüller (1990). With $H_N^{\min} = \alpha_\psi^{\min} \cdot H_N$, Eqn. (2) may be written as

$$\mu_0 H_c = \alpha_K \alpha_{ex} \mu_0 H_N^{\min} - N_{eff} J_s \tag{12}$$

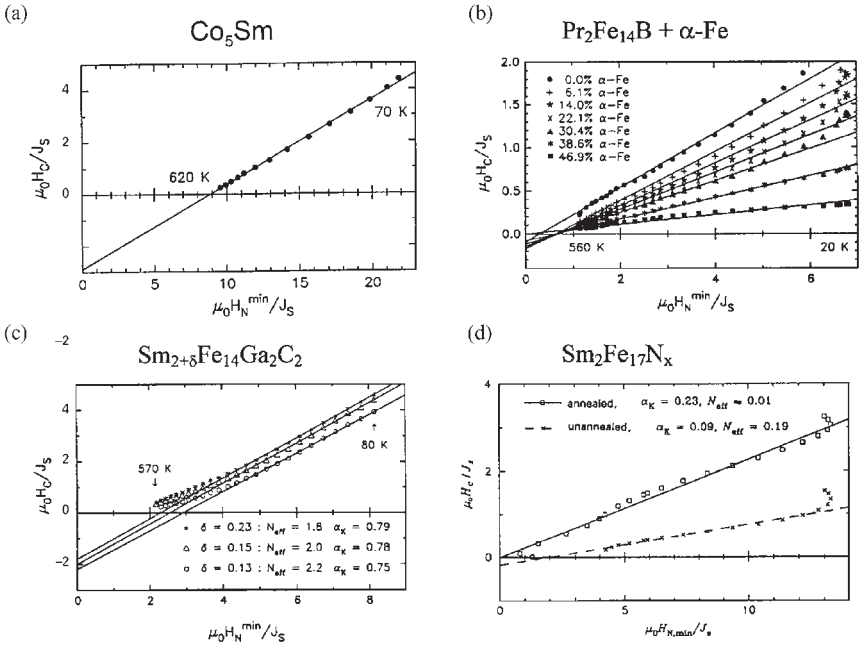

***Figure 8***
Plots of $\mu_0 H_c/J_s$ vs. $\mu_0 H_N^{min}/J_s$ to determine the microstructural parameters $\alpha_K$ and $N_{eff}$: (a) $Co_5Sm$ sintered PM; (b) composite $Pr_2Fe_{14}B + \alpha$-Fe melt-spun PMs; (c) $Sm_{2+\delta}Fe_{14}Ga_2C_2$ carbides with $\delta = 0.0$, 0.05, 0.14; (d) $Sm_{10.7}Fe_{89.3}N_x$ nitride annealed at $T_a = 850\,^{\circ}C$ for $t_a = 17$ min and nitrided at 460 °C.

from which it is possible to derive the plot

$$\mu_0 H_c(T)/J_s(T)|_{exp} \text{ vs. } \mu_0 H_c^{min}(T)/J_s(T)|_{theor} \qquad (13)$$

The left-hand side represents the experimental and the right-hand side the theoretical values. In the case of a linear plot the parameters $\alpha_K \cdot \alpha_{ex}$ and $N_{eff}$ are obtained as the slope and the ordinate intersection of the straight line, respectively. These parameters have been determined for a large number of rare-earth-based PMs. Figure 8 shows the $\mu_0 H_c(T)/J_s(T)$ plots for sintered $Co_5Sm$, nanocrystalline $Pr_2Fe_{14}B + \alpha$-Fe, $Sm_{2+\delta}Fe_{14}Ga_2C_2$ (with $\delta = 0.0$, 0.05, and 0.14), and the nitride $Sm_{10.7}Fe_{89.3}N_x$. In all cases a linear relationship is found with minor deviations in the case of the carbide, because the determination of $H_N^{min}$ suffers from a large error in $K_1$ and $K_2$ at high temperatures. The results presented so far clearly show that linear plots of Eqn. (13) are obtained for nanocrystalline and sintered PMs. The validity of the nucleation model therefore seems clear. From the measured $\alpha$ parameters with the assumption $\alpha_{ex} = 1/2$ for nanocrystalline and $\alpha_{ex} = 1$ for sintered and decoupled PMs, values of $\alpha_K$ are obtained between 0.3 and 0.8, which corresponds to a width of the inhomogeneity region of $0.3\delta_B < 2r_0 < \delta_B$. For example, in the case of $Co_5Sm$ with $\alpha_K = 0.33$ and $\alpha_{ex} = 1/2$, $r_0$ is of the order of 1 nm. Similar results have been obtained previously for $Nd_2Fe_{14}B$ PMs (Kronmüller *et al.* 1988). Another interesting result is the range of $\alpha$ parameters of nanocrystalline $Pr_2Fe_{14}B$ PMs (Goll *et al.* 1998). For decoupled PrFeB PMs with excess praseodymium $\alpha_K$ values of $\sim 0.8$ are obtained, whereas the stoichiometric exchange-coupled and composite PMs show $\alpha$ values in the range 0.06–0.32. These small $\alpha$ values of nanocrystalline PMs are due to the parameter $\alpha_{ex}$, which reduces the $\alpha$ values by at least 50%. Furthermore, it should be noted that the $N_{eff}$ values of sintered magnets are large with $N_{eff} \geqslant 1$, whereas the values of nanocrystalline PMs range from 0 to 0.2 because the grains have a spherical shape.

### *5.2 The Nucleus Expansion Model*

Besides the spontaneous nucleation model discussed in Sect. 5.1 a so-called phenomenological "global model" has been discussed (Givord and Rossignol 1996). In this model it is assumed that the expansion of a preformed nucleus takes place by means of a thermally excited process within the lifetime of the reversed nucleus that is given by an Arrhenius equation: $\tau = \tau_0 \exp(-\Delta E/kt)$. The pre-exponential factor is of the order of magnitude $\tau_0 \cong 10^{-11}$ s and $\Delta E$

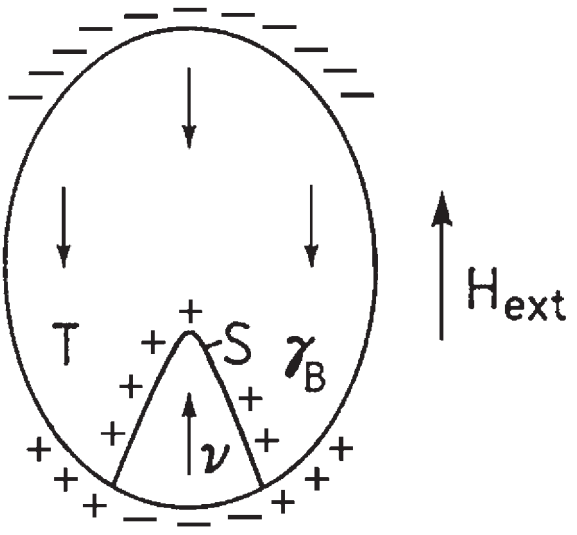

***Figure 9***
Spike-type nucleus of volume $v$, surface area $s$, and wall energy $\gamma'_B$.

denotes the activation enthalpy required to expand the nucleus of volume $v$ spontaneously. For usual measuring times of $t = 1-10^3$ s the activation enthalpy $\Delta E(t) = kT\ln(t/\tau_0)$ is of the order of $\Delta E \cong 25kT$ (Givord and Rossignol 1996).

The activation energy $\Delta E$ is required in order to overcome the magnetic enthalpy required for the expansion of the nucleus. As shown in Fig. 9, at the coercive field $H_c$ the three terms of the magnetic enthalpy are balanced by $\Delta E$, which leads to

$$s\gamma_B' - \mu_0 M_s H_c v - \mu_0 N_{eff} M_s^2 v = \Delta E = 25kT \quad (14)$$

with the domain wall energy, the magnetostatic energy of the external field at $H_c$, and the demagnetization energy. Since it is suggested that the nucleus is formed in a perturbed region, the specific wall energy $\gamma_B$ is reduced as compared to the value of the perfect crystal, giving $\gamma'_B = \alpha_B \gamma'_B = \alpha_B \times 4\sqrt{AK_1}$, where $\alpha_B$ corresponds to a microstructural parameter less than unity. The surface, $s$, of the nucleus may be related to the volume, $v$, by $s = \alpha_s v^{2/3}$, where $\alpha_s$ corresponds to a geometrical parameter relating the nucleus surface to the nucleus volume. From Eqn. (14), one now obtains

$$\mu_0 H_c = \frac{\alpha_s \alpha_B \gamma_B}{M_s v^{1/3}} - \mu_0 M_s \cdot N_{eff} - \frac{25kT}{vM_s} \quad (15)$$

Measurements of the activation volume, $v$, by means of relaxation curves have shown that $v$ obeys a similar temperature dependence as $\delta_B^3$. Therefore, with $v = \alpha_v^3 \delta_B^3$, Eqn. (15) can be rewritten as

$$\begin{aligned}\mu_0 H_c &= \frac{\alpha_s \alpha_B}{\alpha_v} \frac{1}{M_s} \frac{\gamma_B}{\delta_B} - \mu_0 M_s \cdot N_{eff} - \frac{25kT}{vM_s} \\ &= \frac{2K_1}{M_s} \frac{2\alpha_s \alpha_B}{\pi \alpha_v} - \mu_0 M_s \cdot N_{eff} - \frac{25kT}{vM_s} \end{aligned} \quad (16)$$

Here it becomes obvious that the coercive field of the global model is described by the same Eqn. (2) or Eqn. (8) as in the case of the nucleation model. The only difference seems to be that the nucleation model is based on the micromagnetic equations whereas the global model starts from an energetic approach, i.e., the integrated micromagnetic equations. Since the thermal fluctuation field $\mu_0 H_f = 25kT/vM_s$ corresponds only to 5–10% of the coercive field, the micromagnetic energy terms are the dominant ones. Naturally the fluctuation field can also be introduced into the nucleation model as a term reducing the nucleation field. The microstructural parameters $\alpha_s$ and $\alpha_B$ can be derived from the plot

$$\left.\frac{H_c + H_f}{M_s}\right|_{exp} \text{ vs. } \gamma_B/\mu_0 M_s^2 v^{1/3} \text{ or vs. } \mu_0 \gamma_B / J_s^2 v^{1/3} \quad (17)$$

where $H_c$, $v$, and $H_f$ are determined experimentally and $M_s$ and $\gamma_B$ are obtained from the intrinsic material parameters. Figure 10 shows the temperature dependence of the activation volume of three types of magnets (melt-spun, sintered and annealed, and as-sintered). The corresponding plots, according to Eqn. (17), are shown in Fig. 11 (Becher *et al.* 1998). For all three magnets linear plots are obtained and the microstructural parameters vary between 0.66 and 1.07. For a nucleus of spherical or conical shape (apex angle $\theta = 15°$) $\alpha_s$ varies between 4.8 and 2.3. In the case of the nanocrystalline melt-spun magnet this means that $\alpha_B$ varies between 0.2 and 0.4.

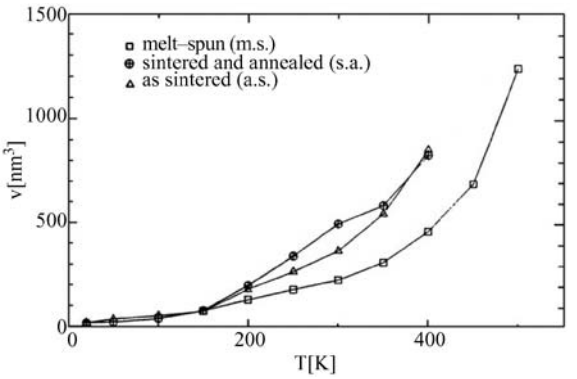

***Figure 10***
Temperature dependence of the activation volume of three types of magnets.

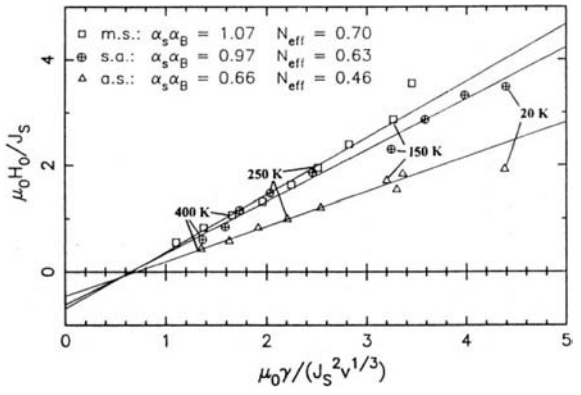

***Figure 11***
Plots for the determination of $\alpha_s\alpha_B$ and $N_{eff}$ for the global model of the PMs of Fig. 10.

Since the measured activation volumes are of the order of 300 nm$^3$ the reduction of the wall energy should extend over dimensions of $\sim 5\delta_B$ ($\sim 20$ nm). The problem arising here is the fact that from high-resolution transmission electron microscopy images (Kronmüller *et al.* 1996) it is known that the nanocrystalline grains are perfect with the exception of the grain boundaries of width 1–3 nm. Accordingly, neither the values measured for $v$ nor for $\alpha_B$ are compatible with the real microstructure. The situation is different for the nucleation model where the reversion of magnetization starts in regions of width 0.5–2 nm in agreement with the microstructure. Since the global theory is just the integrated expression of the micromagnetic equation, the microstructural parameters, $\alpha_s$, $\alpha_B$, and $\alpha_v$ may be identified with the parameters $\alpha_K$ and $\alpha_{ex}$, i.e., $4\alpha_s\alpha_B/\pi\alpha_v \equiv \alpha_K\alpha_{ex}$, which enlightens one as to the seeming existence of two different theories.

## 6. *Pinning of Domain Walls by Planar Barriers in $Sm_2Co_{17}$-based Magnets*

Planar defects of atomic width are stacking faults, phase and antiphase boundaries, and planar precipitates as the cell walls of copper-doped $Sm_2Co_{17}$ PMs. The pinning of domain walls by planar defects has been treated by the continuum theory of micromagnetism (Kronmüller 1973, Friedberg and Paul 1975, Hilzinger 1977, Gaunt and Mylvaganam 1981) and on the basis of the Heisenberg model (Hilzinger and Kronmüller 1975). The pinning effect is due to the modification of the wall energy by the planar defect. If the planar defect has extensions larger than the wall width the coercive field is given by

$$H_c = \frac{1}{2J_s}\frac{1}{\cos\psi_0}\left.\frac{d\gamma(z)}{dz}\right|_{max} - N_{eff}M_s \qquad (18)$$

where $d\gamma(z)/dz|_{max}$ denotes the maximum slope of wall energy. In the case of a linear barrier, $d\gamma(z)/dz|_{max}$ is given by $|\gamma^{II}-\gamma^{I}|/D$, where $\gamma^{I,II}$ denote the wall energies in the two neighboring phases and $D$ corresponds to the width of the defect.

In the case of a narrow defect with $D < \delta_B$ the coercive field is determined by the discrete Heisenberg model (Hilzinger and Kronmüller 1975) where the planar defect is described by its $n$ individual lattice planes of distance $d$. Each plane, $i$, is characterized by a local anisotropy constant, $K^i$, and an exchange constant, $A^{i,i+1}$, between neighboring planes. The result of a lengthy calculation is

$$H_c = \frac{\pi}{3\sqrt{3}}\frac{2K_1}{J_s}\frac{1}{\cos\psi_0}\frac{d}{\delta_B}\sum_{i=1}^{n-1}\left|\frac{A}{A^{i,i+1}} - \frac{K_1^i}{K_1}\right| \qquad (19)$$

where $A$, $K_1$, and $J_s$ are the material constants of the matrix phase and $\delta_B$ is the wall width. Equation (19) has a wide range of applications and may be applied for the interpretation of the $Sm_2Co_{17}$-based magnets with additives of iron, copper, and zirconium. For these PMs the largest coercivities of the order of 3–4 T have been found. These hard magnetic properties are obtained after a homogenizing treatment at 1100–1200 °C (30 min), isothermal aging at 850 °C (10–25 h), and a subsequent slow cooling (0.5–1.0 °C min$^{-1}$) to 400 °C followed by quenching to room temperature. During the annealing procedure a cellular pyramidal structure develops composed of three phases (Livingston and Martin 1977, Hadjipanayis 1982): cells of about 100 nm in size corresponding to an iron-rich 2:17 matrix, cell walls of $SmCo_5$ structure separating the cells enriched in copper and poor in iron and zirconium, and a zirconium-rich lamellar platelet phase, called a Z-phase, which is oriented perpendicular to the $c$-axis of the cells. The cell walls of width 5–10 nm may act as a barrier or pinning center depending on the copper content and the degree of order in the 1:5 cell wall. In the particular case of $Sm(Co_{bal}Cu_{0.08}Fe_{0.22}Zr_{0.02})_{8.5}$ Goll *et al.* (2000) have performed an analysis of the element distributions within the cells and cell walls by HRTEM-EDX. The corresponding profile of the copper and iron distribution and of the anisotropy constant is shown in Fig. 12 (Goll 2001). The anisotropy constant varies from a value of $K_1^{2:17} = 2.9$ MJ m$^{-3}$ to $K_1^{1:5} = 8.1$ MJ m$^{-3}$ within a narrow width of $\sim 2$ nm. Assuming that this increase of nearly a factor 3 takes place over 10 atomic layers, where $d = 0.2$ nm and $\delta_B = 5$ nm, $\mu_0 H_c = (2K_1/M_s) \times 0.22$ is obtained from Eqn. (19) for a constant exchange energy. With the $\alpha$ parameter for the pinning $\alpha^{pin} = 0.22$ for room temperature a coercive field of 2.8 T is obtained, in excellent agreement with the experimental results. Figure 13 shows plots of $\mu_0 H_c/J_s$ vs. $2\mu_0 K_1/J_s^2$ for different annealing treatments of sintered magnets. Over a wide temperature range between 170 K

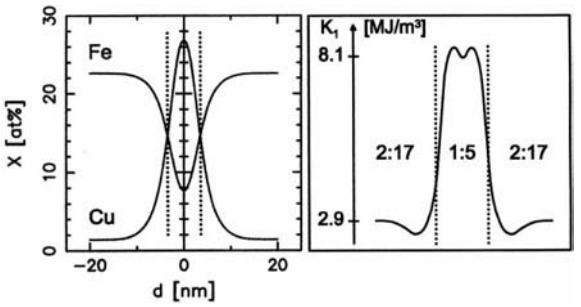

*Figure 12*
Copper and iron profiles of the cell wall in $Sm(Co_{bal}Cu_{0.08}Fe_{0.22}Zr_{0.02})_{8.5}$ as measured by high-resolution EDX transmission electron microscopy and the corresponding profile of the anisotropy constant.

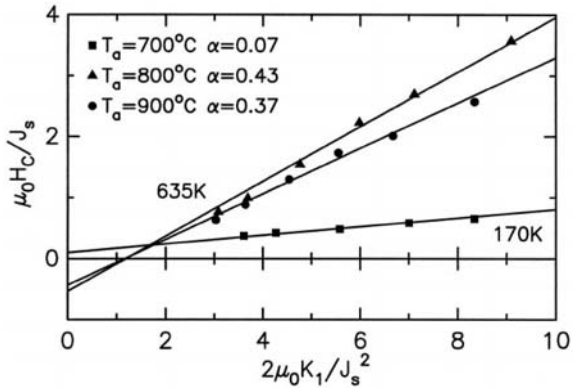

*Figure 13*
Plots of $\mu_0 H_c/J_s$ vs. $2\mu_0 K_1/J_s^2$ for different annealing treatments of a sintered $Sm_2(CoCuFeZr)_{17}$ PMs showing the validity of Eqn. (2).

and 635 K a linear relationship is found with $\alpha$ parameters between 0.07 and 0.43. As is well known annealing at 800 °C gives the optimal values of the coercive field. The dominance of the 2:17-based PMs above 650 K is clearly shown by Fig. 14 where the coercive fields of several prominent PMs are compared with each other.

## 7. Statistical Pinning Theory of Domain Walls

In soft magnetic materials based on amorphous, crystalline, or nanocrystalline alloys the coercive field is determined by the interaction of domain walls with a large number of imperfections such as grain boundaries, dislocations and point defects, or impurity atoms. In the case of a dislocation density of $10^{10}\,cm^{-2}$, there are $10^4$ dislocations within a domain wall (DW) of cross-section $10^{-6}\,cm^2$. The resulting

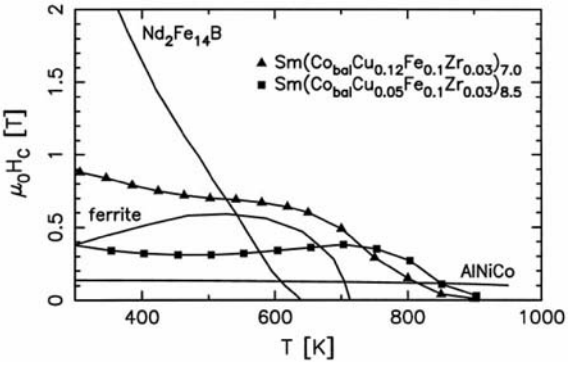

*Figure 14*
Comparison of the temperature dependence of different types of PMs showing the dominance of the $Sm_2Co_{17}$-type PMs at high temperatures.

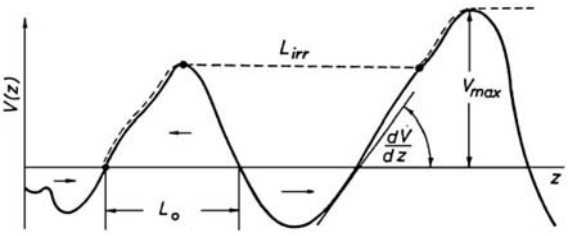

*Figure 15*
Characteristic parameters of the statistical field of force.

force acting on a DW in this case has to be determined by statistical methods. The force of a defect at position $z_j$ acting on a DW at position $z$ is described by $v(z-z_j)$, where $z$ is the coordinate parallel to the DW normal. The total force acting on a DW is then given by (Kronmüller 1997)

$$V(z) = \sum_j v(z - z_j) \qquad (20)$$

where the sum extends over all defects. The statistical field of force, shown schematically in Fig. 15, is characterized by three parameters:

(i) the average wavelength $2L_0$ defined as twice the distance between neighboring zeros $\overline{V}(z) = 0$;

(ii) the average value $V_{max}$ of the maximum of $V(z)$; and

(iii) the average of the reciprocal slopes of $V(z)$ at $V(z) = 0$ given by $\overline{1/R} = \overline{1/(dV/dz)}$.

These parameters may be determined by means of correlation functions under the assumption that the total forces $V$ obey a Gaussian distribution function $f(V)$. The probability, $f$, of finding an interaction force between $V$ and $V + dV$ or a slope $R = dV/dz$

between $R$ and $R + \mathrm{d}R$ is given by

$$f(V) = \frac{1}{(2\pi B_0)^{1/2}} \exp\left(\frac{-V^2}{2B_0}\right);$$
$$f(R) = \frac{1}{(2\pi B_1)^{1/2}} \exp\left(\frac{-R^2}{2B_1}\right) \qquad (21)$$

The correlation functions $B_0$ and $B_1$ are related to the individual interaction forces, $v$, by the following integrals:

$$B_0 = \frac{F_B N}{L_3} \int_{-L_3/2}^{L_3/2} [v^2(z) - \langle v(z) \rangle^2] \mathrm{d}z$$
$$B_1 = \frac{F_B N}{L_3} \int_{-L_3/2}^{L_3/2} \left\{ \left[\frac{\mathrm{d}v(z)}{\mathrm{d}z}\right]^2 - \left\langle \frac{\mathrm{d}v(z)}{\mathrm{d}z} \right\rangle^2 \right\} \mathrm{d}z \qquad (22)$$

where $F_B$ is the DW area, $L_3$ the DW distance, and $N$ the defect density. The characteristic parameters of the statistical potential are related to the correlation functions as follows:

$$2L_0 = 2\pi (B_0/B_1)^{1/2}; \bar{V}_{\max} = (B_0/2\pi)^{1/2};$$
$$\overline{1/R} = (\pi/2B_1)^{1/2} \qquad (23)$$

In the following the relationship of the coercive field is considered. It is given by

$$\mu_0 H_c = \frac{\pi^{1/2}}{M_s F_B |\cos\psi_0|} \bar{V}_{\max} \left(\frac{\ln L_3}{2L_0}\right)^{1/2}$$
$$\frac{\chi_0 H_c}{M_s} = |\cos\psi_0| \frac{\pi^{1/2}}{2} \frac{L_0}{L_3} \left(\frac{\ln L_3}{2L_0}\right)^{1/2} \qquad (24)$$

From Eqns. (23) and (24) the dependence of $H_c$ and $\chi_0$ on the defect density is obtained as

$$H_c \propto \sqrt{N}; \qquad \chi_0 \propto 1/\sqrt{N} \qquad (25)$$

Equation (25) has been tested for plastically deformed nickel single crystals where the dislocation density, $N$, is related to the applied flow stress, $\tau$, by (Kronmüller 1972)

$$\tau - \tau_0 = 0.36 G b (N l)^{1/2} \qquad (26)$$

where $\tau_0$ is the initial flow stress, $G$ the shear modulus, and $l$ the length of dislocation lines interacting with the DW. In this case the interaction force is due to the magnetoelastic coupling energy (Kronmüller 1997) and is proportional to the magnetoelastic stresses of the DW. As a function of the applied flow stress according to Eqns. (25) and (26) a linear relationship is expected for $H_c$ and $1/\chi_0$ as demonstrated by Fig. 16, which also shows the dependence of the Rayleigh constant $\alpha$ (Kronmüller 1997) following a $1/N \propto 1/(\tau - \tau_0)^2$ law. Another interesting feature is the temperature dependence of $H_c$, which,

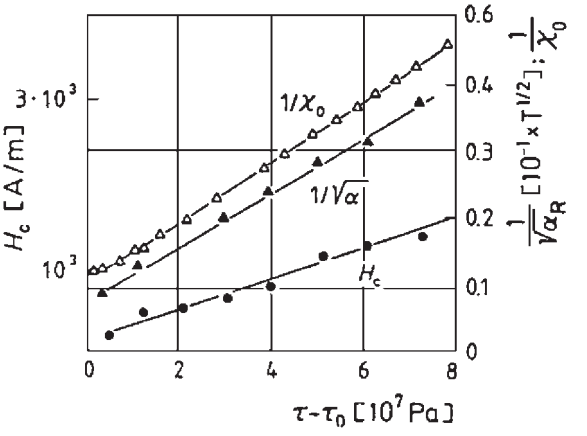

***Figure 16***
Test of the dependence of $H_c$, $\chi_0$, and the Rayleigh constant, $\alpha_R$, on the dislocation density of plastically deformed single crystals (Kronmüller 1972).

in the case of straight dislocations, is determined by the intrinsic material parameters $M_s$, $K_1$, and the magnetostriction $\lambda_s$, and is given by

$$\mu_0 H_c(T) \propto \frac{\lambda_s}{M_s} \delta_B^{1/2} \propto K_1^{-1/4} \qquad (27)$$

With increasing anisotropy constant $K_1$, i.e., decreasing wall width $\delta_B$, the pinning strength of dislocations decreases. If one deals with dislocation dipoles the interaction forces are proportional to the gradients, $\nabla\sigma$, of the magnetoelastic stresses of the DW leading to a temperature dependence of $H_c$ given by

$$\mu_0 H_c(T) \propto \frac{\lambda_s}{M_s} \delta_B^{-1/2} \propto K_1^{1/4} \qquad (28)$$

In contrast to the case of individual dislocations, $H_c$ increases in the case of dislocation dipoles with decreasing wall width because this leads to an increase of, $\nabla\sigma$, i.e., of the pinning force $v$. According to Eqn. (28) the temperature dependence of $H_c$ follows a $K_1^{1/4}$ law that has been demonstrated to be valid for amorphous FeNi-based alloys (Kronmüller 1997) where the stress sources correspond to dipole type precipitates of free volume. The existence of the $K_1^{-1/4}$ and the $K_1^{1/4}$ dependence of $H_c$ has been found for the case of nickel single crystals as shown in Fig. 17. In as-grown nickel single crystals the main pinning centers are dislocations leading to the $K_1^{-1/4}$ law, whereas in neutron-irradiated single crystals dislocation dipoles exist owing to the agglomeration of vacancies giving rise to the $K_1^{1/4}$ law for $H_c$. $H_c$ and $\chi_0$ are governed by the self-consistency relationship of Eqn. (24), which may be written as

$$\chi_0 \cong \frac{M_s}{H_c} \cdot \frac{\delta_B}{L_3} \qquad (29)$$

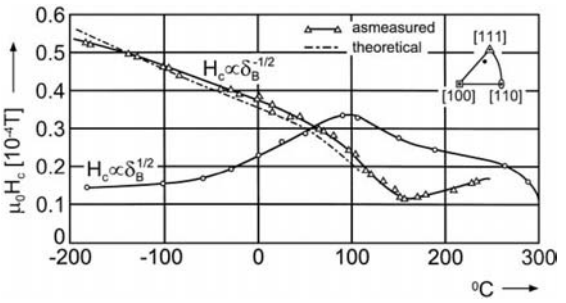

*Figure 17*
Temperature dependence of the coercive field of a nickel single crystal owing to dislocations ($\propto \delta_B^{1/2}$) and to dislocation dipoles ($\delta_B^{-1/2}$) after heavy neutron irradiation (xxx $= 3 \times 10^{18}$ n cm$^{-2}$) (Kronmüller 1966).

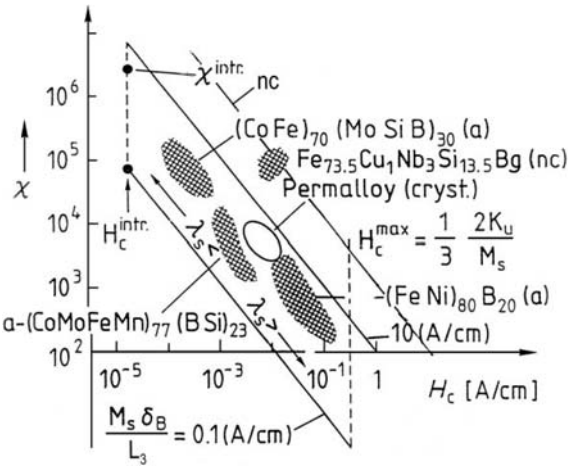

*Figure 18*
Upper and lower bounds for the $\chi_0$ vs. $H_c$ self-consistency relationship (Eqn. (24)) for crystalline, nanocrystalline, and amorphous alloys. The upper bound for $\chi^{intr}$ and the lower bound for $H_c^{intr}$ are obtained for $K_1 = 0$ and $\lambda_s = 0$ (Kronmüller 1981).

if one takes into account that the average wavelength, $2L_0$, of the pinning force is of the order of $2\delta_B$. Owing to Eqn. (29), $\chi_0$ and $H_c$ may vary only between upper and lower bounds as determined by the ratio $\delta_B/L_3$. This ratio with $L_3 \sim 100\delta_B$–$10\,000\delta_B$ may vary between $10^{-4}$ and $10^{-2}$ giving values of $10\,\mathrm{A\,m^{-1}} < M_s\delta_B/L_3 < 10^3\,\mathrm{A\,m^{-1}}$ for $M_s = 100\,\mathrm{kA\,m^{-1}}$. The double logarithmic plot of Fig. 18 shows that the CoFe- and NiFe-based amorphous and crystalline alloys in fact lie between these two limits, which means that $L_3$ has been chosen correctly. Nanocrystalline materials (see *Amorphous and Nanocrystalline Materials*) such as FeSiNbCuB alloys (Herzer 1990) have a position with $M_s\delta_B/L_3 = 5\,\mathrm{kA\,m^{-1}}$, which reflects the fact that in nanocrystalline materials owing to the random anisotropy effect the DW widths are a factor of 5–10 larger than in amorphous alloys. Figure 18 also includes the absolute lower and upper limits of $H_c$ and $\chi_0$, respectively, as expected in ideal amorphous materials with $K_1 \to 0$ and $\lambda_s \to 0$ (Kronmüller 1981).

## 8. *Computational Micromagnetism of Coercivity*

The experimental results for $H_c$ of hard magnetic materials show a discrepancy by a factor of 4–5 with respect to the theoretical predictions. In Sects. 2–4 this is attributed to the role of the microstructure, the effect of which is described by the microstructural parameters $\alpha$ and $N_{eff}$. In the case of assemblies of grains, an explicit calculation of the parameters $\alpha$ and $N_{eff}$ is not possible. Therefore, numerical calculations have been performed by means of the finite element method (FEM) (Schrefl *et al.* 1994). Simulations of magnetization processes of assemblies of grains start from a minimization of the magnetic free enthalpy $G$ with respect to the direction of the spontaneous polarization $\underline{J}_s$:

$$\delta G = \delta \int (\phi_A + \phi_K + \phi_s + \phi_H)\mathrm{d}V = 0 \qquad (30)$$

The free enthalpy is composed of four contributions: exchange energy $\phi_A = A(\nabla\varphi)^2$, crystal anisotropy $\phi_K = K_1\sin^2\varphi + K_2\sin^4\varphi$, stray field energy $\phi_s = -(1/2)\underline{H}_s \cdot \underline{J}_s$, and magnetostatic energy $\phi_H = -\underline{H}_{ext} \cdot \underline{J}_s$. The stray field, $\underline{H}_s$, follows from a scalar potential $U$ by $H_s = -\nabla U$ and $U$ obeys Poisson's equation $\Delta U = \mu_0^{-1}\mathrm{div}\,\underline{J}_s$.

For three-dimensional numerical calculations usually a cubic particle composed of polyhedral regular or irregular grains is considered. This model allows the variation of the average grain size, the modification of the magnetic material parameters within grain boundaries, and the formation of composite PMs. As an example of the FEM calculations, Fig. 19 shows the distribution of $\underline{J}_s$ in the remanent state within a model composite PM of 35 grains with an average grain diameter of 10 nm with easy axes distributed isotropically and 51% of soft magnetic grains of $\alpha$-Fe, embedded in hard magnetic grains of $Nd_2Fe_{14}B$ (Fischer *et al.* 1995). At the grain boundaries the direction of $\underline{J}_s$ changes smoothly from one easy direction to the other within a region of width $2\delta_B$. Under the assumption of a perfect exchange coupling between the grains, Fig. 20 illustrates the dependence of $J_r$, $\mu_0 H_c$, and $(BH)_{max}$ on the grain size $D$ for the irregular grains shown in Fig. 19, and also for a hypothetical regular grain structure of dodecahedral grains. All three quantities decrease with increasing grain size and $J_r$ and $H_c$ can be fitted empirically by the following logarithmic laws

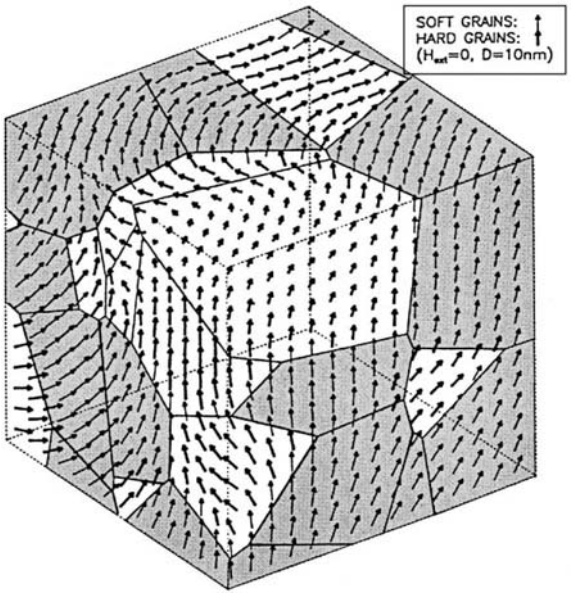

***Figure 19***
Distribution of polarization within 35 irregular grains of average diameter 10 nm within a cube with volume fraction of 51% α-Fe (shaded) and 49% $Nd_2Fe_{14}B$.

(Fischer *et al.* 1996):

$$J_r = J_{sat}\left[0.84 - 0.085\ln\left(\frac{D}{\delta_B^{hard}}\right)\right]$$
$$H_c = H_c^{(0)}\left[0.22 - 0.041\ln\left(\frac{D}{\delta_B^{hard}}\right)\right] \qquad (31)$$

with $H_N^{(0)} = 2K_1^{hard}/J_s$ and $J_{sat} = J_s^{hard}v^{hard} + J_s^{soft}v^{soft}$, where the superscripts refer to the saturation polarizations and volume fractions of the hard and soft magnetic phases. It turns out that for grain sizes of 20 nm, i.e., $5\delta_B^{hard}$, the coercive field is only 15% of the ideal field $H_N^{(0)}$, and the remanence is considerably larger than the isotropic value of $0.5J_s$. Figure 21 shows the numerical results for the three characteristic properties of the hysteresis loops as a function of the percentage of α-Fe content (Fischer *et al.* 1995). Whereas the numerical results for $J_r$ agree fairly well with the experimental data, the theoretical predictions for $\mu_0 H_c$ and $(BH)_{max}$ are appreciably larger than the experimental values. In the case of $(BH)_{max}$, this is due to the fact that for the experimental results the condition $\mu_0 H_c > 0.5\ J_r$ is only valid for α-Fe concentrations $<30\%$ whereas the numerical results fulfill this condition up to 50% α-Fe. The observed discrepancy between numerical and experimental results can be explained by allowing a modification of the intrinsic material

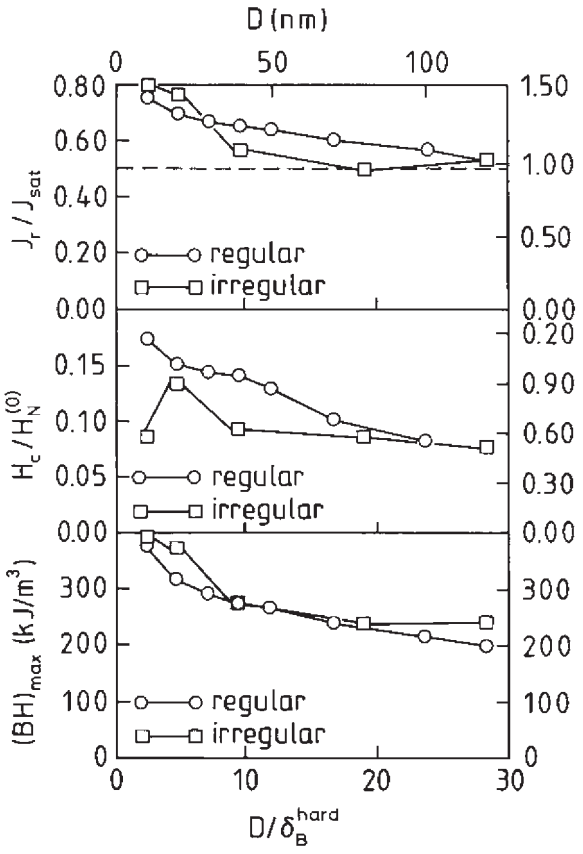

***Figure 20***
Remanence $J_r$, coercivity $\mu_0 H_c$, and maximum energy product $(BH)_{max}$ for the irregular configuration of Fig. 19 and a regular dodecahedral grain structure as a function of mean grain size $D$.

parameters within the grain boundaries. Owing to the atomic disorder within a grain boundary it can be assumed that in particular $A$ and $K_1$ have reduced values (Fischer and Kronmüller 1996). Figure 22 shows the influence of the reduction of these two parameters on the demagnetization curve for a cube of 64 grains of average diameter 20 nm (Fischer and Kronmüller 1998). For the model calculations a width of 3 nm of the grain boundaries is assumed where $A$ and $K_1$ suffer a step-like reduction. With decreasing $A$ and $K_1$ within the grain boundaries $\mu_0 H_c$ and $J_r$ also decrease. If the parameter $f = A^{gb}/A = K_1^{gb}/K_1$ is introduced where the superscript gb refers to the grain boundary, $H_c$ and $J_r$ obey the following relationships:

$$H_c/H_N^{(0)} = 0.304 + 0.098f$$
$$J_r/J_{sat} = 0.646 + 0.036f \qquad (32)$$

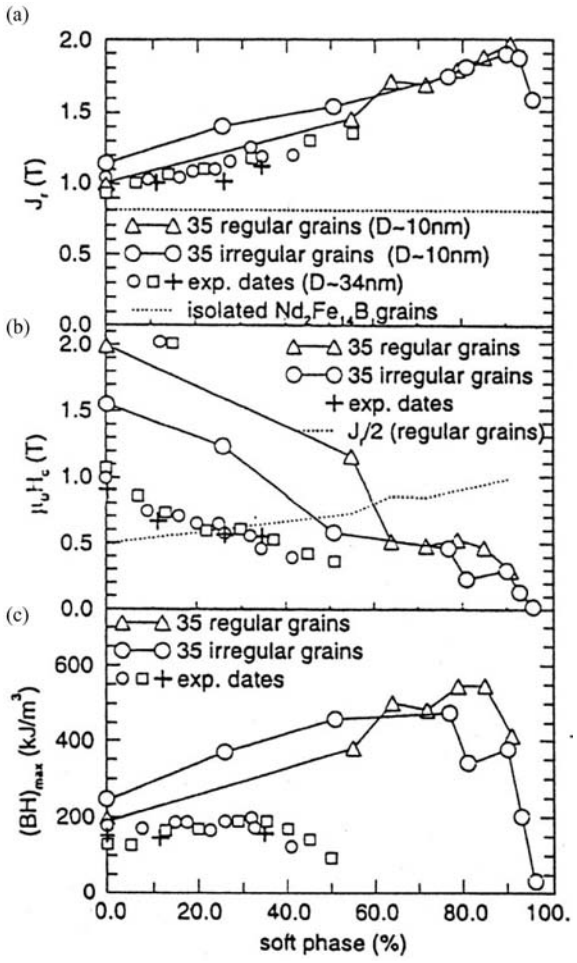

*Figure 21*
Numerical results for $J_r$, $\mu_0 H_c$, and $(BH)_{max}$ of nanocrystalline composite magnets for regular and irregular distributions of grains (average grain size 10 nm) as a function of the $\alpha$-Fe percentage. Experimental results: +, Wilcox *et al.* (1994); ○, Bauer *et al.* (1996); □, Goll *et al.* (1998).

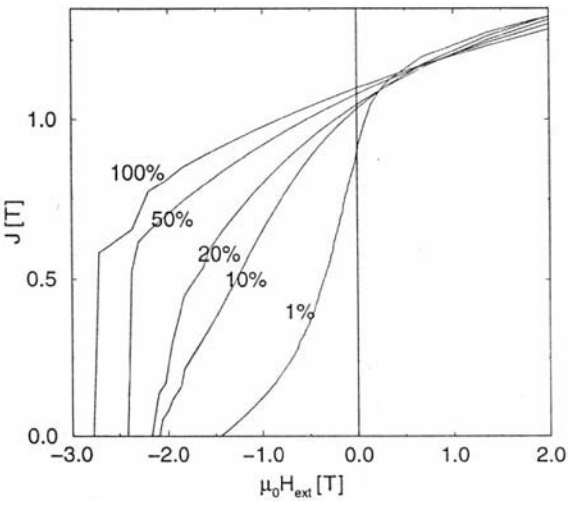

*Figure 22*
Demagnetization curves for an assembly of 64 NdFeB grains of average grain diameter 20 nm and an intergranular phase of reduced anisotropy and exchange constant.

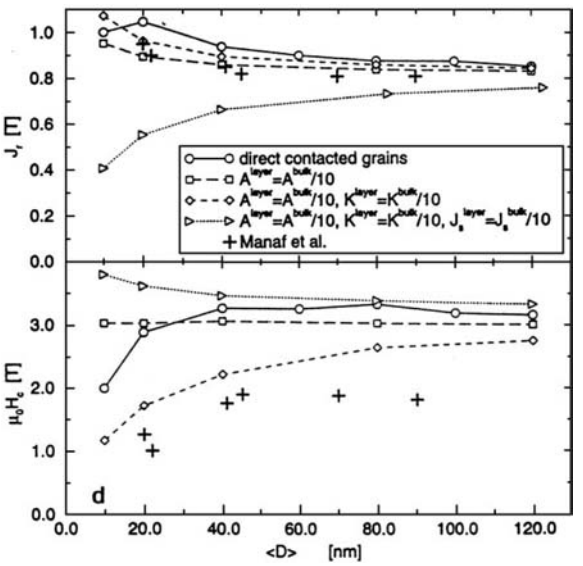

*Figure 23*
Coercive field as a function of the mean grain diameter $\langle D \rangle$ and grain boundaries of reduced material parameters. The computed points (◇) with $f = 0.1$ describe the experimental results of Manaf *et al.* (1991) fairly well.

As a further interesting property, the dependence of the coercive field as a function of the average grain diameter, $\langle D \rangle$, is shown in Fig. 23. Here it turns out that the experimental results obtained by Manaf *et al.* (1991) for nanocrystalline $Nd_{13.2}Fe_{79.6}B_6Si_{1.2}$ can only be simulated by the modification of $A$ and $K_1$ within the grain boundary. Modifications of $J_s$ lead to completely controversial results (Fischer and Kronmüller 1996). Figure 24 shows the magnetization reversal process for an individual grain surrounded by grains of different easy direction. Here it is evident that the reversal of magnetization primarily nucleates within the grain boundaries and the neighboring regions whereas in the bulk of the grain the magnetization starts to rotate reversibly into the direction of the applied field.

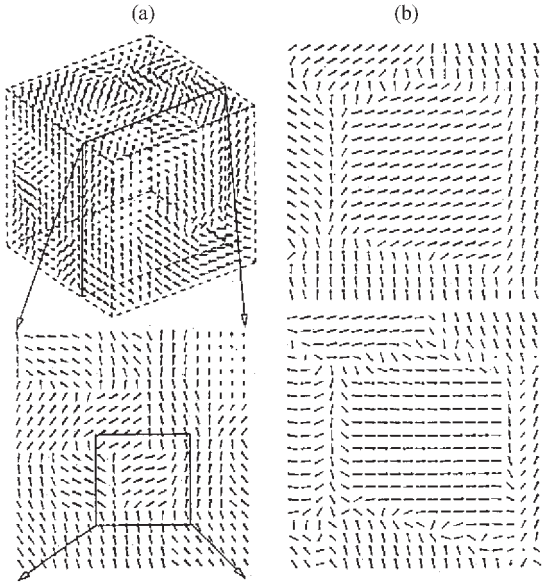

***Figure 24***
Vector plots of the magnetization of a nanocrystalline assembly of grains with $\langle D \rangle = 20\,\text{nm}$. (a) Remanent state. Top: magnetization at the surfaces of the cube; bottom: magnetization along a cut through the PM. Strong arrows refer to the bulk of the grains, weak arrows refer to the magnetization within grain boundaries. (b) Vector plots of magnetization within the square of (a) for nonideal grain boundaries with $f = 0.1$. Top: remanent state ($H_{\text{ext}} = 0$); bottom: applied opposite field $\mu_0 H_{\text{ext}} = 0.6$ T showing the nucleation of reversed magnetization within the grain boundaries (Fischer and Kronmüller 1998).

# Coherence Length, Proximity Effect and Fluctuations

The phenomenological London theory for superconductivity was able to explain the Meissner effect in terms of a rigid wave function under the application of an external magnetic field. Under this assumption, F. and H. London calculated the value of the London penetration depth $\lambda_L$:

$$\lambda_L^2 = \frac{m}{\mu_0 e^2 n_s} \tag{1}$$

where $m$ is the effective mass of the electron and $n_s$ is the superfluid density, which at $T=0$ is equal to the electron density in the normal state. Since the ratio $m/n$ does not vary by more than one order of magnitude among common metals, $\lambda_L$ does not vary much from one superconductor to another: roughly by a factor of 4 from say lead (39 nm) to the high-$T_c$ oxides (about 140 nm in $YBa_2Cu_3O_7$). No explicit dependence of $\lambda_L$ on $T_c$ is predicted.

The main modification to the London theory proposed by Ginzburg and Landau (GL theory) was the introduction of a finite correlation length $\xi$, somewhat unfortunately called the coherence length. This is the minimum length scale over which the superfluid density may vary with only a moderate increase of the free-energy density. Ginzburg and Landau showed that under small applied fields, the spatial variation of the superfluid density remains negligible and the London result (Eqn. (1)) is recovered, whatever the respective values of $\lambda$ and $\xi$. The effect of a finite coherence length is only apparent in strong applied fields and when the GL parameter $\kappa = \lambda/\xi$ is larger than $1/\sqrt{2}$. As shown by Pippard, when $\xi > \lambda$ nonlocal corrections lead to an effective value of $\lambda$ somewhat larger than that given by the London theory.

## 1. Coherence Length

### 1.1 Coherence Length in the GL Theory

Ginzburg and Landau introduced the coherence length in the framework of their treatment of the superconducting phase transition as a second-order transition, occurring at the critical temperature $T_c$. The existence of a coherence length that diverges at the transition is a general property of all second-order phase transitions:

$$\xi(t) = a\xi_0(1-t)^{-\nu} \tag{2}$$

where $a$ is a numerical coefficient of order unity, $\xi_0$ is the zero temperature coherence length, $t$ is the reduced temperature $(T/T_c)$ and $\nu$ is the critical exponent for the coherence length. In the mean-field approximation $\xi(t)$ can be obtained from the GL

free-energy functional:

$$\mathbb{F}_s = \mathbb{F}_n + A|\Delta|^2 + \frac{B}{2}|\Delta|^4 + C|\nabla\Delta|^2 \qquad (3)$$

where the coefficients $A = N(0)\,(t-1)$, $B = 0.098N(0)/(k_B T_c)^2$, $C = 0.55\,\xi_0^2\,N(0)\chi(\alpha)$, $N(0)$ is the normal state density of states and $\chi(\alpha)$ is the Gorkov impurity function. Here $\Delta$ is the pair potential, equal to the superconducting energy gap when it is uniform across the sample.

The pair potential $\Delta$ is related to the order parameter $\Psi$ by $|\Delta|^2 = \hbar^2|\Psi|^2/(4mC)$. In some cases the free-energy functional is written in terms of the *reduced*-order parameter $\psi = \Psi/\Psi_\infty$, where $\Psi_\infty$ is the equilibrium order parameter at the temperature under consideration. Sometimes it is convenient to use the pair *amplitude* $F = \Delta/V$, where $V$ is the BCS interaction parameter (e.g., in a normal metal with $V = 0$ in contact with a superconductor, the pair potential is zero but the pair amplitude is finite, as will be discussed in Sect. 3). In simplified terms $(FV)^2$ and $(F/\pi N(0))^2$ are proportional to $n_s$ in the two regions.

In the notation used here

$$\xi^2 = \frac{C}{|A|} \qquad (4)$$

Since $A \propto 1 - t$, $\nu = \frac{1}{2}$ and $\lambda$ is found in this approximation to diverge with the same exponent. In the clean limit, therefore, $\xi(t) = 0.74\,\xi_0(1-t)^{-1/2}$ while in the dirty limit $\xi(t) = 0.85\,(\xi_0 l)^{1/2}(1-t)^{-1/2}$ where $l$ is the normal state electron mean free path. The applicability of the mean field approximation to the superconducting phase transition will be returned to later.

The GL theory is phenomenological and does not predict what the value of $\xi_0$ should be. However, it does offer a simple method for measuring $\xi(t)$ through the expression for the nucleation field:

$$\mu_0 H_{c2}(t) = \frac{\Phi_0'}{2\pi\xi^2(t)} \qquad (5)$$

where $\Phi_0 = 2.07 \times 10^{-15}\,\mathrm{T\,m^2}$ is the flux quantum. If the superconductor is type II, $H_{c2}$ as given by Eqn. (5) is the upper critical field. If it is type I, $H_{c2}$ is the supercooling field. Coherence lengths in the clean and dirty limits, obtained from $H_{c2}$ measurements, are given in Tables 1 and 2, respectively. Measurements of the supercooling field are usually affected by the Saint James–de Gennes surface nucleation phenomenon which occurs at a field $H_{c3} = 1.69\,H_{c2}$ in regions of the sample where the surface is parallel to the applied field (Saint James and de Gennes 1963, Deutscher 1967). Once the superconducting state has nucleated in some region, it spreads all over the sample. Hence $H_{c3}$ rather than $H_{c2}$ is usually the measured nucleation field and $\xi$ must be calculated accordingly.

***Table 1***
Coherence lengths in the clean limit.

| | $T_c$ (K) | $\xi_0$ (μm) | $\xi_0 T_c$ (μm K) |
|---|---|---|---|
| Aluminum | 1.19 | 1.20 | 1.4 |
| Indium | 3.40 | 0.33 | 1.1 |
| Tin | 3.72 | 0.26 | 0.97 |
| Gallium | 5.90 | 0.16 | 0.94 |
| Lead | 7.20 | 0.08 | 0.58 |
| Niobium | 9.25 | 0.035 | 0.32 |
| $YBa_2Cu_3O_7$ | 93 | 0.0015 | 0.14 |

***Table 2***
Coherence lengths in the dirty limit (practical superconductors).

| | $T_c$ (K) | $\xi(T=0)$ (μm) |
|---|---|---|
| Nb–56 at.% Ti | 10 | 0.0050 |
| $Nb_3Sn$ | 17 | 0.0040 |
| $(Nb, Ta)_3Sn$ | 18 | 0.0035 |

When $H_{c3} > H_c$, a stable superconducting surface sheath of thickness $\xi$ exists below the nucleation field. Its thickness has been measured directly in lead and was found to be about twice the coherence length (Deutscher 1967).

### *1.2 Coherence Length in the BCS Theory*

The microscopic origin of $\xi$ became clear only with the advent of the BCS theory: it is the average radius of a Cooper pair. The value of $\xi_0$ can be simply estimated from the uncertainty principle:

$$\xi_0 \simeq \frac{h v_F}{\pi\Delta} \qquad (6)$$

where $v_F$ is the Fermi velocity and $2\Delta$ is the energy necessary to break a Cooper pair. In the weak coupling limit of the BCS theory, $2\Delta = 3.5\,k_B T_c$. Since $v_F$ does not vary much from one metal to another, the coherence length is essentially inversely proportional to the critical temperature (Table 1). As a rule of thumb, $\xi_0(\mu m) \simeq T_c^{-1}(K^{-1})$. Since $\lambda_L$ is basically independent from $T_c$, low-$T_c$ superconductors should be type I and high-$T_c$ superconductors should be type II. This is well borne out experimentally. Superconductors with a $T_c$ lower than that of lead (7.2 K) are type I, superconductors with a higher $T_c$ are type II (niobium, the A15 compounds, the Chevrel phases and the high-$T_c$ oxides).

The effect of impurities on $\lambda$ and $\xi$ has been calculated by Gorkov. In the limit where the electron

mean free path $l$ is much shorter than $\xi_0$ (the so-called dirty limit):

$$\lambda = 0.64\,\lambda_L(\xi_0/l)^{1/2} \tag{7a}$$

$$\xi = 0.85(\xi_0 l)^{1/2} \tag{7b}$$

As first observed by Shubnikov, the introduction of impurities can turn a type I superconductor into a type II material. Nonmagnetic impurities do not affect the critical temperature (Anderson theorem). However, magnetic impurities strongly depress $T_c$; for a low concentration $x$ of paramagnetic impurities with total angular momentum $J$ this is given by the BCS Gorkov theory

$$\frac{dT_c}{dx} \simeq \frac{-\pi^2 N(0) f^2 (g-1)^2 J(J+1)}{2k_B}$$

where $f$ is the exchange coupling constant and $g$ is the gyromagnetic ratio. Eqns. (5) and (7b) show that $H_{c2}$ is inversely proportional to the mean free path and, hence, proportional to the normal state resistivity, that is, to the concentration of impurities. This result is in excellent agreement with experiment (Serin 1969) and is put into practice in the commercial Nb–Ti wires, which have an upper critical field of about 10 T, roughly 30 times larger than that of pure niobium.

A short coherence length, achieved either in a clean high-$T_c$ superconductor or in a dirty low-$T_c$ superconductor, is therefore the key to practical applications of superconductivity in strong applied fields. However, in general, $\xi$ remains much larger than interatomic distances. The high-$T_c$ oxides are an exception to that rule: along the CuO planes, $\xi$ is about 2 nm in $YBa_2Cu_3O_7$; in the perpendicular direction it is only 0.3 nm. Practical superconductors such as NbTi and $Nb_3Sn$ have coherence lengths of the order of 5 nm.

## 2. *Thermal Fluctuations of the Superconducting Order Parameter*

### 2.1 *Quasi-mean-field Regime*

Thermodynamic fluctuations of the superconducting order parameter can be estimated from the GL free-energy functional. The lowest free energy is achieved for $\Delta = \Delta_0, \Delta_0 = (-A/B)^{1/2}$ below $T_c$ and $\Delta_0 = 0$ above $T_c$. Any other configuration $\Delta = \Delta_0 + \delta\Delta(r)$ can be decomposed into its Fourier components, each of them being characterized by an amplitude and a wavelength. The Fourier components with the largest amplitude have a wavelength of order $\xi$. This is because, for larger wavelengths, the energy cost is high because of the large volume involved and, for shorter wavelengths, the gradient term in Eqn. (3) is prohibitive. Hence, the volume of a typical fluctuation is $\xi^3$. Its amplitude can be estimated by taking its energy to be of the order of $k_B T$. Developing $\mathbb{F}_s$ to second order in $\delta\Delta$, one obtains below $T_c$

$$-2A\langle|\delta\Delta|^2\rangle\xi^3 \simeq k_B T \tag{8}$$

Apart from numerical coefficients, the relative amplitude of the fluctuations is given by:

$$\frac{\langle|\delta\Delta|^2\rangle}{\Delta_o^2} = \frac{k_B T}{\Delta\mathbb{F}\xi^3} \tag{9}$$

where $\Delta\mathbb{F}$ is the condensation energy per unit volume at equilibrium, $\Delta\mathbb{F} = A^2/2B = \mu_0 H_c^2/2$, where $H_c$ is the thermodynamic critical field.

The relative amplitude of the fluctuations is thus essentially given by the ratio of the thermal energy $k_B T$ to the value of the condensation energy per coherence volume. Eqn. (9) can be immediately generalized to the case of a general dimensionality $d$ by replacing $\xi^3$ by $\xi^d$. The relative amplitude of the fluctuations diverges as

$$\frac{\langle|\delta\Delta|^2\rangle}{\Delta_o^2} \propto (1-t)^{-(4-d)/2} \tag{10}$$

where $d<3$ is achieved when one or more of the dimensions of the sample is smaller than the coherence length $\xi(t)$.

In the preceding analysis the fluctuations have been treated as independent of each other (quasi-mean-field approximation). Equations (9) and (10) are thus only valid in the limit where the relative amplitude of the fluctuations is much smaller than unity. This approximation is in general excellent for conventional low-$T_c$ superconductors (LTS), but not for the high-$T_c$ oxides (HTS).

The effects of fluctuations are very small in bulk LTS (e.g., their effect on the heat capacity is negligible; this is not the case for the high-$T_c$ oxides). They are larger for low dimensionalities (thin films, wires, small grains) because the relative amplitude of the fluctuations then diverges with a stronger exponent (see Eqn. (10)). The most easily detected fluctuation effect is an excess conductivity $\Delta\sigma$ above $T_c$. In two dimensions within the quasi-mean-field approximation (Azlamazoff and Larkin 1968)

$$\Delta\sigma = \frac{e^2}{16\hbar}(t-1)^{-1} \tag{11}$$

where the conductivity is expressed in $(\Omega/\text{square})^{-1}$. In a $d$-dimensional sample, the conductivity diverges as $(t-1)^{-(4-d)/2}$, that is, with the same exponent as that of the relative amplitude of the fluctuations given by Eqn. (10). Additional terms to the excess conductivity considered by Maki and Thompson lead to a stronger divergence.

The effect of fluctuations on the conductivity is most easily detected when the background normal state conductivity is small, that is, in dirty films (Glover 1971) or wires. Another case where the excess conductivity is easily observed is that of granular superconductors (Deutscher and Dodds 1977).

On the contrary, the effect of fluctuations on the diamagnetism (which diverges with the same exponent as that of the conductivity) is most easily observed in clean samples, with a large coherence length. Fluctuation diamagnetism has been studied in low-$T_c$ intercalated compounds.

### 2.2 Critical Fluctuation Region

The mean-field approximation is valid as long as the relative amplitude of the fluctuations as given by Eqn. (10) is much smaller than unity. However, since this amplitude diverges at $T_c$, there exists a temperature range near $T_c$ where this approximation fails. This range is called the critical region (for a recent review see Ginzburg 1988). It is customary to measure it on the reduced temperature scale $\varepsilon = (T - T_c)/\ T_c$. If $\varepsilon_c$ is the reduced temperature at which the relative amplitude of the fluctuations is of order unity, it follows from Eqn. (9) that

$$\varepsilon_c = \alpha \left[ \frac{k_B T_c}{\Delta \mathbb{F}(0) \xi_0^3} \right]^2 \tag{12}$$

where $\alpha$ is a numerical factor (actually important, $\alpha = 2^{-11}\pi^{-2}$) and $\Delta\mathbb{F}(0)$ is the condensation energy at $T = 0$. According to the BCS theory:

$$\Delta \mathbb{F}(0) = \frac{1}{2} N(0) \Delta(0)^2 \tag{13}$$

where $N(0)$ is the normal state density of states. In the weak coupling limit, $\Delta(0)$ is proportional to $T_c$ and since as seen before $\xi_0 \propto T_c^{-1}$, it follows that $\varepsilon_c \propto T_c^4$. $\varepsilon_c$ is extremely small for LTS, typically $\varepsilon_c < 10^{-12}$. This fully justifies the use of the GL mean-field approximation. However, for the HTS $\varepsilon_c$ is much larger ($\varepsilon_c \simeq 10^{-3}$) and the critical region can be studied experimentally (Salamon *et al.* 1990).

As seen from Eqn. (12), the width of the critical region is determined by the value of the condensation energy in a coherence volume at $T = 0$, compared with $k_B T_c$. However, $U_0 = \Delta\mathbb{F}\xi^3$ is also the typical energy scale for core pinning of vortices. Through the coherence length, there exists therefore an intimate relationship between the critical temperature, the width of the critical region and the ability of the superconductor to pin vortices. Notice that as $T_c$ goes up, the upper limit for $U_o$ (clean limit) goes down ($U_o \propto T_c^{-1}$). In LTS, $\varepsilon_c$ is small and vortices are easily pinned even close to $T_c$ but, in HTS, $\varepsilon_c$ becomes significant and vortex pinning cannot be achieved when $T$ is of the order of $T_c$ (Deutscher 1990). Full use of their extremely high upper critical field (several hundred tesla) can only be made at temperatures significantly lower than $T_c$. Furthermore, the quasi-mean-field approximation appears to be inadequate for the description of the vortex state near $H_{c2}(T)$ in the bismuth- and thallium-based oxide superconductors (Kes *et al.* 1992).

## 3. Proximity Effect

When a normal metal (N) is in good electrical contact with a superconductor (S), Cooper pairs can leak from S to N. If the electron–electron interaction in N is zero ($V_N = 0$), and in the absence of magnetic impurities and applied magnetic fields, Cooper pairs in N are only destroyed by the thermal energy $k_B T$. Their decay length is then given by (Deutscher and de Gennes 1969)

$$\xi_N = K^{-1} = \frac{\hbar v_{FN}}{2\pi k_B T} \tag{14}$$

where $v_{FN}$ is the Fermi velocity in N. When pair breaking is also induced by magnetic impurities and applied magnetic fields, a multipair breaking model in which the various depairing factors simply add can be used. The value of $K$ is then expressed in terms of a depairing variable $\alpha$ (see Yang and Finnemore 1984).

The probability amplitude for finding a Cooper pair in N at a distance $|x|$ from the SN interface is given by

$$F(x) = \varphi(x) \exp(-K|x|) \tag{15}$$

where $\varphi(x)$ is a slowly varying function of $x$. The probability amplitude $F$ is defined as the ratio of the pair potential $\Delta$ to the BCS interaction parameter $V$. If $V_N = 0$, $\Delta_N = 0$, but $F$ is finite (see later for the boundary conditions for $F$ at the SN interface).

Eqn. (14) is valid when the mean free path in N, $l_N$, is large compared to the decay length as given by Eqn. (14) (clean limit). In the dirty limit

$$K^{-2} = \left( \frac{\hbar D_N}{2\pi k_B T} \right) \tag{16}$$

where $D_N$ is the normal state coefficient of diffusion in N, $D_N = v_{FN} l_N / 3$.

If N is a superconductor at some lower temperature $T_{cN} < T$, $K^{-1}$ diverges as $T \to T_{cN}$. Properties of the SN contact near $T_{cN}$ can be treated with the GL formalism. Very close to $T_{cN}$, $K^{-1} \propto (T - T_{cN})^{-1/2}$, symmetrical with the temperature dependence of the coherence length in the superconducting state below $T_{cN}$. At $T = T_{cN}$, the exponential decay law (Eqn. (15)) must be replaced by a power law dependence $F(x) = F(0)\ [x_0/(x + x_0)]$ (Deutscher and de Gennes 1969). At temperatures slightly above $T_{cN}$, this power

law persists near the interface. It crosses over to the exponential decay far from the interface where the pair amplitude is sufficiently small so that the nonlinear term in the GL functional becomes negligible.

At low temperatures, $K^{-1}$ is a macroscopic length scale. For instance, in copper at 1 K, $K^{-1}$ is of the order of 1 μm. This allows the easy observation of the proximity effect in superconductivity. This is in contrast to other ordering phenomena, such as magnetism, where the basic length scale is much shorter.

In the absence of any significant boundary resistance (which may arise either from imperfections of the boundary, such as a thin insulating layer, or from a mismatch of the normal state properties, that is, different Fermi velocities and electron effective masses), the boundary conditions at the SN interface are (de Gennes 1964)

$$F/N(0) \text{ continuous} \tag{17a}$$

$$D(dF/dx) \text{ continuous} \tag{17b}$$

The pair amplitude is depressed on the S side over a length $\xi(T)$ and has a tail on the N side over a length $K^{-1}(T)$ (see Fig. 1). For this reason $K^{-1}$ is alternatively expressed as the normal state coherence length.

The consequences of the proximity effect are (Deutscher and de Gennes 1969) (a) in zero field, a depressed critical temperature of SN bilayers, an excitation spectrum showing states within the gap if measured from the S side and gapless superconductivity if measured from the N side; (b) in strong applied fields, a reduction of the upper critical field of thin films and suppression of the surface sheath above $H_{c2}$ in bulk superconductors; and (c) in weak applied fields, existence of a Meissner effect on the N side of the contact.

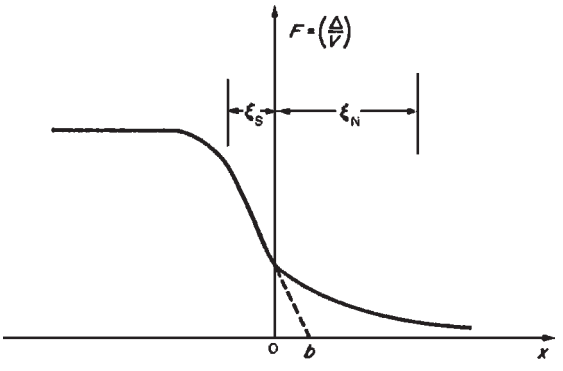

***Figure 1***
Behavior of the pair amplitude $F$ near an SN interface. For simplicity, it is assumed that the normal state density of states is the same in N and in S (otherwise, $F$ is discontinuous at the interface) and that the boundary resistance is negligible (which also leads to a discontinuity of $F$). A case is illustrated where the coefficient of diffusion in S is shorter than in N. In this case, the extrapolation length $b$ is shorter than $K^{-1}(=\xi_N)$

A simplified discussion of the proximity effect on the transition temperature and on the upper critical field can be made in terms of a length $b$ defined by

$$\left|\frac{dF}{dx}\right| = \frac{E}{b} \tag{18}$$

where the value of $F$ and its derivative are taken at the interface on the S side. According to Eqn. (18), $b$ is equal to the distance from the interface to the intercept of the linear extrapolation of $F(x)$ (into N) with the $x$ axis, which is why it is called the extrapolation length (Fig. 1).

In the dirty limit, and in the absence of any boundary resistance, $b$ is given by:

$$b = (\rho_N/\rho_S)K^{-1}\coth(Kd_N) \tag{19}$$

where $\rho_N$ and $\rho_S$ are the normal state resistivities and $d_N$ and $d_S$ are the thicknesses of N and S, respectively. The critical temperature $T_{cNS}$ of a bilayer is given by

$$T_{cNS} = T_{cS} - \frac{\pi^2}{8}\xi_S^2(T=0)\frac{1}{(d_S+b)^2} \tag{20}$$

This expression is only valid in the GL approximation, that is, when $T_{cNS}$ is not too different from $T_{cS}$.

In the same approximation, the parallel upper critical field of a bilayer is given by (Orsay Group 1966)

$$B_{c2}^2 = \frac{1}{\beta}\left(\frac{2\Phi_0}{\pi d_S^2}\right)^2 \frac{d_S^2}{\xi^2(0)}(1-t_{cNS}) \tag{21}$$

where $\beta$ is a function of $(b/d_s)$.

One of the most fundamental manifestations of the proximity effect is the existence of a Meissner effect on the N side of SN contacts. This induced Meissner effect was revealed by the study of the susceptibility of SN contacts in weak fields, which showed that a field applied parallel to the interface is screened out at a distance $\rho_{scr}$ from the interface (Deutscher *et al.* 1969). This induced diamagnetism is easily identified because it is destroyed in fields that are much smaller than the characteristic fields of the S side. The screening length $\rho_{scr}$ was found to be typically of the order of 100 nm in the conventional liquid (helium) range. If N is itself a superconductor at a temperature $T_{cN}$, $\rho_{scr}$ diverges when $T_{cN}$ is approached. This effect is felt well above $T_{cN}$, $\rho_{scr} = 1$ μm in zinc ($T_{cN} = 0.92$ K) at 1.6 K. If N is a "truly" normal metal, $\rho_{scr}$ diverges as $T \to 0$. In the limit of very small applied fields and large N thickness ($d_N \gg \rho_{scr}$)

$$\rho_{scr} = K^{-1}\{\ln[K^{-1}/\lambda(0)] - 0.116\} \tag{22}$$

where $\lambda(0)$ is the value of the local penetration depth at the SN interface. As soon as the temperature is sufficiently low that $[K^{-1}/\lambda(0)] > 1$, $\rho_{scr}$ is typically of the order of $K^{-1}$.

At low temperatures, as $\rho_{scr}$ becomes larger, it is also more sensitive to the applied field:

$$\sigma_{scr}(H) = K^{-1} \ln(2H_0/H) \tag{23}$$

where $H_0$ is a field characteristic of the N side, $H_0 = [\Phi_0 K/2\pi\lambda(0)]$. Notice that $H_0 \to 0$ as $T \to 0$.

These relations apply for a semi-infinite N layer. The main effect of a finite N thickness is that for $d_N \simeq K^{-1}$ and $[K^{-1}/\lambda(0)] > 1$, a first-order transition is observed at a breakdown field $H_b$ at which the pair amplitude in N collapses and $\rho_{scr}$ varies essentially from $d_N$ to zero (Orsay Group 1967). A good approximation for $H_b$ is

$$H_b = 3.8 H_0 \exp(-K d_N) \tag{24}$$

There are at least two important applications where the proximity effect is important. One is in the fabrication of practical Josephson devices. For LTS electronics, niobium, being a refractory metal, is a preferred choice of material for stable, cyclable devices. Unfortunately, it does not have a good insulating oxide. The solution is then to use a niobium film with a thin aluminum coating and to oxidize the surface of the aluminum. The operation of the device is based on the proximity-induced superconductivity in the aluminum coating (see *SQUIDs: Biomedical Applictions; SQUIDs: The Instrument; Josephson Junctions: Low-$T_c$*). Another example is in the design of ultrathin filamentary wires, composed of very fine Nb–Ti filaments in a copper matrix, for ac applications. In these wires, the distance between the filaments is so small that the copper matrix is effectively superconducting; to minimize ac losses the proximity coupling has to be reduced either by separating the filaments or by suppressing the proximity coupling by alloying the copper with magnetic impurities such as manganese (see *Superconducting Wires and Cables: Materials and Processing*).

Special mention should be made of proximity effects where the S side is a high-$T_c$ oxide. In this case $\xi_s$ is very small, typically of the order of 1 nm. This makes the fabrication of high-$T_c$ devices quite difficult, since electron tunnelling occurs into a surface region of thickness $\xi_s$, whose quality is hard to control. One solution consists of using a high-$T_c$–low-$T_c$ (or normal metal) contact, taking care, however, to use a *high-resistivity* normal side. This is essential because of the high normal state resistivity of the oxides: as can be seen from Eqn. (19), the extrapolation length $b$ is very small when $\rho_N \ll \rho_S$, and if $b$ is very small the pair amplitude will be destroyed right at the interface (Fig. 1).

Proximity-coupled weak link structures and tunnel junctions have been made using thin proximity-coupled layers of silver or gold deposited onto $YBa_2Cu_3O_7$ and other high-$T_c$ oxides. Various device heterostructures have been investigated including SNS, SNS′ and SNIS′ junctions, where S′ is usually lead or niobium (Akoh *et al*. 1990, Gijs *et al*. 1990). Properties of these junctions have been calculated within a BCS framework by Kupriyanov and Likharev (1991). Recently, proximity effects have been measured using a semiconducting layer of perovskite-type oxide (e.g., $La_{1.5}Ba_{1.5}Cu_3O_{7-y}$). It appears that the proximity decay length $K^{-1}$ can be as large as 65 nm in this system (Tarutani *et al*. 1991).

The small leakage of Cooper pairs into an insulator is sufficient to weaken the pair amplitude at the interface of an HTS with an insulator (Deutscher and Muller 1987). The extrapolation length $b$ at an SI interface is of the order of $\xi_0^2/a$ where $a$ is an interatomic distance: since in the oxides $\xi_0$ is only a few interatomic distances, $b$ is not much larger than $\xi_0$ and as a rule the pair amplitude will be reduced at all surfaces and interfaces. This explains small critical currents and granular behavior in polycrystalline oxides; a disordered region at grain boundaries is sufficient to depress the pair amplitude at the surfaces of the adjacent grains. This depression results in an anomalous temperature variation of the critical current of grain boundary junctions, $I_c \propto (T - T_c)^2$ instead of the linear dependence of usual Josephson junctions (Gross *et al*. 1990). It also explains why $I_c$ scales with the normal state resistance $R_N$ of the junction as $R_N^{-2}$ instead of the usual dependence $R_N^{-1}$ (Deutscher and Chaudhari 1991). Both effects contribute towards reducing the critical current density in randomly oriented polycrystalline samples.

## Colossal Magnetoresistance Effects: The Case of Charge-ordered $Pr_{0.5}Ca_{0.5}MnO_3$ Manganite Thin Films

Recently, perovskite type manganites such as $RE_{1-x}A_xMnO_3$ (RE = rare-earth and A = alkaline-earth ion) have received renewed interest due to the fact that they display colossal magnetoresistance (CMR), a huge decrease in resistance when applying a magnetic field (Chahara *et al.* 1993, Von Helmolt *et al.* 1993, McCormack *et al.* 1994, Prellier *et al.* 2001). Since most of the technological applications require thin films, it is essential to understand the effects of the substrate-induced strains on the properties of these manganites. These materials are very sensitive to the strains and even very small perturbations may result in observable effects on the properties. These effects have indeed been studied experimentally on various compounds (Prellier *et al.* 1999, Biswas *et al.* 2000). Moreover, among all the properties of these manganite materials, the phenomenon of charge ordering (CO) is probably one of the most remarkable effects which occurs for certain values of $x$ and for a particular average A-site cation radius. It corresponds to an ordering of the charges in two different Mn sublattices. In fact, the metallic state becomes unstable, below a certain temperature ($T_{CO}$) and the material goes to an insulating state. $T_{CO}$ decreases with increasing field and the insulating CO state can be totally suppressed by the application of an external magnetic field (Rao *et al.* 2000). As an example, a 25 T magnetic field is required to melt the CO state in bulk $Pr_{0.5}Ca_{0.5}MnO_3$ (Tokunaga *et al.* 1998) leading to huge CMR effect.

The substrate-induced strain effects and the thickness of the films influence the structural and physical properties of manganite thin films. As an example, $Pr_{0.5}Ca_{0.5}MnO_3$ (PCMO), thin films grown on $LaAlO_3$ (LAO) and $SrTiO_3$ (STO) using the pulsed laser deposition (PLD) technique are considered here. The focus is on the changes in the lattice parameters, the orientation and the transport measurements of the film. On the basis of these results, a temperature–field phase diagram for CO thin films is determined and compared with the bulk material.

Thin films of PCMO were grown *in situ* using the PLD technique on [100]-$SrTiO_3$ (cubic with $a = 3.905$ Å) and [100]-$LaAlO_3$ (pseudocubic with $a = 3.789$ Å) substrates. Detailed optimization of the growth procedure was completed and described previously (Prellier *et al.* 2000, Haghiri-Gosnet *et al.* 2000). The structural study was carried out by X-ray diffraction (XRD) using a Seifert XRD 3000P for the Θ–2Θ scans and a Philips MRD X'pert for the in-plane measurements (Cu Kα, $\lambda = 1.5406$ Å). The in-plane parameters were obtained from the $(1\,0\,3)_C$ reflection (where C refers to the ideal cubic perovskite cell). An electron microscope JEOL 2010 was used for the electron diffraction (ED) study. The resistivity ($\rho$) was measured by a four-probe method with a Quantum Design PPMS and magnetization ($M$) was recorded using a Quantum Design MPMS SQUID magnetometer as a function of the temperature ($T$) and the magnetic field ($H$). The composition of the films was checked by energy-dispersive scattering analyses. It is homogenous and corresponds exactly

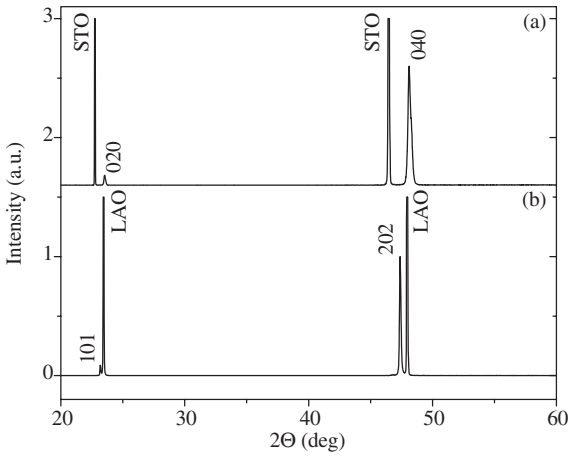

***Figure 1***
Room temperature Θ–2Θ XRD pattern of a 75 nm thick film on (a) STO and (b) LAO. Note the high intensity and the sharpness of the peaks.

to the composition of the target (i.e., $Pr_{0.5}Ca_{0.5}MnO$) in the limit of the accuracy.

The structure of bulk PCMO is orthorhombic (*Pnma*) with $a = 5.395$ Å, $b = 7.612$ Å and $c = 5.403$ Å (Jirak *et al.* 1985). Figure 1 shows a typical Θ–2Θ scan recorded for a 750 Å thick film deposited on STO (a) and LAO (b). Note that the same type of pattern is obtained for all of the films. This shows that the films are single phases and highly crystallized. From the XRD pattern, the out-of-plane lattice parameter is, respectively, calculated to be 3.78 Å on LAO and 3.85 Å on STO indicating that the film is under compression on LAO and under tension on STO as already reported.

Figure 2 shows the ED pattern recorded along a direction perpendicular to the substrate plane. It is clear that the orientations of the films with respect to the substrate are different. In fact, the film is [010]-oriented, i.e., with the [010] axis perpendicular to the substrate plane when grown on STO and [101]-oriented on LAO. This surprising orientation results from the lattice mismatch. Indeed, the mismatch ($\sigma$) between the film and the substrate can be evaluated using the formula $\sigma = 100(a_S - a_F)/a_S$ (where $a_S$ and $a_F$, respectively, refer to the lattice parameter of the substrate and the film). The smaller mismatch on LAO is obtained for a [010]-axis in the plane ($\sigma_{LAO} = -0.4\%$), i.e., the [101]-axis is perpendicular to the substrate plane ($\sigma_{LAO} = -0.7\%$ for a [101] axis in the plane). In contrast, the smaller mismatch on STO ($\sigma_{STO} = 2.2\%$) is found for a [101]-axis in the plane ($\sigma_{STO} = 2.5\%$ for a [010]-axis in the plane). Thus, the [010]-axis is normal to the surface of the substrate as found experimentally (Prellier *et al.* 2000, Haghiri-Gosnet *et al.* 2000).

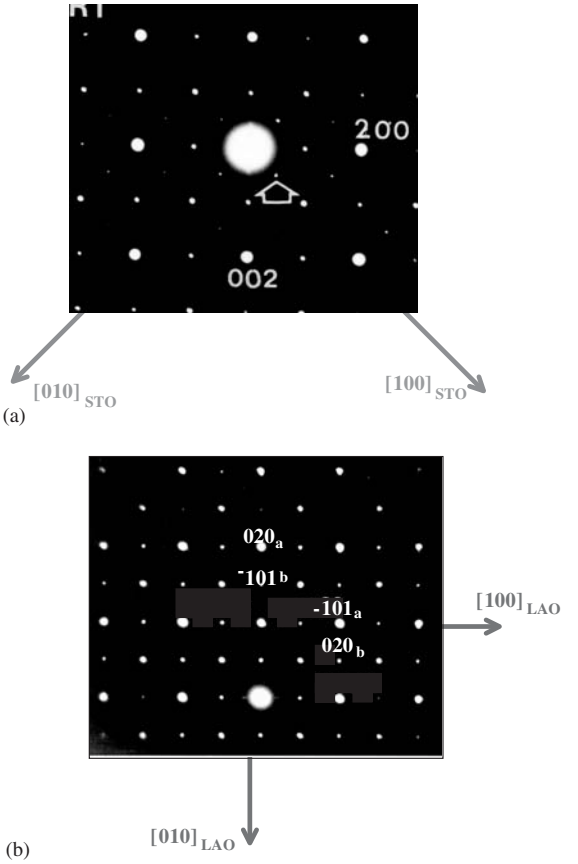

***Figure 2***
Room temperature electron diffraction of PCMO on STO (a) and LAO (b); reproduced from W. Prellier *et al.* (2000) Spectacular decrease of the melting magnetic field in the charge-ordered state of $Pr_{0.5}Ca_{0.5}MnO_3$ films under tensile strain. *Appl. Phys. Lett.* **77**, 1023–5.

The samples were cooled down to 92 K. The diffraction patterns recorded at low temperature in the strained film systematically exhibit a system of extra reflections characteristic of an incommensurate CO parallel to the $a^*$ direction on both substrates (not shown). The $q$ values of the modulation vector are close to 0.45 and STO and 0.38 on LAO and do not vary with the temperature below $T_{CO}$, contrary to what is observed in the bulk samples. This modulation disappears at $T_{CO}$. Small film fragments separated from the substrate were also observed. In this case, a modulation vector close to 0.5 was observed. This value is similar to that of the bulk samples (Barnabé *et al.* 1998). Since the composition is the same, this reinforces the assumption that the deviation from the ideal $q$ value originates from the strain induced by the substrate. This demonstrates that the

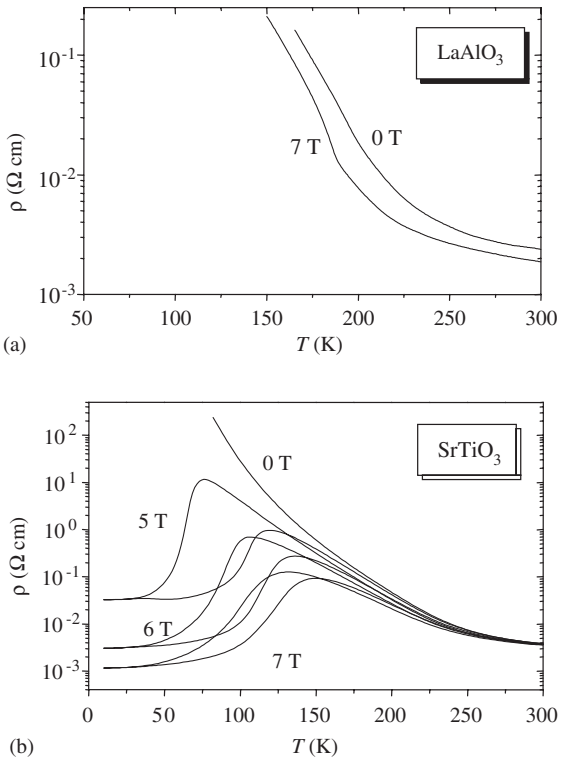

***Figure 3***
$\rho(T)$ in different magnetic fields (0 T, 5 T, 7 T, and 9 T) applied in the plane of the substrate for different films on (a) LAO and (b) STO.

orthorhombic distortion induced by the CO ordering is strongly reduced by the presence of the substrate, preventing the locking of the $q$ value of the CO on the 1/2 value contrary to the bulk sample of the same composition, leading to $q = 0.45$ for the film grown on STO and $q = 0.38$ for the one deposited on LAO.

The $\rho(T)$ curves are presented in Fig. 3. Different magnetic fields (0 T, 5 T, 6 T, and 7 T) were applied perpendicular to the substrate. The behavior of both films is very different. Clearly, the film grown on STO (Fig. 3(b)) shows an insulating behavior in the whole temperature range when the magnetic field is below 4 T. A small anomaly in the resistivity (around 240 K) is associated with the CO. But the most interesting feature is observed when applying a magnetic field of 7 T. The film then becomes metallic at low temperatures and shows an insulator-to-metal transition ($T_{IM}$) at 120 K. When a magnetic field is applied, the $T_{IM}$ upon heating occurs at a higher temperature ($= 140$ K) indicating a clear hysteresis. This melting field of 7 T is much lower than the 20 T one which is necessary to induce the metallic phase in the bulk sample. On the contrary, this effect is not observed for [101]-PCMO films grown on LAO (Fig. 3(a)) with fields up to 7 T.

Figure 4 shows the temperature dependence with different applied magnetic fields (0 T, 5 T, and 9 T) for three film thicknesses deposited on STO. In the absence of an applied field, one always observes a semiconducting behavior with an anomaly around 225 K corresponding to the $T_{CO}$ (this value is close to the one found in the bulk material). On the contrary, the results are drastically different under application of external magnetic fields. A field up to 9 T has almost no effect on the thinner film (15 nm): the film is still semiconducting and the magnetoresistance is very small (Fig. 4(a)). For the intermediate thickness (75 nm), while a 5 T magnetic field keeps the film semiconducting, a field of 9 T renders it metallic with a $T_{IM}$ close to 125 K (see Fig. 4(b)). This feature is a typical characteristic of the melting of the CO state. On the thicker film (110 nm), the melting magnetic field is reduced to 5 T (Fig. 4(c)). The thickness dependence of the properties suggests that the strains play an important role in determining the melting magnetic field. When the thickness of the film is increasing, there is a reduction of the strain on the film at room temperature. However, the properties of the film do not approach those of the bulk as the substrate-induced strain is reduced. In PCMO single crystal, with a 6 T magnetic field, the material remains insulating (Tomioka *et al.* 1996), whereas the 110 nm film becomes metallic.

The magnetic field dependence of the resistivity shows a strong decrease on a logarithmic scale at a critical field ($H_C$) indicating the field-induced melting of the CO state (see insets of Fig. 4). This field-induced insulator-to-metal transition, which accompanies the collapsing of the CO state takes place below $T_{CO}$. The critical fields in the field-increasing scan and in the field-decreasing scan will be represented by $H_C^+$ and $H_C^-$, respectively. This decrease of the resistivity versus magnetic field can be viewed as CMR of about five orders of magnitude at 75 K. A clear hysteresis is seen at these temperatures as previously reported on several CO compounds (Kuwahara *et al.* 1995, Tomioka *et al.* 1996). This hysteretic region is more pronounced when the temperature is decreasing. The temperature dependence of the large hysteresis region is a feature of a first-order transition and has been extensively studied for the composition $Nd_{0.5}Sr_{0.5}MnO_3$ (Kuwahara *et al.* 1995). From the resistivity measurements, a phase diagram for the 110 nm thick film (Fig. 5) and for the 75 nm film (inset of Fig. 5) can be derived. Two remarks should be made: First as already mentioned, the transition to the metastable state (i.e., the field-induced metallic state) is easier or requires a lower field in case of a thin film than in the bulk (Tomioka *et al.* 1996) (5 T for a 110 nm thick film and 9 T for a 75 nm thick film); second, the shape of the $H$–$T$ phase diagram is totally different as

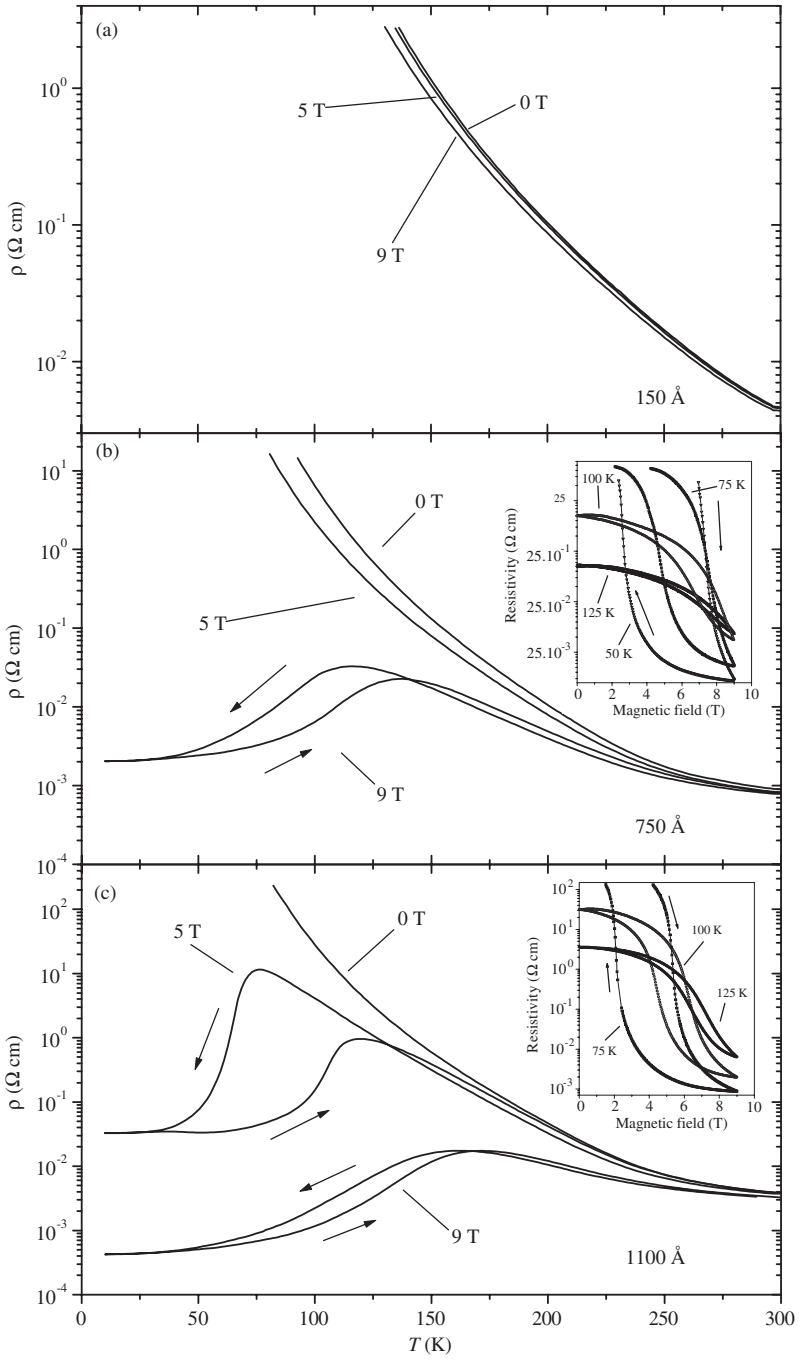

***Figure 4***
$\rho(T)$ in different magnetic fields (0 T, 5 T, and 9 T) applied in the plane of the substrate for different PCMO films on STO: (a) 15 nm, (b) 75 nm, and (c) 110 nm. Arrows indicate the direction of the temperature variation. Experimental points were taken with a stabilized temperature and a control of the sample film itself. The crossing of the curves ramping up and down in temperature is real. The insets of (b) and (c) depict the $\rho(H)$ for a 75 nm and 110 nm film, respectively. Runs with increasing field and decreasing field are denoted by arrows. Reproduced from W. Prellier *et al.* (2000) Thickness dependence of the stability of the charge-ordered state in $Pr_{0.5}Ca_{0.5}MnO_3$ thin films. *Phys. Rev. B* **62**, R16337.

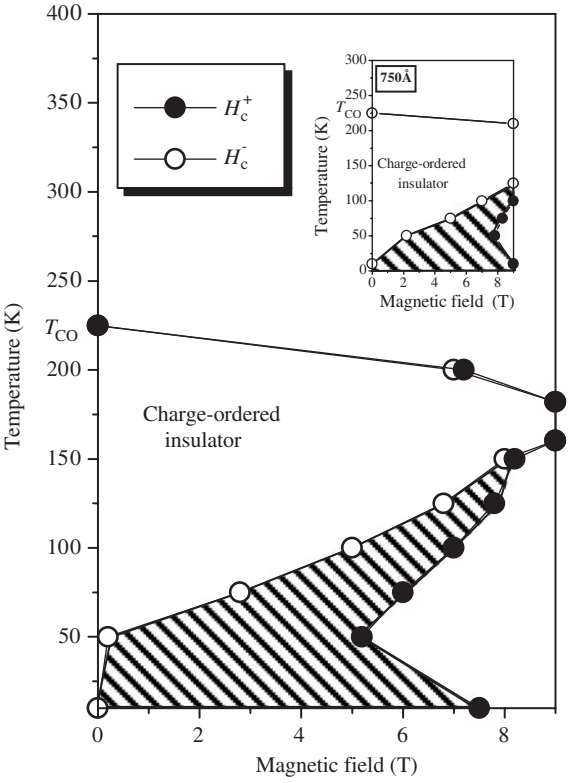

***Figure 5***
Electronic phase diagram of a 110 nm PCMO/STO thin film determined by the critical fields. $H_C^+$ and $H_C^-$ are taken as the inflexion points in $\rho(H)$ for up and down sweeps, respectively. In the dashed region, both CO insulating and metallic states coexist. The inset shows the phase diagram for a 75 nm PCMO film.

compared to the bulk single crystal $Pr_{0.5}Ca_{0.5}MnO_3$. The hysteretic region grows when the temperature is decreasing and rapidly vanishes at 8 T. In other words, $H_C$ is smaller than 9 T at low temperature, then $H_C$ is decreasing when the $T$ is increasing. Above 50 K, $H_C$ begins to increase again to 8 T. In the mean time, the hysteretic region is shrinking. Note that this region is larger in the case of the 75 nm film, indicating that the CO state is more stable as previously seen from the $\rho(T)$ curves (Fig. 3). In fact, the phase diagram of the 110 nm film has almost the same profile as a $Pr_{1-x}Ca_xMnO_3$ single crystal with $0.35 < x < 0.45$. This suggests that the whole electronic structure of $Pr_{0.5}Ca_{0.5}MnO_3$ thin films grown on STO is similar, though the charge transfer is different ($x = 0.5$ instead of 0.4 in $Pr_{1-x}Ca_xMnO_3$). The interesting point is that the modulation vector $q$ is equal to 0.45 in PCMO on STO (Prellier *et al*. 2000), whereas $q$ is always equal to 0.5 in bulk $Pr_{1-x}Ca_xMnO_3$ compounds ($0.35 < x < 0.45$) (Barnabé *et al*. 1998).

In summary, the melting magnetic field of the insulating charge-ordered state, in $Pr_{0.5}Ca_{0.5}MnO_3$ films, is strongly sensitive to the substrate-induced strain and thickness of the film. When deposited on $SrTiO_3$ (tensile stress), the application of magnetic fields up to 9 T has almost no effect on the resistivity of a very thin film, but a 5 T magnetic field can completely melt the CO state of a 110 nm thick film. When the film is under compression (on $LaAlO_3$), the films are insulating in a magnetic field of 7 T. By growing thin films, the properties of the materials can be modified compared to the bulk compounds. We have studied the case of $Pr_{0.5}Ca_{0.5}MnO_3$ on two different substrates that are able to induce two different types of strains (tensile on $SrTiO_3$ and compressive on $LaAlO_3$) and their effects on various parameters. We observed that the lattice parameters of the film, the orientation of the film with respect to the substrate, the transport properties of the film and the stability of the charge/orbital ordered state are influenced by the strains suggesting some similarities between strain and pressure effects in oxides (Wang *et al*. 1995).

# Crystal Field and Magnetic Properties, Relationship between

The crystal-field (CF) model has been very successful in the analysis of $4f^N$ configurations of the triply ionized rare-earth R ions in solids whose energy levels are reproduced through a Hamiltonian which involves both free-atom and CF operators (Morrison and Leavitt 1982, Görller-Walrand and Binnemans 1996). A satisfactory simulation of the experimental scheme of energy levels can be achieved if the number and quality of the operators is adequate. The procedure also provides good quality wave functions associated to the Stark levels, which can be used to simulate other physical properties, depending on them and the energies only. Thus, if there are no magnetic interactions between the lanthanide ions, the effective magnetic moment, the thermal evolution of the paramagnetic susceptibility $\chi$ for any crystallographic direction, as well as the $g$-values of the magnetic splitting factor for each Kramers doublet, can be calculated when the same $L + g_eS$ tensorial operator is applied to the wave function of a level, according to the Van Vleck formalism (Van Vleck 1932).

This article outlines the importance of the CF effects on the explanation of the magnetic properties in a wide group of R-containing materials, prepared as polycrystalline powders. In them, the one single crystallographic position occupied by R has a point symmetry ranging from a relatively high symmetry, $S_4$ for both $R_3Sb_5O_{12}$ and $Na_5R(MoO_4)_4$ series, to a very low symmetry, $C_s$ for $R_3WO_6Cl_3$ and $C_1$ for $R_2Te_4O_{11}$ and $MgR(BO_2)_5$ families (Cascales *et al.* 1995, 1999). The very good agreement found between the calculated paramagnetic susceptibility curves, derived through phenomenological and/or estimated crystal field parameters (CFPs), and the observed $\chi$ vs. $T$ plots constitutes an excellent test of the ability of the CF model to provide correct wave functions for the $4f^N$ configurations.

## 1. Crystal-field Analysis and Simulation of the Energy Level Schemes

In the development of a complete Hamiltonian for $4f^N$ configurations, the central-field approximation allows considering separately the Hamiltonians corresponding to the gaseous free-ion and to the CF interactions, which arise when R is in a crystalline environment. Thus the total Hamiltonian (Carnall *et al.* 1989) consists of two parts, $H = H_{FI} + H_{CF}$. The $H_{FI}$ free-ion part includes the spherically symmetrical one-electron term of the Hamiltonian, the electrostatic interaction between equivalent f electrons, the spin-orbit interaction, and terms accounting for higher-order corrections, as it is described in Carnall *et al.* 1989.

In the presence of a crystalline electric field the degeneracy of each state of the free-ion will be lifted according to the site symmetry of R in the crystal lattice. Calculations are usually carried out within the single-particle CF theory, and following Wybourne's formalism (Wybourne 1965), the CF $H_{CF}$ Hamiltonian is expressed as a sum of products of spherical harmonics and CFPs.

$$H_{CF} = \sum_{k=2}^{4,6}\sum_{q=0}^{k}\left[B_q^k(C_q^k + (-1)^q C_{-q}^k) + iS_q^k(C_q^k - (-1)^q C_{-q}^k)\right]$$

Whereas for the $S_4$ symmetry of the $R^{3+}$ site in $R_3Sb_5O_{12}$ the serial development of the CF potential

involves five real $B_q^k$ and two complex $S_q^k$ parameters, for the lowest $C_1$ symmetry found in $MgR(BO_2)_5$ all 27 CFPs are kept nonzero. For R ions with low point-group symmetries the constraints imposed by group theory are weak and it becomes difficult, with polycrystalline samples but even with polarized optical absorption and emission measurements on single crystals, to unravel the optical spectra unambiguously. Even if this has been done, it is not straightforward to fit the data with a total Hamiltonian. The number of adjustable parameters are very large, and the nonlinear least square fits are unreliable, unless a good initial set of CFPs is known. Besides *the descent of symmetry* method (Wybourne 1965), various theoretical models for calculating the CF interactions have been proposed (Garcia and Faucher 1995). The *simple overlap model* SOM (Porcher *et al*. 1999), a simplified semi-*a priori* calculation model used to obtain the initial set of CFPs from the crystallographic structure (Malta *et al*. 1991), was used for the limit situations represented by the $Na_5R(MoO_4)_4$ or $R_3Sb_5O_{12}$ series, and by the $MgNd(BO_2)_5$ compound. Finally, to verify the consistency and reliability of the final fitted parameters, simultaneous simulations performed for different $4f^N$ configurations either in the same or in an isostructural crystalline matrix, should provide sets of CFPs with only smooth variations (Morrison and Leavitt 1982).

## 2. Magnetic Susceptibility and Crystal-field Levels

The calculation of the magnetic susceptibility for above R-compounds (Cascales *et al*. 1993, 1995, 1996, 1997, 1999) has been carried out from the consistent sets of wave functions and energy levels previously determined (Cascales *et al*. 1990, 1992a, b, c, 1998), by diagonalizing the total Hamiltonian. This is done using the Van Vleck formalism (Van Vleck 1932) the result of an application of the perturbation theory,

$$\chi^{(i)} = N\beta^2 \sum_a \left[ \frac{\langle \phi_a | H | \phi_a \rangle^2}{kT} - 2 \sum_b \frac{\langle \phi_a | H | \phi_b \rangle \langle \phi_b | H | \phi_a \rangle}{E_a - E_b} \right] B_a$$

in which $N$ is the Avogadro's number, $\beta$ the Bohr magneton, $k$ the Boltzmann constant, and E and $\phi$ the nonperturbed energy levels and wave functions, respectively, described in the $|SLJM_J\rangle$ basis, and H is the magnetic tensor operator $L + g_e S$. The different values of the tensor components (or combinations of them) destroy the isotropy observed for the free-ion or even for an ion in a cubic symmetry. For polycrystalline samples, the mean observed paramagnetic susceptibility is $\chi_{av} = (\chi_x + \chi_y + \chi_z)/3$. The sums run over thermally populated levels, according to the Boltzmann population,

$$B_a = \exp(-E_a^{(0)}/kT) / \sum_a \exp(-E_a^{(0)}/kT).$$

In the expression, the matrix elements are calculated using the Racah algebra rules.

The formula is the sum of a temperature-dependent diagonal term and a temperature-independent off-diagonal term, which is reminiscent of the classical Curie–Weiss law. The off-diagonal term, a result of the second order perturbation, usually has little importance, with the exception of the ground states with $J = 0$. The sum runs over all other states ($b \neq a$). Energy levels up to $5000\,cm^{-1}$ and $10000\,cm^{-1}$, for the diagonal and off-diagonal terms, respectively (which are largely sufficient to cover the thermal population effect above 300K), were accounted in the calculation along with the J mixing of the levels.

The simulation of Stark levels for $4f^N$ configurations as well as the calculations of the $\chi$ vs. $T$ curves were performed by the programs REEL and IMAGE (Porcher personal communication, 1989).

## 3. Results

The calculation of the thermal variation of the paramagnetic susceptibility (Cascales *et al*. 1993, 1995, 1996, 1997, 1999) has been carried out with two different collections of energy levels and associated wave functions: (i) Those derived from CFPs obtained through spectroscopic data. (ii) Calculated from CFPs obtained by using SOM, through crystallographic data. Values of $\chi$ have been found to be independent of the field because of the relatively weak applied field. With the well-known exceptions of Eu and Sm-compounds, $\chi^{-1}$ vs. $T$ curves at high temperatures follow a Curie–Weiss-type behavior. Deviations from linearity observed at low temperature can be attributed to the splitting of the corresponding free-ion ground state under the influence of the CF, and the Weiss constants for these materials are entirely due to CF effects since they do not undergo any magnetic exchange interactions.

Figure 1 presents the comparison between experimental and calculated average $\chi^{-1}$ (or $\chi$ for $R = Eu^{3+}$) vs. $T$ curves for some selected compounds of $R_3Sb_5O_{12}$ and $MgR(BO_2)_5$ . The choice of these series is related to the very different number of real and complex parameters that the CF potential involves in each case. As it can be seen, a very satisfactory concordance is found between the experimental and calculated curves, especially when these last ones are from optical data. The observed slight discrepancy between them when the temperature increases is related with a variation of the CF, usually assumed to be temperature-independent, since, in fact, the network parameters smoothly vary with the temperature.

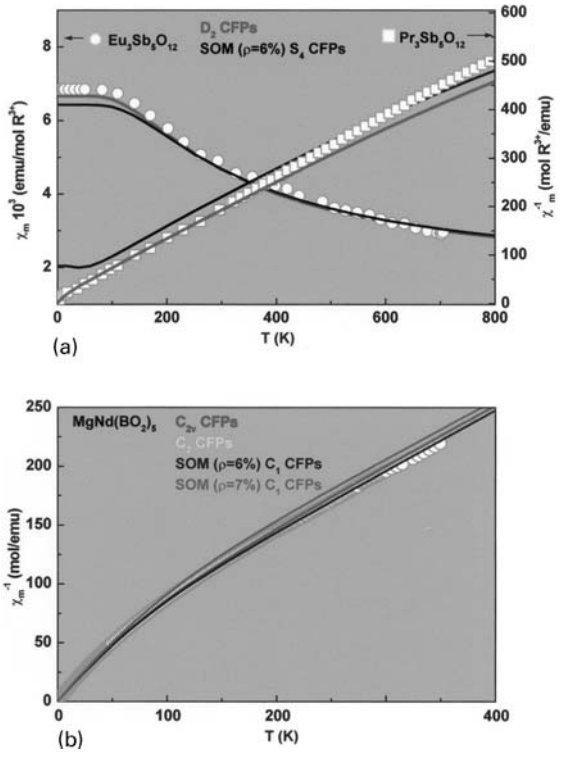

***Figure 1***
Comparison between experimental (symbols) and calculated (solid lines) $\chi^{-1}$ (or $\chi$ for the $Eu^{3+}$ compound) curves: (a) for selected $R_3Sb_5O_{12}$ compounds; (b) for $MgNd(BO_2)_5$ (reproduced by permission of Elsevier Science from *J. Solid State Chem.*, 1995, **114**, 52–6; *Chem. Phys.*, 1999, **240**, 291–301).

## *4. Concluding Remarks*

The good reproduction of experimental data, especially the observed deviation from the Curie–Weiss behavior at low temperature in the $\chi^{-1}$ vs. $T$ plots, underscores that the standard CF treatment of $4f^N$ configurations can explain the magnetic properties of these ions, whatever the number of parameters involved in the simulation, with no need to consider any sort of exchange interactions between them. These calculations are extremely dependent on the composition of the CF wave functions; hence the comparison with experimental measurements constitutes an excellent opportunity to test the ability of the model to give adequate wave functions for the considered ion. Anyway, the correct simulation of physical properties can be considered as a proof of obtaining ''good wave functions'' if it is done through ''good CFPs,'' i.e., those deduced from a high-quality spectroscopically-observed energy level scheme for the given $4f^N$ configuration. The oversimplified SOM model seems to be useful at providing estimations of CFPs, especially when the point symmetry of R involves a reasonable number of nonzero CFPs. This kind of calculation is of particular interest for opaque materials, for which only a reduced number of Stark levels can be observed from experimental techniques.

# Crystal Field Effects in Intermetallic Compounds: Inelastic Neutron Scattering Results

The crystal field (CF) interaction in rare-earth compounds is responsible for an enormous variety of magnetic phenomena. The electrostatic interaction experienced by the rare-earth ion, arising from the presence of near neighbor ions and outer valence electrons, is much smaller than the spin–orbit coupling, because of the minute spatial extent of the 4*f*-wave functions. This CF interaction gives rise to splittings of the ground-state multiplet of the order of tens of meV for the lanthanides. A precise determination of CF parameters is a necessary precondition for detailed analysis of bulk magnetic properties such as the static susceptibility, magnetic contribution to the specific heat, and complex magnetization processes and transitions in a large host of magnetic materials. The CF interaction intimately reflects the crystallographic point symmetry of the lanthanide ion and splits the $(2J+1)$-fold degeneracy of the ground state according to rules dictated by group theory. In combination with an exchange interaction, the result is a truly phenomenal array and variety of magnetic properties. The situation pertaining to compounds, such as those based on Ce, with an unstable or delocalized 4*f*-shell leads to complications due to the manner in which conduction electrons can couple to 4*f*-electrons, giving rise to valence fluctuating or Kondo systems (see *Intermediate Valence Systems*; *Kondo Systems and Heavy Fermions: Transport Phenomena*). Similar circumstances are also pertinent for 5*f*-electron heavy-fermion systems.

The most direct experimental method for the determination of CF eigenvalues and eigenfunctions in crystalline rare-earth intermetallics is provided by inelastic neutron scattering (INS), a truly fundamental and unique investigative probe of the microscopic magnetization which yields the spatial and time dependence of the dynamical magnetic susceptibility. In the specific case of CF effects, the neutron induces transitions between CF levels and these are most easily observed by the INS technique. The investigation of the CF interaction in more than 1000 rare-earth intermetallic compounds by INS and complementary techniques has been reviewed in detail by Moze (1998) whilst a briefer review of the INS technique, with specific reference to tetragonal REAg and $RNi_2Si_2$ compounds, has been compiled by Blanco (1998). The INS technique is also widely used for the determination of CF parameters and associated linewidth of CF transitions in rare-earth-based high-temperature superconductors (Furrer *et al.* 2001). The CF interaction and INS for rare-earth ions in icosahedral and amorphous environments have been briefly summarized by Moze (1998).

## 1. Crystal Electric Field

The CF Hamiltonian is most commonly expressed as

$$H_{\mathrm{CF}} = \sum_{m,n} B_n^m O_n^m \qquad (1)$$

where $B_n^m$ and $O_n^m$ are, respectively, CF energy parameters (typically in meV) and Stevens operator equivalents (Hutchings 1964). Alternatively, it can be expressed in terms of CF coefficients $A_n^m$:

$$H_{\mathrm{CF}} = \sum_{m,n} A_n^m \langle r^n \rangle \theta_n O_n^m \qquad (2)$$

where $\langle r^n \rangle$ are radial averages over the 4*f*-electron wave functions and $\theta_n$ are the Stevens coefficients $\alpha_J$, $\beta_J$, $\gamma_J$ for $n = 2$, 4, 6, respectively. These expressions are only valid for the CF split ground-state multiplet. A well-known exception to the rule is the case of the $Sm^{3+}$ ion. The number of CF parameters required to characterize the interaction appropriate to the point symmetry in which the rare-earth ion resides are tabulated in Table 1. For triclinic and monoclinic crystal point groups, where imaginary terms appear, the relevant matrix elements have been derived by Takegahara (2000).

The interaction represented in Eqn. (1) or (2) splits the $(2J+1)$-fold degenerate ground-state multiplet into a series of CF energy level eigenvalues with energy $E_i$ and corresponding eigenstate, labeled by its irreducible representation $\Gamma_i$. The uniqueness of the INS technique in this regard is that CF eigenstates can be obtained from the intensities of observed INS transitions whilst eigenvalues are determined from the energy positions of these transitions. It still remains by far the most indispensable and direct

***Table 1***
CF parameters relevant for the 32 point groups. Complex values are indicated by $\underline{B}_n^m$.

experimental technique for investigating the ground-state properties of a large class of modern magnetic materials. These cover a wide range of interests, from fundamental to technological, and in many cases their magnetic properties are partially governed by the CF interaction. It is hence of utmost importance to be able to determine the characteristics of the CF, for example, and for this purpose INS plays a very prominent role in experimental magnetism.

## 2. *Inelastic Neutron Scattering*

The parameters of the CF Hamiltonian invariably need to be determined by a number of different experimental techniques, of which INS is undoubtedly the most powerful, since it is extremely sensitive to the details of the CF. With no exchange interactions between rare-earth ions, which is the case for a pure CF system, the dynamic magnetic susceptibility is simply related to the CF eigenstates $|\Gamma_m^n\rangle$. The widely used equation for the INS cross-section for transitions within a purely CF split multiplet was first derived and presented by de Gennes (1963). The INS master formula for CF transition intensities and energies is given by the double differential magnetic scattering cross-section from $N$ rare-earth ions, in the dipole approximation, for neutrons scattered into an element of solid angle $\mathrm{d}\Omega$ and with a corresponding energy change given by $\hbar\omega = E_\mathrm{i} - E_\mathrm{f}$ (where $E_\mathrm{i}$ is the incident neutron energy and $E_\mathrm{f}$ is the final neutron energy after scattering) as

$$\frac{\mathrm{d}^2\sigma}{\mathrm{d}\Omega\,\mathrm{d}E} = N\frac{k_\mathrm{f}}{k_\mathrm{i}}(\gamma r_0)^2 \mathrm{e}^{-2W}\left[\frac{1}{2}g_J f(Q)\right]^2 \times \sum_{i,j} p_i \langle\Gamma_i|\boldsymbol{J}_\perp|\Gamma_j\rangle\langle\Gamma_i|\boldsymbol{J}_\perp^*|\Gamma_j\rangle \times \delta(\hbar\omega - E_i + E_j) \quad (3)$$

The terms in this equation are defined by the usual nomenclature: $k_\mathrm{i}$ is the initial neutron wavevector, $k_\mathrm{f}$ the final neutron wavevector, $\gamma$, the neutron gyro-magnetic ratio, $= -1.913$, $r_0 = (e^2/m_\mathrm{e}c^2)$, the classical electron radius, $(0.2818 \times 10^{-15}\,\mathrm{m})$, exp(−2W) is the Debye–Waller factor, representing the thermal vibrational motion of atoms, $g_J$ the Landé $g$-factor, $f(Q)$ the Fourier transform of the magnetization density of unpaired electrons and comprises both spin and orbital magnetization terms, $p_i$ the CF thermal occupation factor, $J_\perp$ the component of the angular momentum operator perpendicular to the scattering vector $\boldsymbol{Q}$. The term $(\gamma r_0)^2$ corresponds to a magnetic cross-section of 0.2906 barn ($1\mathrm{barn} = 10^{-28}\,\mathrm{m}^2$). The subscripts $i$ and $j$ refer to different CF eigenfunctions.

The delta function $\delta(\hbar\omega - E_i + E_j)$ is appropriate only for vanishing CF linewidths, but in practice the linewidth always has an intrinsic temperature-dependent CF component, with a distribution characterized by a Lorentzian component $P(\hbar\omega, T)$. In such cases, the delta function is replaced by

$$P(\hbar\omega,\ T) = \frac{1}{\pi}\left(\frac{\Gamma}{\Gamma^2 + (\hbar\omega)^2}\right) \quad (4)$$

The Lorentzian full width at half height maximum $2\Gamma$ is inversely proportional to the relaxation rate of the magnetization fluctuation energy. Intrinsic CF linewidths are usually associated with magnetic interactions at low temperatures by a Korringa law. CF excitations are nondispersive and are most conveniently studied with polycrystalline material. The relative intensities between CF levels, suitably averaged for a powder, are given by the squared matrix elements:

$$\langle\Gamma_i|J_\perp|\Gamma_j\rangle^2 = \tfrac{1}{3}\Big(\langle\Gamma_i|J_+|\Gamma_j\rangle^2 + \langle\Gamma_i|J_-|\Gamma_j\rangle^2 + 2\langle\Gamma_i|J_z|\Gamma_j\rangle^2\Big) \quad (5)$$

As can be appreciated by inspection of Table 1, a lowering of the point symmetry corresponds with an increase in the number of parameters needed to completely specify the CF interaction. For systems with cubic point symmetry there exists an ingenious and

widely employed method (commonly referred to as LLW) of parametrizing the eigenfunctions and eigenvalues of the CF Hamiltonian by setting the two parameters required for description of the CF in terms of parameters $x$ and $W$ defined by

$$B_4^0 = \frac{Wx}{F(4)}, \quad B_6^0 = \frac{W(1-|x|)}{F(6)} \tag{6}$$

where $-1 \le x \le 1$, and listing all the eigenvalues and eigenfunctions as functions of only one parameter $x$ (the factors $F(4)$ and $F(6)$ are functions only of $J$; Lea *et al*. 1962). In the context of the INS cross-section for CF excitations, the matrix elements for magnetic dipole transitions for cubic symmetry in terms of the LLW parameter $x$ have been conveniently tabulated by Birgeneau (1972). Once the intensities of CF transitions have been determined, it is a relatively simple matter to determine the two CF parameters using this tabulation. With further reference to cubic symmetry, an important point which has been recently brought to light is a subtle difference in the CF eigenfunction composition and INS transition probabilities between point groups $(T_h, T)$ and $(O_h, O, T_d)$, respectively (Takegahara *et al*. 2001). For systems with a lower point symmetry, no similar method of the same ingenuity and simplicity as the LLW method is available for parametrizing the CF parameters.

CF transitions in the INS spectrum are usually identified by their unique dependence on temperature and the scattering vector $Q$. Analysis of the neutron polarization can be used in specific circumstances when it is necessary to isolate a particularly weak magnetic scattering signal from scattering due to nonmagnetic lattice vibrational modes (Janoušavá *et al*. 2003).

## 3. Complimentary Techniques

When the crystal point group is progressively lowered, the INS technique used on its own is generally not sufficient to give a unique set of parameters. In this context, bulk techniques are most vital for verification of parameters determined by the INS technique for rare-earth intermetallic compounds (Moze 1998). The most widely used and significant of these are summarized in brief in the following sections.

### 3.1 Magnetic Susceptibility

A limited amount of information about the CF interaction can be obtained from the temperature dependent magnetic susceptibility in the noninteracting regime via the Van Vleck susceptibility

$$X_z^{VV}(T) = N_A (g_J \mu_B)^2 \left\{ \sum_n p_n \frac{\langle \Gamma_n | J_z | \Gamma_n \rangle^2}{k_B T} + 2 \sum_{n,m} p_n \frac{|\langle \Gamma_m | J_z | \Gamma_n \rangle|^2}{E_m - E_n} \right\} \tag{7}$$

with $E_n$ and $|\Gamma_n\rangle$ eigenvalues and eigenfunctions, respectively, of the CF Hamiltonian and $Z$ the partition function. There is an explicit dependence on the energy of the CF levels and the matrix elements connecting the eigenstates, but the limiting proviso is that the sum is over all levels at any particular temperature and hence any information about one particular level or set of levels is lost. However, a determination of the three paramagnetic Curie temperatures $\theta_z$, $\theta_x$, and $\theta_y$, as measured along the three principal axes of a single crystal, the CF parameters, $B_2^0$ and $B_2^2$ are uniquely determined, viz.

$$\begin{aligned} k_B \theta_z &= -\frac{1}{5} B_2^0 (2J-1)(2J+3) \\ k_B \theta_x &= -\frac{1}{10} (B_2^0 - B_2^2)(2J-1)(2J+3) \\ k_B \theta_y &= -\frac{1}{10} (B_2^0 + B_2^2)(2J-1)(2J+3) \end{aligned} \tag{8}$$

If such data are available, $B_2^0$ can be specified immediately for tetragonal and hexagonal CFs, whilst for an orthorhombic CF, $B_2^0$ and $B_2^2$ are similarly determined (Wang 1971, Boutron 1973).

### 3.2 Magnetization

In the presence of combined CF, exchange and applied magnetic fields, the expectation value of the magnetization can be calculated in the mean field approximation. The magneto-crystalline anisotropy energy at any particular temperature is determined by calculation of the variation of the magnetic moment with the direction of the applied magnetic field. The thermal variation of the component $\alpha (\alpha = x, y, z)$ of the magnetic moment (in Bohr magnetons) is given by

$$\langle \mu_z \rangle = \frac{\sum_n \langle \Gamma'_n(h) | g_J J_z | \Gamma'_n(h) \rangle \exp(-\beta E_n(h))}{\sum_n \exp(-\beta E_n(h))} \tag{9}$$

with $\beta = 1/k_B T$ and $|\Gamma'_n\rangle$ the eigenstates of the Hamiltonian if exchange and applied fields are included. In the paramagnetic regime, rather high magnetic fields are required to mix the different CF eigenstates. In the ordered regime, when an exchange field is present, the ordered moment as a function of temperature is calculated, in standard fashion, by obtaining self-consistent solutions which simultaneously satisfy the above equation and the molecular field condition

$$h = \lambda N g_J \mu_B^2 \langle \mu_z \rangle \tag{10}$$

The molecular field constant $\lambda$ is determined by a measurement of the ordering temperature. When the CF is a small perturbation of a dominant rare-earth–transition metal exchange interaction, simple relationships exist between the anisotropy constants and

CF parameters (Rudowicz 1987). The transferibility of CF parameters obtained from investigation of systems where the CF is the dominant interaction to those where the exchange dominates must, however, be treated with some caution (Moze and Buschow 1996).

### 3.3 Specific Heat Measurements

The magnetic specific heat is sensitive only to the eigenvalues of the magnetic system (see *Magnetic Systems: Specific Heat*). In the paramagnetic phase, where CF effects are important, the CF levels are evidenced via a Schottky-type contribution. The level degeneracy can also be deduced and the technique is now routinely used in analyses of systems with a significant CF interaction. For a sequence of CF-only eigenstates $E_i$, at a temperature $T$, the magnetic part of the specific heat is given by

$$C(T) = \frac{R_0}{Z^2}\left\{ Z \sum_i (\beta E_i)^2 \exp(-\beta E_i) - \left( \sum_i \beta E_i \exp(-\beta E_i) \right)^2 \right\} \qquad (11)$$

Limitations in the accuracy of this technique arise from spin-phonon contributions and experience has shown that several sets of CF parameters can equally well fit the specific heat data.

Raman scattering can be used to induce CF transitions in rare-earth intermetallics (Martinho *et al.* 2001), but the selection rules for transitions are more restrictive than the INS technique. A recent novelty is the joint use of experimental determinations of CF parameters in rare-earth intermetallics and predictions of the ground-state charge density using density functional theory (DFT) (Liu *et al.* 1999, Strässle *et al.* 2003). This allows at least the low-order CF parameters to be calculated approximately. The relevant full set of CF parameters can then be refined from INS data. This innovative and important methodology is expected to be widely employed in the future.

## 4. Recent INS Results

Since the appearance of a review and compilation of INS investigations concerning the CF interaction in stable rare-earth intermetallic compounds (Moze 1998), further studies have been reported on a wide variety of novel compounds which encompass an equally wide variety of magnetic properties. Amongst these are the following types of compounds: $TmCu_2Si_2$ (Kosaka *et al.* 1997), $Nd_3Pd_{20}Ge_6$ (Dönni *et al.* 1998), PrPdSb (Adroja *et al.* 1999), RNiSb (Karla *et al.* 1999), $PrInAg_2$ (Kelley *et al.* 2000), $HoCr_2Si_2$ (Moze *et al.* 2000), $Tm_{0.05}Y_{0.95}Ni_2^{11}B_2C$ (Sierks *et al.* 2000), ErNiAl (Javorský *et al.* 2001), $TmT_2Si_2$, with T = Co, Ni, Cu (Harker *et al.* 2002), and $ErAl_xGa_{2-x}$ (Strässle *et al.* 2003). For Ce-based compounds displaying valence fluctuation, heavy-fermion, or Kondo-type behavior, a broad INS spectrum is usually the norm, as the CF coexists with other magnetic interactions (Christianson *et al.* 2002, Knafo *et al.* 2003) but well localized CF excitations have been recently observed, for example, in $CeTe_2$ (Liu *et al.* 2003).

In order to illustrate briefly the unique advantadges of the INS technique, displayed in Fig. 1, are the intensities and energies of dipole CF transitions directly observed by INS in the hexagonal compound $NdAl_3$ (Strässle *et al.* 2003). At low temperatures two transitions from the ground state are clearly identified, $\Gamma_9^{(1)} \rightarrow \Gamma_7$ and $\Gamma_9^{(1)} \rightarrow \Gamma_9^{(2)}$ respectively, as well as an excited state transition $\Gamma_8^{(1)} \rightarrow \Gamma_8^{(2)}$. The pressure dependence of these transitions has also been reported and their energy-level scheme at ambient and elevated pressure is displayed in Fig. 2, together with the energy-level scheme determined for $PrAl_3$ at ambient pressure. There are four CF parameters which need to be determined, as the appropriate point group is of hexagonal symmetry. DFT predictions of the CF parameters at ambient and elevated pressures for $NdAl_3$ were also compared with those obtained from a careful fitting of the INS spectra. The parameters calculated within DFT predict the same signs and orders of magnitude (within at least 50%) for all four CF terms: $B_2^0$, $B_4^0$, $B_6^0$, $B_6^6$. The only parameter which is seriously underestimated is $B_4^0$. Overall, this is highly encouraging given that within a DFT approach applied to CF interactions it is still difficult to accurately treat highly correlated 4*f*-electron states.

Phys.: Condens. Matter* **15**, 3257–66; © IOP Publishing).

## 5. Summary

The technique of neutron inelastic scattering is a unique and hugely successful spectroscopic technique which has been used with large effect for the determination of CF levels and level composition in a vast number of rare-earth intermetallic compounds. An intimate knowledge of the CF interaction allows for detailed microscopic modeling and subsequent understanding of the principal mechanisms responsible for complex magnetic structures and phase transitions in systems composed of lanthanide intermetallics. In systems where the R-ion resides in a site of low symmetry, a determination of the large number of CF parameters is an enormously difficult task, and the energy-level scheme and level composition can only be determined by combined analysis of INS and bulk measurements. On a more recent note, experimental INS data combined with DFT calculations of the ground-state charge density are a novel and extremely promising methodology for an unambiguous determination of CF parameters. The field is very vibrant and rich and there are many systems, relevant for either fundamental or technological reasons, which will surely be investigated by INS in the future.

## Demagnetization: Nuclear and Adiabatic

### 1. *Principles of the Method*

Adiabatic demagnetization (AD) is one of the cooling methods that have a common principle: the entropy of the working medium (helium, spins, etc.) is controlled by some parameter like pressure or magnetic field. The working medium in AD is a system of magnetic moments (nuclear spins, electronic spins, or orbital moments) and the magnetic field is the control parameter when the magnetocaloric effect is employed. The magnetization, $M$, of a paramagnet or a ferromagnet increases with an applied magnetic field, $H$, and simultaneously both the energy of magnetic moments in the field and the internal energy of their exchange interaction decrease. Supposing negligible pressure and volume effects, the entropy can be expressed by the following thermodynamic relation:

$$\mathrm{d}S = \frac{1}{T}\left(\frac{\partial U}{\partial T}\right)_H \mathrm{d}T + \frac{1}{T}\left[\left(\frac{\partial U}{\partial H}\right)_T + M\right]\mathrm{d}H \qquad (1)$$

The internal energy, $U$, is a function of the temperature, $T$, of the sample, and in general it increases with temperature. Consequently, if the magnetization of a paramagnetic sample is reduced adiabatically, the sample temperature should decrease. The cooling cycle of the AD method consist of two steps:

(i) *Isothermal magnetization*. The sample is in thermal contact with a constant temperature bath kept at $T_\mathrm{i}$. The magnetic field is increased from zero to $H_\mathrm{i}$ and the heat released to the bath compensates for the work done on the sample. It leads to an increase in the order of the magnetic moments and, consequently, reducing their entropy, $S$, by

$$\Delta S = \int_0^H \left(\frac{\partial M}{\partial T}\right)_H \mathrm{d}H \qquad (2)$$

This entropy change is determined by the rate of change of magnetic energy with respect to the thermal energy. The efficiency of the process increases with decreasing temperature.

(ii) *Adiabatic demagnetization*. The sample is thermally isolated from the bath, and the field is then reduced from $H_\mathrm{i}$ to $H_\mathrm{f}$. It is an adiabatic process, i.e., $\mathrm{d}Q = T\mathrm{d}S = 0$ and the entropy remains constant. Since the sample performs magnetic work by demagnetizing at the expense of internal energy, it decreases in temperature towards $T_\mathrm{f}$ at a rate given by:

$$\mathrm{d}T_{(\mathrm{d}S=0)} = -\frac{T\left(\frac{\partial M}{\partial T}\right)_H}{C_\mathrm{H}}\mathrm{d}H \qquad (3)$$

where $C_\mathrm{H}$ is the specific heat.

AD is a one-shut process. After demagnetization the system will warm up owing to a parasitic heat load. The energy which can be absorbed, $Q = \int T\mathrm{d}s$, is proportional to the shaded area in Fig. 1.

In modeling a system of noninteracting moments, $\mu$, the entropy is simply a function of $H/T$. For an isoentropic process $T_\mathrm{f} = T_\mathrm{i}H_\mathrm{f}/H_\mathrm{i}$ and absolute zero temperature could be reached for $H_\mathrm{f} = 0$, in contradiction to the third law of thermodynamics. This does not happen in a real system, however, because the assumption of noninteracting spins breaks down and the energy levels in zero applied field are not degenerate. The lowest temperature achievable by the AD method is limited by the existence of an internal interaction in a spin system. This interaction causes spin ordering at sufficiently low temperatures and a spontaneous decrease of the entropy of a system. The detailed nature of the interactions may be complicated. It may be, for example, the direct dipolar interaction between magnetic moments in the case of dielectrics or the RKKY interaction in metals. It simplifies matters to define an effective internal field,

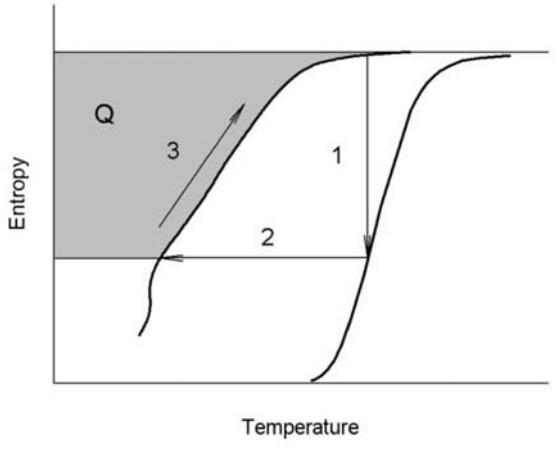

***Figure 1***
Graphical representation of the processes of isothermal magnetization (1) and adiabatic demagnetization (2). The shaded area shows the cooling power during a warm up (3).

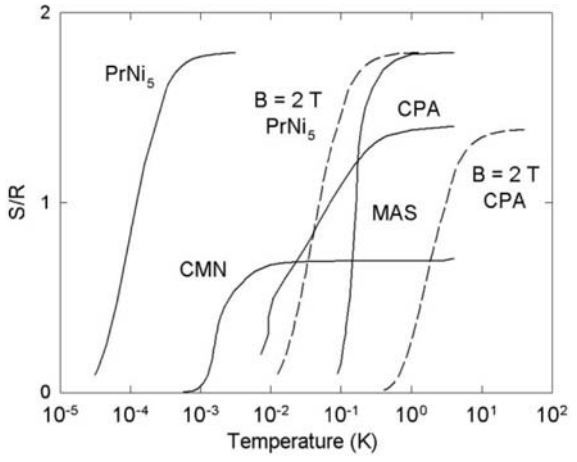

***Figure 2***
Entropies per mole of substance, $S/R$, of four salts and $PrNi_5$ in zero field (solid curves) and in a 2 T field (dashed curves).

$h$, such that it would produce a Zeeman splitting equal to the splitting, $\varepsilon$, due to the interaction, i.e., $\varepsilon = \mu\mu_0 h$. Then:

$$T_f = T_i \sqrt{\frac{H_f^2 + h^2}{H_i^2 + h^2}} \tag{4}$$

The temperature dependence of the entropy of some substances used for this cooling method is shown in Fig. 2.

## 2. *Practical Aspects*

The most common substances used for the AD method are paramagnetic salts such as MAS = $Mn^{2+}SO_4(NH_4)_2SO_4.6H_2O$ ($T_c \approx 0.17$ K; $b \approx 80$ mT), FAA = $Fe_2^{3+}(SO_4)_3(NH_4)_2SO_4.24H_2O$ (0.03 K; 50 mT), CPA = $Cr_2^{3+}(SO_4)_3K_2SO_4.24H_2O$ (0.01K; 10 mT), CMN = $2Ce^{3+}(NO_3)_3 3Mg(NO_3)_2.24H_2O$ (0.002K; 4mT), $Gd_2(SO_4)_3.8H_2O$ (0.18 K), van Vleck paramagnets such as $PrNi_5$ (0.0004 K; 16 mT) and $PrCu_6$ (0.0026 K), and pure metals such as copper (58 nK; 0.3 mT) and silver (0.56 nK). The ordering temperature and the effective internal field are given in parentheses.

Besides cooling magnetic moments by AD, for any practical use it is also necessary to cool the lattice of which the magnetic atoms form a part. The exchange of energy between the spins and the lattice is characterized by the spin–lattice relaxation time, $\tau_1$. For metals the exchange is mediated by the conduction electrons and $\tau_1$ is given by the Korringa relation. In nonmetals, owing to their poor thermal conductivity, $\tau_1$ can reach hours or days at very low temperatures.

The use of the magnetocaloric effect to produce temperatures well below 1 K was proposed by Giauque and Debye in 1926. A practical realization of AD cooling was announced in 1933 by Giauque and MacDougall, reaching 0.53 K using $Gd_2(SO_4)_3.8H_2O$ at starting conditions of 3.4 K and 0.8 T. On the other hand, de Haas, Wiersma, Kramers used $CeF_2$, and after demagnetization from 3 T to 0.1 T decreased the temperature from 1.26 K to 0.27 K. According to present knowledge, 0.001 K is the estimated lower limit achievable by the AD technique employing electronic paramagnetism.

In 1934 Gorter proposed nuclear magnetic refrigeration but owing to severe experimental problems it was only in 1956 that Kurti succeeded in reducing the nuclear spin temperature in copper wires to about 20 $\mu$K. Osgood and Goodking in 1966 were the first to achieve considerable electron and lattice refrigeration. The progress made in the AD technique enabled the Helsinki group, in 1982, to observe spontaneous nuclear order of copper below the Néel temperature $T_N = 58$ nK (Oja and Lounasmaa 1997). The nuclear order in silver with $T_N = 560$ pK has been investigated and the long spin–spin relaxation time of silver made it possible to produce a negative nuclear spin temperature and to find ferromagnetic order in silver above $T_C = -1.9$ nK (Oja and Lounasmaa 1997). The lowest temperature achieved is 280 pK and $-750$ pK is the highest temperature obtained (Oja and Lounasmaa 1997).

Using the known potential of van Vleck paramagnets for nuclear refrigeration, Andres and Lounasmaa (1982) tested many of them. The electronic ground states of van Vleck paramagnets are nonmagnetic singlets. Owing to the nuclear hyperfine interaction of nuclear and electronic spins a magnetic moment is induced into the ground state. This can be formally described by assuming that the nuclear magnetic moment is enhanced by a factor

$$1 + K \equiv 1 + \frac{A\chi_{VV}}{g_J \mu_B g_N \mu_N} \tag{5}$$

where $A$ is the hyperfine interaction constant and $\chi_{VV}$ the van Vleck temperature-independent susceptibility. For Pr or Tm compounds, $K$ is typically 10–100. $PrNi_5$ (hyperfine interaction-enhanced nuclear ferromagnet, $T_C = 0.4$ mK) or $PrCu_6$ ($T_N = 2.6$ mK) serve in a lower stage in many nuclear refrigerators. The starting conditions for demagnetization, $B/T \approx 500$–$1000$ TK$^{-1}$, are fulfilled by available dilution refrigerators and superconducting magnets. Advantages of these materials are a huge cooling power and a short $\tau_1$.

## 3. *Outlook*

AD is mostly used in the temperature range below 1 mK but its ability to work in zero gravity has led to the development of prototypes for satellite

applications. It is a prospective method as AD can reach higher efficiency than traditional vapor compression technology. To apply this method to a wide temperature range up to room temperature, considerable progress in materials research is needed. Materials with a large magnetocaloric effect are fundamental for AD but they are also suitable for regenerators in other types of refrigerators. For devices suitable for cooling at room temperature (see *Magnetocaloric Effect: From Theory to Practice*).

## Density Functional Theory: Magnetism

Spin density functional theory (SDFT) is the basis of most of the modern electronic structure calculations. It has been reviewed in detail by Jones and Gunnarsson (1989), Trickey (1990), Eschrig (1996), and many others, and is only briefly outlined here.

### *1. Spin Density Functional Theory*

#### *1.1 General Theory*

At the quantum mechanical level, magnetic properties of materials are usually well described within the Born–Oppenheimer (*adiabatic*) approximation: the electrons, moving much faster than the heavier atomic nuclei, are considered in the Coulomb potential $v(\mathbf{r}) = \sum_s -Z_s/|\mathbf{r}-\mathbf{R}_s|$ created by the nuclei of charge $Z_s$ in their instantaneous positions $\mathbf{R}_s$. In most cases, the values of $\mathbf{R}_s$ are approximated by the rest positions of the atoms in a regular structure.

For each set of $\{\mathbf{R}_s\}$ there is a state of the electrons with the lowest energy, the ground state $|\psi_0\rangle$. Its energy can be written as a functional of the potential, $E_0[v]$, i.e., the ground state energy depends on the Coulomb potential of the nuclei at each point $\mathbf{r}$ of space. The exact functional dependence $E_0[v]$ is in general unknown, but reasonable approximations will be discussed below. They allow for a determination of the atomic rest positions in molecules and solids with an accuracy of a few percent, by minimization of the energy $[E_0 + \sum_{ss'} Z_s Z_{s'}/|\mathbf{R}_s - \mathbf{R}_{s'}|]$ with respect to $\{\mathbf{R}_s\}$ (Moruzzi *et al.* 1978).

The calculation of observable quantities from the true wave function $\psi_0$ is not feasible in the case of many, strongly interacting electrons, since $\psi_0$ depends on the coordinates $\mathbf{r}_i$ and on the spin quantum numbers $\sigma_i$ of all $N$ electrons, although the total energy may be expressed in terms of the spin and pair densities. Hohenberg and Kohn (1964) went further and proved that the ground state density function $n_0(\mathbf{r})$ alone determines $v(\mathbf{r})$ and hence $\psi_0$, together with all ground state properties uniquely. Since the ground state spin density matrix $\mathbf{n}_0(\mathbf{r})$

$$\begin{aligned}\mathbf{n}_0(\mathbf{r}) &= n_{0,\sigma\sigma'}(\mathbf{r}) \\ &= N \sum_{\sigma_2} \int \mathrm{d}^3 r_2 \ldots \sum_{\sigma_N} \int \mathrm{d}^3 r_N \psi_0 \\ &\quad \times (\mathbf{r},\ \sigma,\ \mathbf{r}_2,\ \sigma_2, \ldots,\ \sigma_N) \\ &\quad \times \psi^*{}_0(\mathbf{r},\ \sigma',\ \mathbf{r}_2,\ \sigma_2, \ldots,\ \sigma_N) \end{aligned} \tag{1}$$

comprises the information on the electron density, $n = \mathrm{tr}\mathbf{n}$, the unique determination of the ground state by the spin density follows as a corollary. It allows, as an important generalization, the inclusion of the action of an external magnetic field $\mathbf{B}$ on the spin, by the definition of the spin-dependent external potential $\mathbf{v} = v + \mu_\mathrm{B}\boldsymbol{\sigma}\mathbf{B}$. Here, $\boldsymbol{\sigma} = (\sigma_x, \sigma_y, \sigma_z)$ denote the Pauli spin matrices. The vector spin density is given as $\boldsymbol{\Sigma} = \mathrm{tr}(\boldsymbol{\sigma}\mathbf{n})$. Further, the total spin in a given volume $V$ is $\boldsymbol{S} = \int_V \mathrm{d}^3 r\, \boldsymbol{\Sigma}/2$, and the related spin magnetic moment is defined by $\boldsymbol{\mu}_s = -\mu_\mathrm{B} \cdot 2\boldsymbol{S}$.

The calculation of $E_0$ and $\mathbf{n}_0$ becomes possible with the help of the Hohenberg–Kohn variational principle:

$$\begin{aligned} E_0[\mathbf{v}] &= \min_{\psi} \langle \psi | \hat{H} | \psi \rangle \\ &= \min_{\mathbf{n}} \left\{ \int \mathrm{d}^3 r \mathrm{tr}(\mathbf{vn}) + \min_{\psi_\mathbf{n}} \langle \psi_\mathbf{n} | \hat{T} + \hat{U} | \psi_\mathbf{n} \rangle_{\int \mathrm{d}^3 r n = N} \right\} \end{aligned} \tag{2}$$

where $\psi_\mathbf{n}$ means the class of all normalized fermionic wave functions with the spin density $\mathbf{n}$. The electronic

Hamiltonian $\hat{H}$ consists of the potential $\mathbf{v}$ plus the operators of the kinetic energy, $\hat{T}$, and of the electron–electron interaction energy, $\hat{U}$. The latter terms are further subdivided (Kohn and Sham 1965):

$$\min_{\psi_{\mathbf{n}}} \langle \psi_{\mathbf{n}} | \hat{T} + \hat{U} | \psi_{\mathbf{n}} \rangle = T_{\mathrm{s}}[\mathbf{n}] + E_{\mathrm{H}}[n] + E_{\mathrm{xc}}[\mathbf{n}] \quad (3)$$

Here, $T_{\mathrm{s}}$ is the ground state kinetic energy of a model system of electrons that are assumed to have no mutual Coulomb interaction and to possess the spin density matrix $\mathbf{n}$:

$$T_{\mathrm{s}}[\mathbf{n}] = \sum_{i}^{N} \sum_{\sigma} \langle \phi_i(\sigma) | -\Delta/2 | \phi_i(\sigma) \rangle ,$$

$$\delta_{ij} = \sum_{\sigma} \langle \phi_i(\sigma) | \phi_j(\sigma) \rangle \quad (4)$$

$$n_{\sigma\sigma'} = \sum_{i}^{N} \phi_i(\sigma) \phi_i^*(\sigma') \quad (5)$$

The $\phi_i$ denote the $N$ lowest single-particle eigenstates in a corresponding, yet unknown, effective potential. Further, $E_{\mathrm{H}}$ is the spin-independent Hartree energy:

$$E_{\mathrm{H}} = \frac{1}{2} \int \int \mathrm{d}^3 r \mathrm{d}^3 r' \frac{n(\mathbf{r}) n(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} \quad (6)$$

and $E_{\mathrm{xc}}[\mathbf{n}]$, the so-called exchange-correlation (xc) energy, is an unknown functional of the spin density matrix, containing all contributions beyond the mean field approximation from electron–electron interactions in the ground state.

The essence of the Kohn–Sham procedure is to subdivide the total energy into large contributions that are either well-known functionals ($\int \mathrm{d}^3 r$ tr($\mathbf{vn}$) and $E_{\mathrm{H}}$), or at least computable quantities ($T_{\mathrm{s}}$), and a much smaller remaining part ($E_{\mathrm{xc}}$). Then, approximations applied to the latter part are expected to introduce only reasonably small errors. However, all known approximations to $E_{\mathrm{xc}}$ are unfortunately on a heuristic level and cannot be systematically improved. Thus, the spin density functional theory (SDFT) described here and in the following has to be considered as a model theory, in the sense that the applicability of any chosen approximation is justified *a posteriori* by experience from comparison with experiment. On the other hand, within a given approximation, the calculations are usually carried out without adjustable parameters. In this way, after validating the approximation for a certain class of materials, reliable forecasts of experimental results on this class can be expected from theory.

For this aim, a numerically tractable formulation is needed to allow for the calculation of $\mathbf{n}_0$ and $E_0$. Such a formulation is given by the Kohn–Sham equations that are obtained by: (i) inserting Eqn. (3) in Eqn. (2), (ii) using the Ansatz Eqn. (5) also in the case with electron–electron interaction, and (iii) varying with respect to the $\phi_i^*$:

$$\sum_{\sigma'} \left[ -\frac{\Delta}{2} \delta_{\sigma\sigma'} + v_{\mathrm{eff},\sigma\sigma'} \right] \phi_i(\sigma') = \varepsilon_i \phi_i(\sigma) \quad (7)$$

The Kohn–Sham equations (Eqn. (7)) contain the above-mentioned effective potential:

$$v_{\mathrm{eff},\sigma\sigma'} = v_{\sigma\sigma'}(\mathbf{r}) + \int \mathrm{d}^3 r' \frac{n(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} \delta_{\sigma\sigma'} + v_{\mathrm{xc},\sigma\sigma'} \quad (8)$$

consisting of external, Hartree, and xc potentials. The latter is defined by: $v_{xc,\sigma\sigma'} = \delta E_{xc}[\mathbf{n}]/\delta n_{\sigma\sigma'}$.

Together with Eqn. (5), these equations form a nonlinear system of integro-differential equations which have to be solved by iteration (*self-consistent solution*). Due to the complexity of the Kohn–Sham equations (reflecting part of the complexity of nature), more than one stationary solution may exist. The further solutions can be related to physically relevant metastable magnetic states (for instance, low-spin/high-spin states, see Sect. 3.3, or different magnetic moment arrangements). This problem is investigated in some detail by Moruzzi and Marcus (1993).

### *1.2 Approximations*

The most widely used approximation for $E_{\mathrm{xc}}[\mathbf{n}]$ is the local spin density approximation (LSDA):

$$E_{\mathrm{xc}}[\mathbf{n}] \approx E_{\mathrm{xc}}^{\mathrm{LSDA}}[\mathbf{n}] = \int \mathrm{d}^3 \mathbf{r} \mathbf{n}(\mathbf{r}) \varepsilon_{\mathrm{xc}}^{\mathrm{hom}}\left(\mathbf{n}^{\uparrow}(\mathbf{r}),\ \mathbf{n}^{\downarrow}(\mathbf{r})\right) \quad (9)$$

Here, $\varepsilon_{\mathrm{xc}}^{\mathrm{hom}}$ means the exchange-correlation energy per electron of the spin-polarized homogeneous electron gas, a model system frequently used in electronic structure theory. The quantities $n^{\uparrow}$ and $n^{\downarrow}$ denote spin-up and spin-down densities. They are obtained by rotating the spin quantization axis at each point in space in the direction that yields a diagonal spin density matrix.

Another, more recent, approximation is called the generalized gradient approximation (GGA). At variance with the LSDA, it takes into account not only the local value of $\mathbf{n}$, but also its spatial derivatives.

If electrons in one of the open shells do not contribute to the chemical bonding, like 4f states in most rare-earth systems, they should be distinguished from the valence electrons in the theoretical treatment as well. Then, the so-called open-core approximation, or the self-interaction-corrected (SIC) LSDA, are modern approximations to be used (Richter 1998). The latter approximation is also relevant to finite systems like atoms and small molecules.

The energy $\varepsilon_{\mathrm{xc}}^{\mathrm{hom}}$ can be subdivided into $\varepsilon_{\mathrm{xc}}^{\mathrm{hom}} = \varepsilon_{\mathrm{x}}^{\mathrm{hom}} + \varepsilon_{\mathrm{c}}^{\mathrm{hom}}$. Here, $\varepsilon_{\mathrm{x}}^{\mathrm{hom}}$ describes the effect of exchange interaction: according to the Pauli exclusion

principle, electrons with the same spin quantum number should have a zero probability density of being at the same point in space. For this reason, the Coulomb energy between pairs of electrons with the same spin is lower than between pairs with different spin, and $\varepsilon_x^{hom} < 0$. The energy $\varepsilon_c^{hom}$ describes the effect of Coulomb correlation: electrons with arbitrary spin do not move in a stochastic way either, but tend to avoid each other due to their mutual Coulomb repulsion. This correlated motion yields a smaller total energy than estimated by a mean field treatment, and $\varepsilon_c^{hom} < 0$ holds as well.

### *1.3 Hund's Rules*

In atoms, exchange interaction is the reason for incompletely filled shells to maximize their spin polarization (SP) in the ground state. This behavior is known as Hund's First Rule (see *Magnetism in Solids: General Introduction*). It is driven by an energy gain $E_{SP} \sim S(S-1/2)$ in comparison to an unpolarized shell (Melsen *et al*. 1994), where the total spin $S$ is zero. If LSDA is applied to an atom, then $E_{SP} \approx \Delta E_{xc} = E_{xc}^{LSDA}(S) - E_{xc}^{LSDA}(0) \approx -IS^2$, yielding a good approximation for the relation above in the case of large total spins. This fact indicates that LSDA is particularly suited for extended systems which are closer to the idealized homogeneous electron gas than atoms are. The prefactor $I$ is called the Stoner parameter.

While free atoms in their ground state always carry a maximum spin moment, this is not the case in condensed matter. The reason for this difference is that band splitting lifts the degeneracy of the atomic states. As a consequence, energy is gained when the spin polarization is reduced, since then states at the majority spin Fermi surface with a higher Fermi momentum are emptied in favor of states at the minority spin Fermi surface with a lower Fermi momentum. The energy gain $\Delta T_s$ is the bigger the broader the band is, and vanishes in the atomic limit.

This consideration is the essence of Stoner theory (see *Itinerant Electron Systems: Magnetism (Ferromagnetism)*), which evaluates the counterbalance of $\Delta E_{xc}$ and $\Delta T_s$ to give a criterion for the onset of long-range spin order when starting from a spin-compensated state. The condition for the instability of the Pauli paramagnetic state is that:

$$IN(E_F) > 1 \tag{10}$$

where $N(E_F)$ denotes the density of states at the Fermi energy for one spin direction. Detailed discussion of the first-principles investigation of the magnetic ordering is given in Sect. 2.

Orbital magnetism also plays a big role in solids, e.g., for the phenomenon of magnetocrystalline anisotropy. It arises if the other two of Hund's rules are considered. Hund's Second Rule states that of all atomic terms with maximum spin, the term with the largest total angular momentum $L$ is the lowest in energy. The related energy gain is called orbital polarization (OP) energy, $E_{OP}$, which vanishes for s- and p-shells. Coulomb correlation is the reason behind OP. Though the LSDA accounts for a part of Coulomb correlation contributions, OP cannot be obtained in a local approximation, since any definition of an angular momentum density is ambiguous, due to the gauge freedom of this quantity. Reasonable heuristic approximations, called OP corrections, (Eriksson *et al*. 1989) use the local gauge where the angular momentum density vanishes in the interstitial regions. The angular momenta of the individual atomic shells are assumed to give contributions to the xc energy of the form $E_{OP} \approx E_{xc}(L) - E_{xc}(0) = \text{const.} \cdot L^2 < 0$, resembling the form of the SP term.

Finally, Hund's Third Rule determines the coupling between spin and orbital degrees of freedom to be antiparallel or parallel in the ground state of less or more than half-filled atomic shells, respectively. This behavior is a relativistic effect: the fast-moving electrons experience a magnetic field generated by the relative motion of the nuclear charges with respect to the rest system of the electrons. This field interacts with the individual electron spins and yields an additional contribution to the kinetic energy of the form: $E_{SO} = \sum_i \xi_i \langle \sigma_i \mathbf{l}_i \rangle_i$, where $\xi_i$ are radial integrals called spin-orbit coupling (SOC) constants, and $\mathbf{l}_i$ are single-particle angular momentum operators. The important role of SOC in solid state magnetism is discussed in more detail in Sects. 2 and 3.

Figure 1 shows the range of energies related to Hund's rules couplings in those atomic shells that are most important in solid-state magnetism: transition metal 3d, rare-earth 4f, and actinide 5f shells. The spin polarization energy, $E_{SP}$, is maximum for half-filled shells, while the orbital polarization energy, $E_{OP}$, and the spin–orbit coupling energy, $E_{SO}$, are large for shell fillings close to 1/4 and 3/4. In metals and compounds, spin and orbital polarization energy can be much smaller, or even zero, since losses of $T_s$ and $E_H$ due to polarization compensate at least part of the polarization gains: for instance, $E_{SP} \approx 0.4\,\text{eV}$ in iron metal. In general, the atomic values given in Fig. 1 put an upper boundary on the energy scales observed in solids.

### *1.4 Single Particle Excitations*

The Kohn–Sham orbitals $\phi_i$, with related single-particle energies $\varepsilon_i$, have been introduced above as auxiliary quantities needed to compute the spin density matrix. In a hypothetical system without electron–electron interaction, these Kohn–Sham states would coincide with the quasi-particle excitations of the system, which can be probed by optical, x-ray or electron spectroscopies (Sections 3.4 and 3.5). To

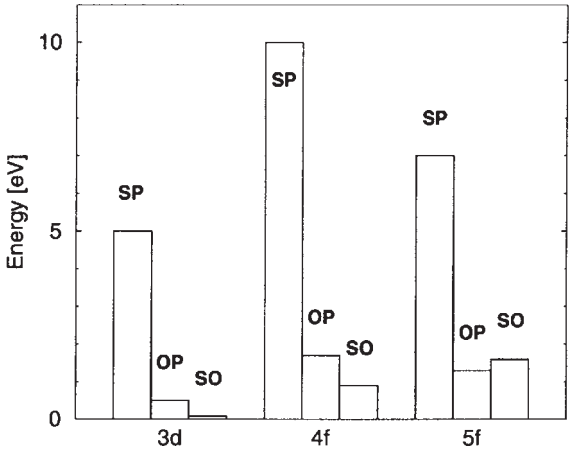

***Figure 1***
Range of energies related to Hund's rules in atoms: transition metal 3*d* shells, rare-earth 4*f* shells, and actinide 5*f* shells. The labels **SP**, OP, and **SO** denote the maximum values, within the related shell, of the energies $E_{SP}$, $E_{OP}$, and $E_{SO}$ (Hund's First, Second, and Third Rule coupling energies, respectively).

evaluate single-electron or single-hole excitations $\psi_i$ close to the Fermi level of a realistic system, the Dyson equation:

$$\left[-\frac{\Delta}{2}+\int \mathrm{d}^3r'\frac{n(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|}\right]\psi_i(\sigma,\ \mathbf{r}) + \sum_{\sigma'}\left[v_{\sigma\sigma'}+\int \mathrm{d}^3r' M_{\sigma\sigma'}(\mathbf{r},\ \mathbf{r}';\ E_i)\right]\psi_i(\sigma',\ \mathbf{r}') = E_i\psi_i(\sigma,\ \mathbf{r}) \qquad (11)$$

has to be solved. However, full knowledge of the self-energy operator kernel $M$ is even further away than full knowledge of $v_{xc}$; both quantities must rather be approximated on the basis of physical intuition. As a matter of fact, the replacement of $M_{\sigma\sigma'}$ by $\delta(\mathbf{r}-\mathbf{r}')v_{xc,\sigma\sigma'}(\mathbf{n})$, i.e., the LSDA, turns out to work fairly well for many systems (*weakly correlated systems*). In particular, the spectra related to s and p valence states of simple and transition metals, as well as rare-earth 5d and actinide 6d states, are well described.

These states form broad bands; the quasi-particle is extended over many atoms due to the large hopping rate, and thus correlation effects are small. If the bands become narrower, the hopping rate is lower, and hence a stronger intra-atomic Coulomb repulsion/attraction is felt by additional electrons/holes. Strong on-site correlations result in a jump of $M$, as a function of energy, at the Fermi level $E_F$ by an amount $U_{eff}$. This quantity is related to the on-site Coulomb matrix element $U$, but is strongly screened in metals. A simple approximation for this situation is called LSDA + $U$, where the energy dependence of $M$ is reduced to the jump at $E_F$ and otherwise the LSDA is used. A certain problem in this approach is that the screening depends much on chemical composition and on local structure, such that the value of $U_{eff}$ is not just an atomic property as $U$ is; it has to be estimated for each individual situation.

Finally, the relationship between $U_{eff}$ and the band width $W$ determines if the related states contribute to the chemical bonding or not. Accordingly, these states may exhibit itinerant or localized magnetic behavior. The rare-earth 4f shells where $U_{eff} \gg W$ show local moment behavior in most cases. On the other hand, elemental 3d metals ($U_{eff} < W$) are itinerant magnets. Actinide systems as well as transition metal compounds may show both types of behavior.

### *1.5 Model Parameters*

Model parameters like $U_{eff}$ may be obtained by means of *constrained* SDFT calculations (Dederichs *et al*. 1984). The general idea behind this method is to impose a symmetry restriction on the considered system that models, in a static way, a certain quasi-particle excitation. If the time-scales of the excitation and of the remaining degrees of freedom are different enough, the response of the latter, treated in a self-consistent calculation, provides a fairly realistic description of the screening process (Gunnarsson 1990).

Prominent examples are so-called frozen magnon calculations, where the atomic spin directions are fixed to form a periodic wave. Then, the ground-state energy is calculated for both the relaxed and the constrained system, and the energy difference is equated with the related excitation energy. Heisenberg model parameters describing the interatomic exchange coupling may be fitted to frozen magnon spectra or to other constrained magnetic configurations. They are used to describe thermodynamic properties of magnetic substances.

Finally, crystal field model parameters should be mentioned. They enter model theories for the description of magnetism related to localized 4f states (see *Localized 4f and 5f Moments: Magnetism*). The parameters may be obtained by applying shape restrictions on the atomic 4f charge density (Brooks *et al*. 1997, Richter 1998).

## *2. Magnetic Ordering*

One of the major tasks of the SDFT is the first-principles description of the ground-state magnetic order. There is a great variety of possible magnetic ground states, for example: Pauli paramagnetism in vanadium, ferromagnetism in nickel, antiferromagnetism in chromium, spiral magnetic structures in $\gamma$-iron and rare-earth metals, complex noncollinear magnetic

structures in compounds of the transition metals and actinides, and disordered magnetic state in amorphous iron. In principle, the machinery of the SDFT allows one to start with an arbitrary magnetization and, by calculating to self-consistency, to determine the ground state magnetization. However, in this general approach the study of even the simplest magnetic system becomes a complex computational problem. This kind of calculation is unavoidable for the systems with no regular magnetic structure, but otherwise available experimental and theoretical information about the magnetic ground state is usually used to simplify calculations.

According to its basic theorems (Sect. 1.1), the SDFT supplies physical information about the state of the system which realizes the minimum of the energy-functional. The applications of the theory can, however, be extended by the possibility of the constrained calculations, where the process of minimization takes place under certain restricting conditions (Dederichs *et al.* 1984) imposed upon, for example, the symmetry of the magnetic density and effective potential.

An important example of the constraint is the constraint of zero magnetisation: $\mathbf{m}(\mathbf{r}) = 0$ for any $\mathbf{r}$. Even for magnetic systems, it is possible to calculate the lowest energy nonmagnetic state and to study the physical reasons for the instability of this state with respect to the formation of the magnetic structure (see *Magnetism in Solids: General Introduction*).

### 2.1 Ferromagnetic Structure

The best-studied magnetic crystals are the elementary 3d metals with ferromagnetic magnetic ordering: α-iron (iron with the body-centered cubic lattice), cobalt, and nickel. The instability of the nonmagnetic state of a 3d metal with respect to the formation of a ferromagnetic structure can be studied with the help of the Stoner criterion, Eqn. (10). The density of states (DOS) of the nonmagnetic α-iron is shown in *Itinerant Electron Systems: Magnetism (Ferromagnetism)* (Fig. 3). The DOS has a peak at the position of the Fermi level that indicates the instability of the nonmagnetic state. Indeed, if the constraint of zero magnetization is removed by placing a small magnetic moment at each iron site, the calculation results in the ferromagnetic state with the atomic magnetic moment which is close to the observed value (e.g., $2.15\,\mu_B$ in the calculation of Moruzzi *et al.* (1978)). One obtains a similar situation in cobalt and nickel (Moruzzi *et al.* 1978).

### 2.2 Antiferromagnetic Structure

For chromium, the Stoner product is less than 1. Still the nonmagnetic state of chromium is unstable, but in this case with respect to the formation of an antiferromagnetic structure. The antiferromagnetic structure can be treated as a magnetic structure with the spatial variation of the atomic magnetic moments defined by the wave vector $\mathbf{q} = \frac{1}{2}\mathbf{K}$, where $\mathbf{K}$ is a vector of the reciprocal lattice. The Stoner criterion generalized to the case of the magnetic structures characterized by an arbitrary value of $\mathbf{q}$ takes the form:

$$I\chi(\mathbf{q}) > 1 \tag{12}$$

where $\chi(\mathbf{q})$ is the unenhanced magnetic susceptibility of the nonmagnetic state of the system in a nonuniform static magnetic field, with spatial variation defined by vector $\mathbf{q}$. For a ferromagnet, $\mathbf{q} = 0$ and the susceptibility is equal to the density of states at the Fermi level.

For a finite $\mathbf{q}$, the susceptibility is given by the formula:

$$\chi(\mathbf{q}) = \sum_{\mathbf{k}\nu\mu} \frac{f(\varepsilon_{\nu\mathbf{k}}) - f(\varepsilon_{\mu\mathbf{k}-\mathbf{q}})}{\varepsilon_{\mu\mathbf{k}-\mathbf{q}} - \varepsilon_{\nu\mathbf{k}} + \mathrm{i}\delta} \left| \langle \mathbf{k}\nu | \mathrm{e}^{\mathrm{i}\mathbf{q}r} | \mathbf{k} - \mathbf{q}\mu \rangle \right| \tag{13}$$

and cannot be expressed through the DOS. Here, ν and $\mu$ are band indices, $\delta$ is an infinitesimal, and $f(\varepsilon)$ is the Fermi–Dirac distribution function.

In Fig. 2, we compare the calculated $\mathbf{q}$-dependences of the susceptibility of α-iron and chromium. The two curves are essentially different. In the case of α-iron, the susceptibility is maximum for $\mathbf{q} = 0$ and decreases monotonically with increasing $\mathbf{q}$, clearly revealing the origin of the ferromagnetic instability. In the case of

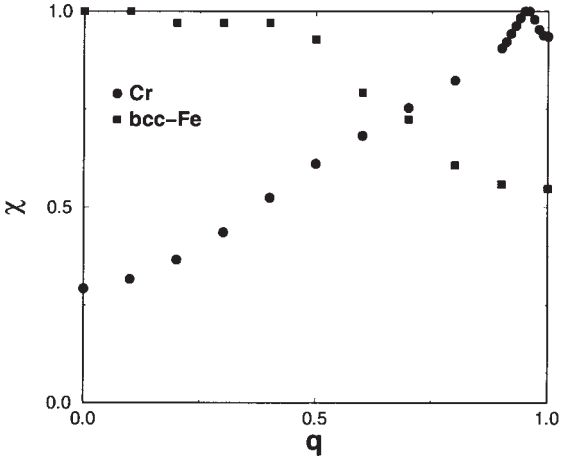

***Figure 2***
**q**-dependence of the unenhanced magnetic susceptibility of α-Fe (lattice parameter $a = 5.27$ atomic units) and Cr ($a = 5.45$ atomic units); $\mathbf{q}$ is given in units of $2\pi/a$. The susceptibilities are scaled to assume a unity value at the point of maximum. Calculation was carried out with the scheme of Sandratskii and Kübler (1992).

chromium, the behavior is the opposite: the susceptibility for $\mathbf{q} = 1$(in units of $\frac{1}{2}>\mathbf{K}$) is more than three times that for $\mathbf{q} = 0$. The difference between these two cases reflects the tendency for systems with half-filled d-bands to be antiferromagnetic, in contrast to the systems at the end of the 3d series, which order ferromagnetically (Heine and Samson 1983).

From Eqn. (13), it is seen that the largest contribution to the susceptibility is given by the pairs of states which are separated in reciprocal space by the vector $\mathbf{q}$ and are close in energy. Since the energy difference contains one occupied and one unoccupied state, these states lie close to the Fermi level. Indeed, the Fermi surface of chromium possesses two similar sheets shifted in the reciprocal space by the vector $\mathbf{q}$, which is close to $\frac{1}{2}\mathbf{K}$ (see Fawcett (1988) for details). This nesting of the sheets of the Fermi surface is important for the formation of the antiferromagnetic instability.

### 2.3 *Spiral Magnetic Structure*

The spatial variation of the directions of the atomic magnetic moments in the simplest magnetic structures—ferromagnetic and two-sublattice antiferromagnetic—can be described by the wave vectors equal, respectively, to 0 or $\frac{1}{2}\mathbf{K}$. Also, the magnetic structures described by an intermediate value of vector $\mathbf{q}$ were found experimentally.

The spiral magnetic structure can be defined by the formula:

$$\mathbf{m}_n = m(\cos(\mathbf{q}\cdot\mathbf{R}_n)\sin\theta,\ \sin(\mathbf{q}\cdot\mathbf{R}_n)\sin\theta,\ \cos\theta) \qquad (14)$$

where $\mathbf{m}_n$ is the magnetic moment of the $n$th atom and $(\mathbf{q}\cdot\mathbf{R}_n)$, $\theta$ are polar coordinates. For vector $\mathbf{q}$ incommensurate with the vectors of the reciprocal lattice, the magnetic unit cell representing a translationally invariant part of the magnetic crystal is infinite. The spiral structure possesses, however, a special symmetry which, for an arbitrary $\mathbf{q}$, allows reduction of the consideration to the unit cell of the *chemical* lattice.

The spiral structure, Eqn. (14), is invariant with respect to the translation of the crystal by an arbitrary lattice vector $\mathbf{R}_n$, accompanied by the rotation of all atomic moments by an angle $\mathbf{qR}_n$ about the z axis. Such operations, $\{(\mathbf{qR}_n)|\mathbf{R}_n\}$, are called generalized translations. The Kohn–Sham Hamiltonian of the magnetic moments of the spiral structure (Sandratskii 1998) commutes with the generalized translations $\{(\mathbf{qR}_n)|\mathbf{R}_n\}$. As a consequence of the generalized translational symmetry, a generalized Bloch theorem can be formulated:

$$\{(\mathbf{qR}_n)|\mathbf{R}_n\}\psi_{\mathbf{k}}(\mathbf{r}) = \exp(-i\mathbf{kR}_n)\psi_{\mathbf{k}}(\mathbf{r}) \qquad (15)$$

where the vectors $\mathbf{k}$ lie in the first Brillouin zone of the chemical lattice. The theorem, Eqn. (15), is sufficient for the reduction of the problem, for an arbitrary value of $\mathbf{q}$, to the consideration of the chemical unit cell of the crystal.

The formation of spiral structure leads to the hybridization of the states of the nonmagnetic crystal which are separated in the reciprocal space by vector $\mathbf{q}$. The importance of this hybridization is reflected in the formula for the susceptibility, Eqn. (13), and is closely related to the phenomenon of the Fermi surface nesting discussed in the case of chromium.

Figure 3 shows the calculated $\mathbf{q}$-dependence of the total energy for a number of transition metals (Sandratskii and Kübler (1992); see also the paper by Mryasov *et al.* (1991) for the first, first-principles calculation of $\gamma$-iron). In agreement with experiment, the ground state was found to be ferromagnetic for all metals, except for the case of $\gamma$-iron. In $\gamma$-iron, the minimum of the total energy occurs at a finite value of $\mathbf{q}$, i.e., the ground state is spiral.

Another example of the spiral structure is that in the heavy rare-earth metals (REM) (see *Localized 4f and 5f Moments: Magnetism*; *Magnetism in Solids: General Introduction*). The intra-atomic exchange interaction between the 4f states and the valence 5d and 6s states leads to the spin polarization of the valence states. In the crystal, the valence states of different atoms hybridize and form energy bands. The energy of the hybridized valence states depends on the directions of the 4f moments of different atoms.

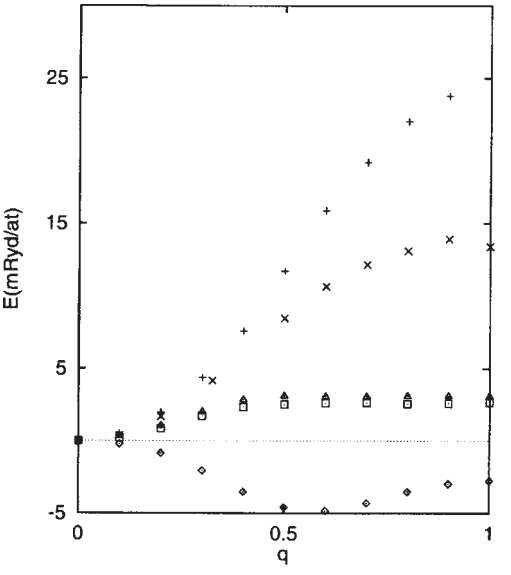

***Figure 3***
The total energy as a function of $\mathbf{q}$ for the (001) direction. $\diamond$ = $\gamma$-Fe; + = $\alpha$-Fe; $\square$ = fcc-Co; $\times$ = hcp-Co; = Ni. In all calculations $\theta = 90^\circ$. (Sandratskii and Kübler (1992)).

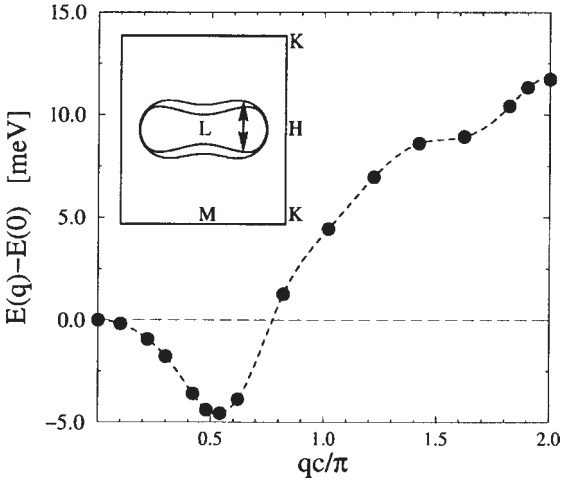

***Figure 4***
The $q$-dependence of the total energy of $T_m$. The inset shows the nesting property of the Fermi surface. (Nordström and Mavromaras (1999))

Early calculations of the **q**-dependence of the unenhanced susceptibilities (Jensen and Mackintosh 1991) gave the maximum at the **q** values close to the experimentally determined wave vectors of the spiral structures. In Fig. 4, a first-principles calculation by Nordström and Mavromaras (1999) of the total energy of thulium as a function of **q** is shown.

### *2.4 Role of the Spin–Orbit Coupling*

In the calculations of the magnetic structure discussed up to now, the SOC (see Sect. 1.3) was not taken into account. With the SOC being neglected, an arbitrary rotation of all atomic magnetic moments by the same angle does not change the energy. However, the dependence of the energy of the system on the direction of the magnetic moments with respect to the lattice, that is, the magnetic crystalline anisotropy, is a property of primary importance in numerous technical applications (see also Sect. 3).

In bcc iron, the energy of magnetic anisotropy is of the order of $10^{-4}$ mRy per atom, and is five orders of magnitude smaller than the interatomic exchange interaction. In the case when the SOC energy becomes comparable with the interatomic exchange interaction, it influences substantially not only the direction of the atomic moments with respect to the lattice, but also the relative directions of the moments. Indeed, experimental determination of the magnetic structure in heavy REM revealed a distortion of the spiral structure due to the influence of the magnetic anisotropy (Jensen and Mackintosh 1991).

The influence of the SOC on the formation of the magnetic structure increases further when one moves from the 4f systems (see *Localized 4f and 5f Moments: Magnetism*) to the 5f systems (see *5f Electron Systems: Magnetic Properties*). The most effort has been devoted to the magnetic structure of uranium compounds. The hybridization of the 5f states with the states of other atoms is essential for the physics of the uranium compounds. On the other hand, the 5f states experience strong spin–orbit coupling.

The importance of the SOC can be illustrated by the phenomenon of the symmetry-predetermined noncollinearity of the magnetic structure. To introduce this effect, let us consider a collinear magnetic structure, and let $\theta$ be a parameter which describes the noncollinear magnetic structures obtained with the deviation of the magnetic moments from the collinear directions. $\theta_0 = 0$ corresponds to the collinear structure. The following criterion of the instability of the magnetic structure can be formulated: the structure corresponding to $\theta = \theta_0$ can be stable only in the case that this state is distinguished by symmetry, compared to the states obtained with infinitesimal variation of parameter $\theta$ (Sandratskii (1998) and references therein). Indeed, only in this case can the minimum of the total energy be at $\theta = 0$.

The effect of the symmetry-predetermined noncollinearity is illustrated in Fig. 5 by the example of $U_3P_4$. The inset shows the experimentally determined magnetic structure of $U_3P_4$. An SDFT calculation starting with the collinear ferromagnetic

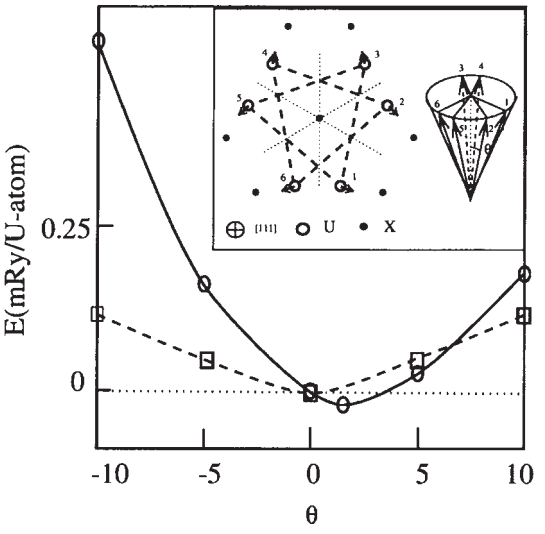

***Figure 5***
The total energy of $U_3P_4$ as a function of the deviation of the magnetic moments from the (111) axis. Solid/dashed line shows the result of the calculation with/without the spin–orbit coupling, respectively. The inset shows the projection of the crystal and magnetic structure to the (111) plane. The magnetic moments form a cone structure.

configuration results immediately in the noncollinear magnetic structure similar to the structure found in the experiment. The deviation of the magnetic moments does not influence the symmetry of the magnetic structure. The minimum of the total energy is at an accidental point.

With the SOC being neglected, the curve of the total energy as a function of the deviation angle $\theta$ is symmetrical with respect to the change of the sign of $\theta$ (Fig. 5). Therefore, the collinear configuration corresponding to $\theta = 0$ is distinguished by symmetry and is stable. The reason for different symmetry properties of the total energy in relativistic and nonrelativistic problems is the different types of symmetry groups which describe the relativistic and nonrelativistic problems.

The phenomenon of the symmetry-predetermined noncollinearity observed in $U_3P_4$ has the same physical nature as the effect of weak ferromagnetism in $Fe_2O_3$, where the iron moments deviate from their antiparallel directions and result in a finite ferromagnetic component.

## 3. Calculated Magnetic Properties

Magnetic ordering in itinerant magnets is driven by the spin density, but the orbital contribution to the magnetic moment,

$$\mathbf{m}_{or} = \mu_B \sum_{i,\mathbf{k}}^{occ} \langle \phi_{i,\mathbf{k}} | \mathbf{L} | \phi_{i,\mathbf{k}} \rangle \qquad (16)$$

where $\phi_{i,\mathbf{k}}$ is an energy band eigenfunction for the $i$th branch, with wave vector $\mathbf{k}$ and angular momentum $\mathbf{L}$, is responsible for such technologically important effects as intrinsic magnetocrystalline anisotropy energy (MAE), magnetostriction, the magneto-optical Kerr effect, and magnetic circular dichroism in itinerant magnets. In iron, cobalt, and nickel, the calculated spin (orbital) contributions to the magnetic moment are, respectively, $2.13\,\mu_B$ ($0.08\,\mu_B$), $1.52\,\mu_B$ ($0.14\,\mu_B$) and $0.57\,\mu_B$ ($0.05\,\mu_B$) and are parallel (Ebert *et al*. 1988, Eriksson *et al*. 1990). The orbital moment is carried almost entirely by the 3*d* electrons, whereas the spin contribution is the sum of local (*3d*) and diffuse (*sp*) parts aligned antiparallel. However, the calculated orbital moments are smaller than measured (Ebert *et al*. 1988, Eriksson *et al*. 1990).

Experimental information on ground-state spin and orbital magnetization densities may be obtained from elastic neutron scattering measurements (see *Magnetism in Solids: General Introduction*; *Magnetic Excitations in Solids*). The neutron magnetic form factor, $f(Q)$, where $Q$ is the momentum transfer ($= 4\pi \sin\theta/\lambda$) is a direct measure of the Fourier transform of the magnetization. In the dipole approximation the form factor is given by:

$$f(Q) = \langle j_0 \rangle + \mu_L \langle j_2 \rangle / \mu \qquad (17)$$

where $\langle j_n \rangle = 4\pi \int r^2 n_s(r) j_n(r)$ is a Bessel transform of the calculated spin density, $\mu$ is the total and $\mu_L$ the orbital magnetic moment. The orbital contribution to the magnetic moment is small for transition metal systems, but can be large in rare earths and actinides (Brooks and Kelly 1983). Analysis of the form factors of actinides has been used to show that they have large orbital moments. In systems that do not order, or above the ordering temperature in systems that do order, the application of a magnetic field allows the induced form factor to be measured. Calculations have been used to show that the relationship between spin and orbital moments can be quite different when the form factor is induced, compared with the ordered state due to the breaking of Hund's rules by the applied field (Hjelm *et al*. 1993).

### 3.1 Hyperfine Interactions

The interactions between the nuclear and electronic charge and current densities produce hyperfine structure, for which a comparison of calculated and measured contributions is therefore an excellent test of density functional theory. Since the length scale of the nucleus ($r_N \approx 10^{-4} a_0$) is small compared with the atomic length scale of one Bohr radius, ($a_0 = \hbar^2/me^2$), the Coulomb potential, $-Ze^2/r$, is large in the region of the nucleus, and the concomitant large electronic kinetic energy makes relativistic effects important. Therefore either the Dirac equation, or some approximation to the Dirac equation that takes proper account of the boundary condition for the relativistic case at small values of radius, should be used in any theory of hyperfine interactions. The interaction between nuclear and electronic charges and currents is usually expressed in terms of a multipole expansion:

$$H_{\text{int}} = \sum_{k=0}^{k=2} \mathbf{T}_n^k \cdot \mathbf{T}_e^k \qquad (18)$$

since the contribution of multipoles with rank greater than 2 is negligible.

The monopole ($k = 0$) interaction gives rise to the isomer (or chemical) shift, which is proportional to the contact charge density at the nuclear radius and is used to study trends in charge transfer, particularly in Mössbauer experiments (see *Mössbauer Spectroscopy*). For example, the isomer shift at the iron site in dilute FeX alloys is essentially periodic across the periodic table, being a minimum (more contact charge) if X is at the start of a row and maximum (less contact charge) if X is at the end (Akai *et al*. 1986). The self-consistently calculated isomer shifts are in good agreement with measurements, and broadly follow the argument that charge flows from atoms at the beginning of a period to those at the right which are more electronegative. However, detailed calculations show that there is a strong angular

momentum dependence in the charge transfer and that, particularly in the case of transition metals, *sd*-hybridization is important.

The dipole ($k=1$) interaction may be separated into Fermi contact, dipolar, and orbital contributions. The Fermi contact interaction is between the electronic spin density at the nucleus and the nuclear dipole moment which experiences a magnetic field:

$$H_{\mathrm{hf}}^{1} = \frac{8\pi}{3}\mu_{\mathrm{B}} m_{\mathrm{av}} \tag{19}$$

where $m_{\mathrm{av}} = \int \delta_T(\mathbf{r})\mu_{\mathrm{s}}(\mathbf{r})\mathrm{d}^3 r$ is the average spin magnetic moment density over a sphere with the diameter of the Compton radius, $r_T = Ze^2/mc^2$.

$$\delta_T(\mathbf{r}) = (1/4\pi r^2)(\partial S(\mathbf{r})/\partial r),$$

where $S^{-1}(\mathbf{r}) = 1 + ((\varepsilon - v_{\mathrm{eff}}(\mathbf{r}))/2mc^2)$ is the relativistic mass enhancement.

The dipolar interaction is between the electronic vector spin density and the nuclear moment which experiences a field:

$$H_{\mathrm{hf}}^{2} = \mu_{\mathrm{B}} \int \left[ \Sigma(\mathbf{r}) - 3\frac{\mathbf{r}\cdot\Sigma(\mathbf{r})}{r^2}\mathbf{r} \right] \frac{\mathrm{d}^3 r}{r^3} \tag{20}$$

Finally, the orbital interaction is between the electronic current distribution and the nuclear moment which experiences a field:

$$H_{\mathrm{hf}}^{3} = -2\mu_{\mathrm{B}} L_{\mathrm{av}} \tag{21}$$

where $L_{\mathrm{av}} = \int L(\mathbf{r})S(\mathbf{r})/r^3$ is the weighted orbital moment density measured in units of $\hbar$.

The Fermi contact interaction, which is proportional to the spin density at the nucleus, is normally far larger than the dipolar and orbital contributions, especially in crystals with cubic symmetry and small spin–orbit interaction, where the dipolar term is negligible. The spin density at the nucleus, which arises entirely from *s*-states, is composed of the contribution from the unpaired spins of the valence electrons and a contribution from core polarization. Detailed calculations have shown that the contact interaction is dominated by core polarization. For example, in iron the calculated hyperfine field due to core polarization is 235 kG, compared with a valence contribution of 42 kG (Ebert 1988, Ebert *et al.* 1988).

The most thoroughly studied itinerant electron metals are the transition metals iron, cobalt, and nickel (Ebert *et al.* 1988). The *s*-electrons—both core and valence—are polarized by exchange interactions with the *d*-electrons. Since the core spin density is dominant, comparison with measured hyperfine fields is a severe test of the calculated exchange interactions between transition metal *d*-states and core *s*-states. In practice, the calculated and measured hyperfine fields for cobalt are 194 kG and 215 kG, respectively, where in addition to the Fermi contact contribution, the contribution from the orbital currents (moment) of the *d*-electrons of −50 kG is included. Although this result is quite reasonable, the calculated hyperfine fields for iron and nickel are poor.

In iron, the measured and calculated hyperfine fields are 339 kG and 253 kG, respectively; and in nickel the corresponding quantities are 75 kG and 39 kG. Since the calculated dipolar contribution from the orbital currents is relatively small in iron (−24 kG), the errors are due to the calculated core polarization. In nickel, the orbital current contribution is relatively larger (−37 kG), but is of the wrong sign to rectify the errors. Since the calculated magnetic moments of the transition metals compare well with experiment, it is difficult to escape the conclusion that errors in LSDA are connected with its description of core polarization (Akai *et al.* 1990).

The hyperfine fields at impurity sites in transition metal alloys have also been studied in some detail. When the impurity atom is non-magnetic, the measured hyperfine field is due to the induced *s*-spin density at the impurity nucleus, which arises from hybridization with the magnetic transition metal *d*-electrons and, since the core of the impurity atom is unpolarized (there is no impurity *d*-moment to do this), core polarization plays no role. The induced spin density at the impurity nucleus depends both upon the local occupation of the spin-up and spin-down states and the magnitude of the spin-up and spin-down wave functions. When transition metal *d*-states hybridize with conduction electrons from other atoms, the sign of the wave function at the impurity site can change as the energy in the hybridized bands changes, passing from bonding to anti-bonding orbitals. The effect upon the spin density at the impurity nucleus is a quite remarkable systematic trend throughout the periods in the periodic table, illustrated by the measured and calculated hyperfine fields for impurities in nickel (Akai *et al.* 1990) (see Fig. 6).

The hyperfine fields are negative at the beginning of each period and change sign, reaching a maximum near the end of each period before changing sign again at the beginning of the next period. When the impurities are themselves transition metals the mechanism controlling the hyperfine fields is different, since *d–d* hybridization is important and an impurity *d*-moment is induced which, particularly in the case of 3*d* impurities, can be quite large. At the beginning of a period, the less tightly bound impurity *d*-bands lie higher in energy than the nickel 3*d*-bands, and an impurity *d*-moment is induced anti-parallel to the nickel 3*d*-moment. However, for impurities towards the end of the transition metal series, the induced moment can flip to ferromagnetic alignment. On the whole, although there are some discrepancies, both trends and magnitude of the hyperfine fields at the impurity sites are obtained from LSDA calculations.

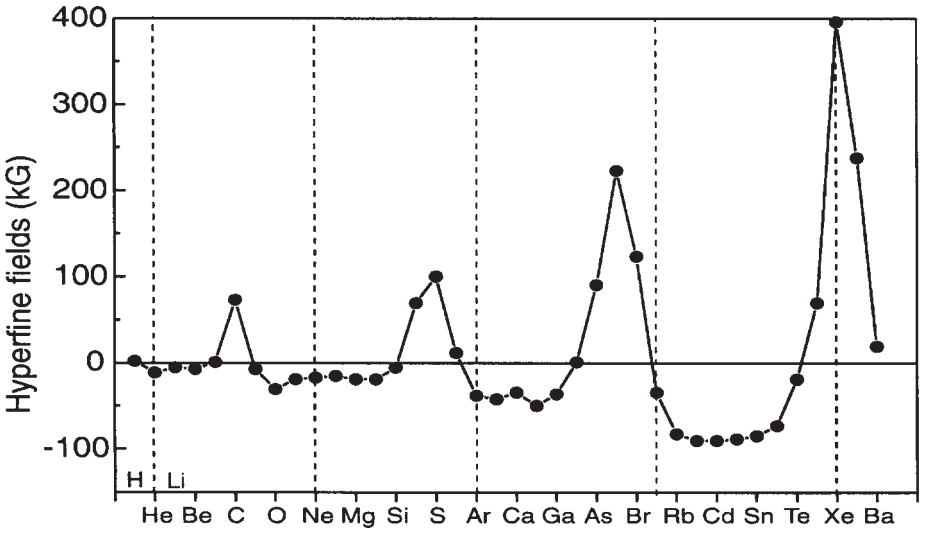

***Figure 6***
The calculated hyperfine fields for impurities from the short periods in Ni (Akai *et al.* 1990).

The next term in the multipole interaction ($k = 2$) is the interaction between the nuclear electric quadrupole moment and the electric field gradient produced by the electron density:

$$E_{zz} = \sqrt{\frac{5}{\pi}} \lim_{r \to 0} \frac{v_{20}(r)}{r^2} \tag{22}$$

where $v_{20}$ is the quadrupolar electronic charge density. The accurate calculation of electric field gradients requires accurate treatment of non-spherical components of the charge density. In particular the quadrupolar charge density, when weighted by $1/r^3$, is directly related to the field gradient. The field gradient vanishes for cubic crystals, but it has been found for hcp transition metals that, due to the radial weighting, the *p*-electron contribution to the field gradient becomes dominant, since the first radial node of the *p*-states lies inside that of the *d*-states (Blaha *et al.* 1988).

### *3.2 Magnetocrystalline Anisotropy*

The magnetic anisotropy energy (MAE) is normally calculated as the difference in total energy for moment alignment along an easy and a hard axis. For iron, cobalt, and nickel, the magnetic anisotropy energy is of the order of $\mu$eV, which demands extremely accurate numerical treatment. The magnitude of the MAE from self-consistent calculations is too small for iron and cobalt, and has the wrong sign for nickel (Daalderop *et al.* 1990, Jansen 1990). Inclusion of the orbital polarization correction term improves the results, except for nickel.

The magnetic anisotropy constants are the coefficients in the expansion of the energy in terms of spherical harmonics which depend upon the moment direction. In cubic crystals, the lower order anisotropy constants vanish by symmetry; consequently the anisotropy energy is small. Of the non-cubic symmetries where the magnetic anisotropy is larger, the most important is tetragonal, since this is the symmetry of many thin films and multilayers. It is possible to take the crystal symmetry from fcc to bcc via tetragonal along a Bains path, simply by changing the $c/a$ ratio. Self-consistent total energy calculations have shown that the anisotropy energy should increase by orders of magnitude as the structure is taken to tetragonal and, since the final structure is also cubic, it has at least one maximum along the path, which for cobalt is about 600 $\mu$eV. If the exchange splitting were larger than the bandwidth (which is seldom true) and the spin–orbit interaction, a small perturbation in the magnetic anisotropy would be proportional to the anisotropy of the orbital moment (Bruno 1989). No such approximations are made in total energy calculations, but experience has shown that the easy (hard) direction is that in which the orbital moment is largest (smallest).

### *3.3 Magnetovolume, Invar Effect, and Magnetostriction*

Magnetostriction is the lattice deformation which accompanies magnetization (see *Magnetoelastic*

*Phenomena*). Since magnetostriction is due to the coupling of magnetic and elastic forces, it is of immense technological importance for the conversion of energy between magnetic and elastic degrees of freedom. The magnetovolume effect is the isotropic (or volume) component of magnetostriction. Itinerant magnetic materials may have quite large magnetovolume effects, since the electrons responsible for the magnetism are also responsible for chemical bonding. For example, the Friedel (1969) model of transition metal bonding attributes to the cohesive energy a term proportional to $f(1-f)$, where $f$ is the fractional occupation of the $d$-band, which is responsible for the parabolic trend in cohesive energy across a transition metal series.

More detailed modelling has shown that the change of this term with volume, contributes an electronic pressure:

$$P = (2l+1)^2 W_d[g^2 - f(1-f)]/3V \qquad (23)$$

where $W_d$ is the width of the $d$-band, $l=2$ for $d$-states, $f_\pm$ are the fractional occupations of the spin-up and spin-down bands and $g$ is the fractional magnetic moment, $(f_+ - f_-)/2$. The magneto-volume effect is due to the repulsive contribution proportional to $g^2$, which is a maximum when $f=m=1/2$ and the spin-up band is filled.

The Invar effect (see *Invar Materials: Phenomena*) arises when high and low volume magnetic states have about the same energy, such that the latter may be populated by thermal excitations, thus compensating thermal expansion due to lattice vibrations. The low volume magnetic state was proposed by Weiss (1963) to be anti-ferromagnetic, but both the paramagnetic state and the ferromagnetic state can be simultaneously stable if the Fermi level of the paramagnetic state density lies in a dip between two peaks. Williams *et al*. (1982) used SDFT to show that in iron–nickel alloys, the total energy of the low volume paramagnetic state is a function of composition, and lies about 10 meV above the total energy of the high volume ferromagnetic state for $Fe_3Ni$. Subsequently, the low volume state has been shown to be disordered when non-collinear spin ordering is included in the simulation (van Schilfgaarde *et al*. 1999).

The anisotropic part of the magnetostrictive energy may be obtained from self-consistent calculations if the anisotropy energy is calculated as a function of strain. Calculations for transition metals (James 1999) reveal proportionality between the magnitude of the magnetostriction energy and the MAE, and between the MAE and the anisotropy of the orbital magnetic moment. Although the absolute values of the calculated magnetostrictive energy for Fe/Co and Co/Ni alloys tend to be too large by up to an order of magnitude, the correct trend as a function of cobalt concentration is reproduced.

### 3.4 X-ray Magnetic Circular Dichroism

First-principles calculations of optical properties are usually made in two stages. Firstly, the self-consistent ground state charge and spin densities are calculated; then the optical conductivity tensor is calculated for the Kohn–Sham energies and wave functions corresponding to the ground-state density (Sect. 1.4). The conductivity tensor, $\sigma(\omega)$, derived from linear response theory, is:

$$\sigma(\omega) = \frac{-ie^2}{3m^2\hbar v}\sum_{\mathbf{k}}\sum_{nn'}\frac{f(\varepsilon_{n\mathbf{k}}) - f(\varepsilon_{n'\mathbf{k}})}{\omega_{nn'}(\mathbf{k})}\frac{|\Pi_{n'n}(\mathbf{k})|^2}{\omega - \omega_{nn'}(\mathbf{k}) + i/\tau} \qquad (24)$$

where $v$ is the volume of the unit cell, $f(\varepsilon_{n\mathbf{k}})$ is the Fermi function, $\hbar\omega_{nn'}(\mathbf{k}) = \varepsilon_{n\mathbf{k}} - \varepsilon_{n'\mathbf{k}}$, the energy difference of the Kohn–Sham energies $\varepsilon_{n\mathbf{k}}$, $\tau$ is the average lifetime of excited electron states, and $\Pi_{n'n}(\mathbf{k})$ are the matrix elements of the momentum operator.

When circularly polarized x-rays are absorbed by a magnetic material, the absorption depends upon whether the light is left-or right-polarized. The absorption is determined by the imaginary part of conductivity tensor, where the initial states are the core states of the x-ray edge. The source of X-ray magnetic circular dichroism (XMCD) is that the off-diagonal elements of the conductivity tensor are non-zero, which is due to spin–orbit interaction in either initial or final states. Calculations for transition metals (Ebert 1996) have shown that pronounced XMCD can occur when there is a large spin–orbit splitting of the core states and a small moment in the conduction bands, as for the $L_{2,3}$ edges of 5$d$ impurities in magnetic 3$d$ transition metal hosts. Alternatively, in pure transition metals the 2$p$-core state spin–orbit splitting is relatively small, but the conduction band moment is large. In both cases agreement with measurements is good (for experimental aspect of XMCD, see *Demagnetization: Nuclear and Adiabatic*).

### 3.5 Magneto-optical Kerr Effect

When linearly polarized light is reflected from a magnetized sample, the reflected light becomes elliptically polarized, with the plane of polarization rotated (see *Faraday and Kerr Rotation: Phenomenological Theory*). The complex Kerr rotation angle, $\phi = \theta + i\varepsilon$ where $\theta$ is the rotation and $\varepsilon$ the ellipticity, is given by:

$$\phi \approx \frac{\sigma_{xy}}{\sigma_{xx}\sqrt{1 + (4\pi i/\omega)\sigma_{xx}}} \qquad (25)$$

The sign of the Kerr angle changes when the magnetization is reversed; therefore, information stored in the form of a reversed magnetization may be read by measuring the Kerr rotation. Since high data density is desirable, and blue light is easier to focus than

red, a large Kerr rotation in the 2–3 eV region is considered optimal. Since the Kerr rotation is proportional to the off-diagonal elements of the conductivity tensor, which increase with spin–orbit interaction, materials with large magnetic anisotropy are also likely to have a large Kerr rotation for some energy of incident light (Oppeneer 1998). However, the fact that the Kerr rotation should be large in the 3 eV region has made Fe/Pt and Co/Pt intermetallics of particular interest.

The magnitude of the Kerr rotation for transition metal compounds rarely exceeds 0.5°, but for Heusler alloys, particularly the half-metallic ferromagnets XMnSb (X = Ni, Pd, Pt), it can have higher values (see *Half-metallic Magnetism*). Calculations, which are in good agreement with experiment, for PtMnSb yield a Kerr rotation of over 1° at 1.6 eV (Ebert 1996). The Kerr rotation for actinide compounds, where the 5*f* state spin–orbit interaction is large, can reach several degrees (Oppeneer *et al*. 1998). Magnetic multilayers possessing perpendicular anisotropy are excellent candidates for recording materials since, apart from the fact that they yield a polar Kerr effect, the magnetic layers may be tailored. Here theoretical predictions are most useful, and extensive investigations of, for example, multilayers of the type *n*A/*m*B (A = Fe, Co and B = Cu, Ag, Au, Pd, and Pt) have been made (see *Magneto-optics: Inter- and Intraband Transitions, Microscopic Models of*).

# Dilute Magnetic Semiconductors

This family of materials encompasses standard semiconductors, in which a sizable portion of atoms is substituted by elements which produce localized magnetic moments in the semiconductor matrix. Usually, magnetic moments originate from 3*d* or 4*f* open shells of transition metals (TMs) or rare-earth metals (lanthanides), respectively, so that typical examples of diluted magnetic semiconductors (DMS) are $Cd_{1-x}Co_xSe$, $Ga_{1-x}Mn_xAs$, $Pb_{1-x}Eu_xTe$ and, in a sense, Si:Er. A strong spin-dependent coupling between the band and localized states accounts for outstanding properties of DMS. This coupling gives rise to spin-disorder scattering, giant spin-splitting of the electronic states, and strong indirect exchange interactions between the magnetic moments, the latter leading to collective spin-glass, antiferromagnetic or ferromagnetic spin ordering.

Owing to the possibility of controlling and probing magnetic properties by the electronic subsystem or vice versa, DMS have successfully been employed to address a number of important questions concerning the nature of various spin effects in various environments and at various length and time scales. At the same time, DMS exhibit a strong sensitivity to the magnetic field and temperature as well as constituting important media for generation of spin currents and for manipulation of localized or itinerant spins by, e.g., strain, light, and electrostatic or ferromagnetic gates. These properties, complementary to both nonmagnetic semiconductors and magnetic metals, allow applications of DMS as functional materials in spintronics devices.

## 1. Historical Background and Survey of Growth Methods

Extensive studies of DMS started in the end of the 1970s, when appropriately purified manganese was employed to grow bulk II–VI Mn-based alloys by various modifications of the Bridgman method. Compared to magnetic semiconductors, such as europium chalcogenides (e.g., EuS) and chromium spinels (e.g., $CdCr_2Se_4$) which were investigated earlier, DMS exhibited smaller defect concentrations and were easier to dope by shallow impurities. Accordingly, it was possible to examine their properties by powerful magneto-optical and magnetotransport techniques. Since, in contrast to magnetic semiconductors, neither narrow magnetic bands nor long-range magnetic ordering affected low-energy excitations, DMS were named *semimagnetic semiconductors*. More recently, studies of DMS have been extended towards materials containing magnetic elements other than manganese as well as to IV–VI, III–VI, and III–V compounds. As a consequence, a variety of novel phenomena have been discovered, including effects associated with narrow-bands and magnetic phase transformations, making the borderline between properties of DMS and magnetic semiconductors more and more elusive.

Rapid progress of DMS research in the 1990s stemmed, to a large extent, from the development of methods of crystal growth far from thermal equilibrium, primarily by molecular beam epitaxy (MBE), but also by laser ablation. These methods have made it possible to obtain DMS with the content of the magnetic constituent beyond thermal equilibrium solubility limits. Similarly, the doping during the MBE process allows the electrical activity of shallow impurities to be increased substantially. In the case of III–V compounds, in which divalent magnetic atoms supply both spins and holes, the use of the low-temperature MBE (LT MBE) provides thin films of, for example, $Ga_{1-x}Mn_xAs$ with $x$ up to 0.07 and the hole concentration in excess of $1 \times 10^{20}\,cm^{-3}$, in which ferromagnetic ordering is observed above 100 K. Remarkably, MBE and processes of nanostructure fabrication make it possible to add magnetism to the physics of semiconductor quantum structures.

## 2. Magnetic Impurities in Semiconductors

A good starting point for the description of DMS is the Vonsovskii model, according to which the electron states can be divided into two categories: (i) localized magnetic *d* or *f* shells and (ii) extended band states built up of *s*, *p*, and sometimes *d* atomic orbitals. The former give rise to the presence of local magnetic moments and intracenter optical transitions. The latter form bands, which are alike as in the case of nonmagnetic semiconductor alloys. Indeed,

the lattice constant of DMS obeys the Vegard law, and the energy gap $E_g$ between the valence and the conduction band depends on $x$ in a manner qualitatively similar to nonmagnetic counterparts. According to the Anderson model, the character of magnetic impurities in solids results from a competition between (i) hybridization of local and extended states, which tends to delocalize magnetic electrons, and (ii) the on-site Coulomb interactions among electrons, which stabilize magnetic moments.

Figure 1 shows positions of local states derived from 3*d* shells of TM impurities in respect to the band energies of the host II–VI compounds. The levels labeled *donors* denote the ionization energy of the magnetic electrons ($TM^{2+} \rightarrow TM^{3+}$ or $d^n \rightarrow d^{n-1}$), whereas the *acceptors* correspond to their affinity energy ($TM^{2+} \rightarrow TM^{1+}$ or $d^n \rightarrow d^{n+1}$). The difference between the two is the on-*d*-shell Coulomb (Hubbard) repulsion energy $U$ in the semiconductor matrix. In addition, the potential introduced by either neutral or charged TM can bind a band carrier in a Zhang-Rice-type singlet or hydrogenic-like state, respectively. Such bound states are often experimentally important, particularly in III–V compounds, as they correspond to lower energies than the competing *d*-like states, such as presented in Fig. 1.

In the case of manganese, in which the *d* shell is half filled, the *d*-like donor state lies deep in the valence band, whereas the acceptor level resides high in the conduction band, so that $U \approx 7\,\text{eV}$ according to photoemission and inverse photoemission studies. Thus, manganese-based DMS can be classified as charge transfer insulators, $E_g < U$. The manganese ion remains in the 2+ charge state, which means that it does not supply any carriers in II–VI materials. However, it acts as a hydrogenic-like acceptor in the case of III–V arsenides. According to Hund's rule the

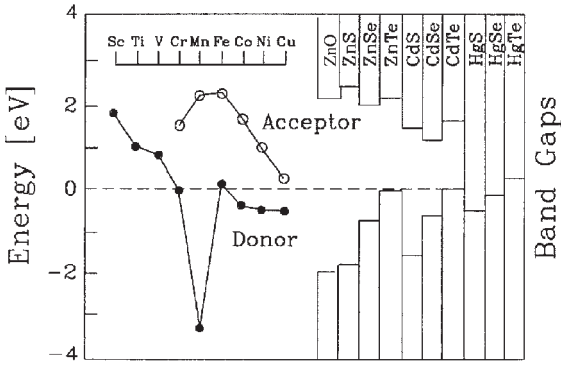

***Figure 1***
Approximate positions of donor (full points) and acceptor (open circles) levels derived from *d*-states of transition metal impurities in II–VI DMS (courtesy of Heiman and Dobrowolski, data after Zunger 1986 and Langer *et al*. 1988).

total spin $S = 5/2$ and the total orbital momentum $L = 0$ for the $d^5$ shell in the ground state. The lowest excited state $d^{*5}$ corresponds to $S = 3/2$ and its optical excitation energy is about 2 eV.

Thus, if there is no interaction between the spins, their magnetization is described by the Brillouin function. In the case of other transition metals, the impurity-induced levels may appear in the gap, and then compensate shallow impurities, or even act as resonant dopant, e.g., scandium in CdSe, iron in HgSe, and copper in HgTe. Transport studies of such systems have demonstrated that intersite Coulomb interactions between charged ions lead to the Efros–Shklovskii gap in the density of the impurity states, which makes resonant scattering inefficient in semiconductors. Furthermore, spin-orbit interaction and the Jahn–Teller effect control positions and splittings of the levels in the case of ions with $L \neq 0$. If the resulting ground state is a magnetically inactive singlet there is no permanent magnetic moment associated with the ion, as in the case of $Fe^{2+}$, whose magnetization is of the Van Vleck-type at low temperatures.

## *3. Exchange Interaction Between Band and Localized Spins*

The important aspect of DMS is a strong spin-dependent coupling of the effective mass carrier into the magnetic electrons. Neglecting nonscalar corrections that can appear for ions with $L \neq 0$, this interaction assumes the Kondo form,

$$H_K = -\sum_i \hat{I}(\vec{r} - \vec{R}_i)\, \vec{s}\, \vec{S}_i \qquad (1)$$

where $\hat{I}$ is the short-range exchange energy operator. When incorporated to the *kp* scheme, its effect is described by matrix elements $\langle u_i|\hat{I}|u_i\rangle$, where $u_i$ are the Kohn–Luttinger amplitudes of the corresponding band extreme. In the case of carriers at $\Gamma$ point of the Brillouin zone in zinc-blende DMS, the two relevant matrix elements $\alpha = \langle S|\hat{I}|S\rangle$ and $\beta = \langle X|\hat{I}|X\rangle$ involve *s*-type and *p*-types wave functions, respectively.

There are two mechanisms contributing to the Kondo coupling: (i) the exchange part of the Coulomb interaction between the effective mass and localized electrons and (ii) the spin-dependent hybridization between the band and local states. Since there is no hybridization between $\Gamma_6$ and *d*-derived ($e_g$ and $t_{2g}$) states in zinc-blende structure, the *s-d* coupling is determined by the direct exchange. The experimentally determined values are of the order of $\alpha N_o \approx 0.25\,\text{eV}$, where $N_o$ is the cation concentration, somewhat reduced from the value deduced from the energy difference between $S \pm \frac{1}{2}$ states of the free singly ionized manganese atom $3d^5 4s^1$, $\alpha N_o = 0.39\,\text{eV}$. In

contrast, there is a strong hybridization between $\Gamma_8$ and $t_{2g}$ states, which affects their relative position, and leads to a large magnitude of $|\beta N_o| \approx 1$ eV. If the relevant effective mass state $\varepsilon_k$ is above the $t_{2g}$ level (e.g., Mn-based DMS), $\beta < 0$ but otherwise $\beta$ can be positive (e.g., $Zn_{1-x}Cr_xSe$).

## 4. Electronic Properties

### 4.1 Effects of Giant Spin Splitting

In the virtual-crystal and molecular-field approximations, the effect of the Kondo coupling is described by $\langle u_i|\hat{I}|u_i\rangle \vec{M}(\vec{r})\ \vec{s}\ /g\mu_B$, where $\vec{M}(\vec{r})$is magnetization (averaged over microscopic regions) of the localized spins, and $g$ is their Landé factor. Neglecting thermodynamic fluctuations of magnetization (the mean-field approximation) $\vec{M}(\vec{r})$ can be replaced by $M_o(T, H)$, the temperature and magnetic field dependent macroscopic magnetization of the localized spins available experimentally. The resulting contribution to the spin-splitting of $s$-type electron states is given by

$$\hbar\omega_s = \frac{\alpha M_o(T,\ H)}{g\mu_B} \tag{2}$$

The effect is known as the giant Zeeman splitting, as in moderately high magnetic fields and low temperatures $\hbar\omega_s$ attains values comparable to the Fermi energy or to the binding energy of excitons and shallow impurities. For effective mass states, whose periodic part of the Bloch function contains spin components mixed up by a spin-orbit interaction, the exchange splitting $\hbar\omega_s$ does not depend only on the product of $M_o$ and the relevant exchange integral, say $\beta$, but usually also on the magnitude and direction of $\vec{k}$, confinement, and strain. The giant Zeeman splitting is clearly visible in magneto-optic phenomena as well as in the Shubnikov–de Haas effect, making an accurate determination of the exchange integrals possible, particularly in wide-gap materials, in which competing Landau and ordinary spin splittings are small.

The possibility of tailoring the magnitude of spin splitting in DMS structures offers a powerful tool to examine various phenomena. For instance, spin engineering has been explored to control by the magnetic field the confinement of carriers and photons, to map atom distributions at interfaces, as well as to identify the nature of optical transitions and excitonic states. Furthermore, a subtle influence of spin splitting on the quantum scattering amplitude of interacting electrons with opposite spins has been put into evidence in DMS in the weakly localized regime.

The redistribution of carriers between spin levels induced by spin splitting has been shown to drive an insulator-to-metal transition as well as to generate universal conductance fluctuations in DMS quantum wires. Since the spin splitting is greater than the cyclotron energy, there are no overlapping Landau levels in modulation-doped heterostructures of DMS in the quantum Hall regime. This has made it possible to test a scaling behavior of wave functions at the center of Landau levels. At the same time, it has been confirmed that in the presence of a strong spin-orbit coupling (e.g., in the case of $p$-type wave functions) the spin polarization can generate a large extraordinary (anomalous) Hall voltage. Finally, optically and electrically controlled spin-injection has been observed in all-semiconductor structures containing DMS.

### 4.2 Spin-disorder Scattering

Spatial fluctuations of magnetization, disregarded in the mean-field approximation, lead-to-spin disorder scattering. According to the fluctuation-dissipation theorem, the corresponding scattering rate in the paramagnetic phase is proportional to $T\chi(T)$, where $\chi$ is the magnetic susceptibility of the localized spins. Except in the vicinity of ferromagnetic phase transitions, a direct contribution of spin-disorder scattering to momentum relaxation turns out to be small. In contrast, this scattering mechanism controls the spin lifetime of effective mass carriers in DMS, as evidenced by studies of universal conductance fluctuations, line-width of spin-flip Raman scattering, and time-resolved magneto-optics. Furthermore, thermodynamic fluctuations contribute to the temperature dependence of the bandgap and band off-set. In the case when the total potential introduced by a magnetic ion is greater than the width of the carrier band, the virtual crystal and molecular field approximations break down, a case of the holes in $Cd_{1-x}Mn_xS$. Various nonperturbative schemes have been developed to describe nonlinear dependencies of the band gap on $x$ and of the spin splitting on $M$ observed in such situations.

### 4.3 Magnetic Polarons

Bound magnetic polaron (BMP), that is a bubble of spins ordered ferromagnetically by the exchange interaction with an effective mass carrier in a localized state, modifies optical, transport, and thermodynamic properties of DMS. BMP is formed inside the Bohr radius of the occupied impurity state but also around a trapped exciton, as the polaron formation time is typically shorter than the exciton lifetime. The BMP binding energy is proportional to the magnitude of local magnetization, which is built up by two effects: the molecular field of the localized carrier and thermodynamic fluctuations of magnetization. The latter enlarges width of optical lines, particularly in the case of quantum dots and wires, in which self-trapped magnetic polaron is stable even without pre-localizing potential. In contrast, a free magnetic polaron—a

delocalized carrier accompanied by a traveling cloud of polarized spins—is expected to exist only in magnetically ordered phases. This is because coherent tunneling of quasi-particles dressed by spin polarization is hampered, in disordered magnetic systems, by a small quantum overlap between magnetizations in neighboring space regions.

## 5. *Exchange Interactions Between Localized Spins*

As in most magnetic materials, classical dipole–dipole interactions between magnetic moments are weaker than exchange couplings in DMS. Direct *d–d* or *f–f* exchange interactions, known from properties of magnetic dimmers, are thought to be less important than indirect exchange channels. The latter involve a transfer of magnetic information via spin polarization of bands, which is produced by the exchange interaction or spin-dependent hybridization of magnetic impurity and band states. If magnetic orbitals are involved in the polarization process, the mechanism is known as *superexchange*, which is merely antiferromagnetic and dominates, except for *p*-type DMS. If fully occupied band states are polarized by the *sp–d* exchange interaction, the resulting indirect *d–d* coupling is known as the *Bloembergen–Rowland mechanism*. In the case of *Rudermann–Kittel–Kasuya–Yosida* (RKKY) interaction, the *d–d* coupling proceeds via spin polarization of partly filled bands, that is by free carriers.

Since in DMS carrier concentrations are usually much smaller than those of localized spins, the energetics of the latter can be treated in the continuous medium approximation, an approach referred to as the *Zener model*. Within this model the RKKY interaction is ferromagnetic, and particularly strong in *p*-type materials, because of large magnitudes of hole mass and exchange integral $\beta$. Finally, in the case of systems in which magnetic ions in different charge states coexist, hopping of an electron between magnetic orbitals of neighboring ions in differing charge states tends to order them ferromagnetically. This mechanism, dubbed the double exchange, can operate in, for example, *n*-type (Zn,Co)O.

In general, the bilinear part of the interaction Hamiltonian for a pair of spins *i* and *j* is described by a tensor *J*,

$$H_{ij} = -2S_i J_{ij} S_j \tag{4}$$

which in the case of the coupling between nearest neighbor cation sites in the unperturbed zinc-blende lattice contains four independent components. Thus, in addition to the scalar Heisenberg-type coupling, $H_{ij} = -2J_{ij}S_iS_j$, there are nonscalar terms (e.g., Dzialoshinskii–Moriya or pseudo-dipole). These terms are induced by the spin-orbit interaction within the magnetic ions or within nonmagnetic atoms mediating the spin–spin exchange. The nonscalar terms, while smaller than the scalar ones, control spin-coherence time and magnetic anisotropy. Typically, $J_{ij} \approx -1\,\text{meV}$ for nearest-neighbor pairs coupled by the superexchange, and the interaction strength decays fast with the pair distance.

Thus, with lowering temperature more and more distant pairs become magnetically neutral, $S_{\text{tot}} = 0$. Accordingly, the temperature dependence of magnetic susceptibility assumes a modified Curie form, $\chi(T) = C/T^{\gamma}$, where $\gamma < 1$ and both $C$ and $\gamma$ depend on the content of the magnetic constituent $x$. Similarly, the field dependence of magnetization is conveniently parameterized by the Brillouin function $B_S$,

$$M_o(T,\ H) = Sg\mu_B N_o x_{\text{eff}} B_S[Sg\mu_B H/k_B(T + T_{\text{AF}})] \tag{5}$$

in which two $x$- and $T$-dependent empirical parameters, $x_{\text{eff}} < x$ and $T_{\text{AF}} > 0$, describe the presence of antiferromagnetic interactions.

## 6. *Magnetic Collective Phenomena*

In addition to magnetic and neutron techniques, a variety of optical and transport methods, including subpicosecond spectroscopy and $1/f$ noise study of nanostructures, have successfully been employed to characterize collective spin phenomena in DMS. Undoped DMS belong to a rare class of systems, in which spin-glass freezing is driven by purely antiferromagnetic interactions, an effect of spin frustration inherent to the randomly occupied f.c.c. sublattice. Typically, in II–VI DMS, the spin-glass freezing temperature $T_f$ increases from 0.1 K for $x = 0.05$ to 20 K at $x = 0.5$ according to $T_f \sim x^{\delta}$, where $\delta \approx 6$, which reflects a short-range character of the superexchange. For $x$ approaching one, antiferromagnetic type III ordering develops, according to neutron studies. Here, strain imposed by the substrate material—the strain engineering—can serve to select domain orientations as well as to produce spiral structures with a tailored period.

Particularly important is the carrier-density controlled ferromagnetism of bulk and modulation-doped *p*-type DMS. The observed values of the Curie temperature $T_C$ are below 5 K in $Zn_{1-x}Mn_x$Te:N but in the case of $Ga_{1-x}Mn_xAs$, in which manganese supplies both spins and holes, $T_C$ reaches 110 K for $x = 0.05$. At the same time, strain engineering makes it possible to design the direction of the easy axis. In the case of *p*-type quantum structures, the hole concentration, and thus the magnetic phase, can be changed isothermally, by light or gate voltage. Furthermore, observations of an exchange coupling via nonmagnetic layers have been followed by demonstrations of giant magnetoresistance (GMR) and tunneling magnetoresistance (TMR) effects in ferromagnetic III–V DMS.

## 7. Concluding Remarks

In addition to being a valuable playground in which to examine various novel phenomena, DMS have already been commercialized as Faraday effect-based optical insulators as well as intracenter light emitters. Future studies will certainly attempt to explore a great potential of ferromagnetic semiconductors and their quantum structures. This requires preparation of ferromagnetic semiconductors with $T_C$ above room temperature, a feasible task according to some theoretical predictions. Indeed, promising results on $T_C$ above 300 K in chalcopirite (Cd,Mn,Ge)$P_2$ and wurzite (Zn,Co)O:Ga have been reported.

Properties of short period ferrimagnetic superlattices containing two different magnetic elements, such as Mn and Co, but perhaps also different rare earths or actinides, are to be explored. Other possible functional materials are hybrid structures of semiconductors and ferromagnetic metals, the latter in the form of overgrowth or inserted layers or inclusions. Magnetoresistance over 10 000% that has been found at room temperature in such a granular system constitutes a good example of the many opportunities ahead.

# DNA Microarrays using Magnetic Labeling and Detection

There are myriad applications for biosensors—from antiterrorism, to food safety, to point-of-care clinical diagnostics. The goal is to create systems that mimic the sensitive and specific sensing abilities that come effortlessly to naturally occurring organisms. A common approach to detecting biological molecules is to attach to the target molecule a chemical label that produces an externally observable signal. Traditionally, this is accomplished using biomolecular recognition between the target molecule and a specific receptor (e.g., an antibody) that incorporates a label such as a radioisotope, enzyme, or fluorescent molecule. Sensing methods have been developed based on a range of transduction mechanisms, including optical, electrical, electrochemical, thermal, and piezoelectrical means, which are covered eloquently by numerous reviews (see, e.g., Pearson *et al.* 2000, Vo-Dinh and Cullum 2000).

Recently, magnetic particles have been developed as labels for biosensing. Magnetic labels have several potential advantages over other labels. They are not subject to degradation over time or photobleaching, making their properties very stable. In addition, magnetic fields are not attenuated by biological material, offering the possibility of *in vivo* sensing. Magnetism may also be used to remotely manipulate the particles. Finally, there are a number of sensitive magnetic field detection methods arising from advances in microelectronics and magnetic storage technologies that will enable the design of compact, low-power sensor systems. Recently described detection methods include the Maxwell bridge (Kriz *et al.* 1996), micro-cantilever-based force amplified biological sensor (Baselt *et al.* 1997), superconducting quantum interference device (SQUID) (Kötitz *et al.* 1997), giant magnetoresistive bead array counter (Baselt *et al.* 1998), frequency-dependent magnetometer (Richardson *et al.* 2001), and silicon Hall sensor (Besse *et al.* 2002).

## 1. Basic Biomolecule Labeling and Detection with Magnetic Particles

As for many other biomolecular labels, magnetic labeling can be easily accomplished using specific ligand–receptor interactions, as illustrated generically in Fig. 1. The illustrated "sandwich" configuration proceeds as follows:

(i) Receptor molecules specific for the target biomolecules are attached to the surface of a solid substrate. Often arrays of different probe spots are used to simultaneously detect multiple targets.

(ii) When target molecules are present in a sample solution, they are captured by the surface.

(iii) Magnetic particles coated with a second set of receptor molecules for the target are introduced, labeling the previously captured targets.

(iv) The label particles are detected by a magnetic sensor.

Sandwich assays are commonly performed using antibody–antigen pairs and complementary DNA strands, and often use the strongly binding biomolecular combination of streptavidin and biotin to attach the particle labels to the receptor molecules.

For biosensing applications, the magnetic particles used as labels should be paramagnetic, i.e., only have a magnetic moment when a magnetic field is applied. The absence of a permanent magnetic moment prevents agglomeration of the particles in solution which would render them ineffective as labels. When selecting label particles, properties of importance include the size and size uniformity, the type of magnetic material and its volume fraction within the particle, and the particle surface chemistry. For example, though nanometer-scale particles are matched in size to biological macromolecules such as DNA, the small magnetic fields they generate are difficult to detect. Second, the surface of the particles must be suitable for chemical attachment of biomolecules. A variety of paramagnetic beads with biocompatible polymer or silica shells are commercially available with diameters that range from 1 μm to 5 μm.

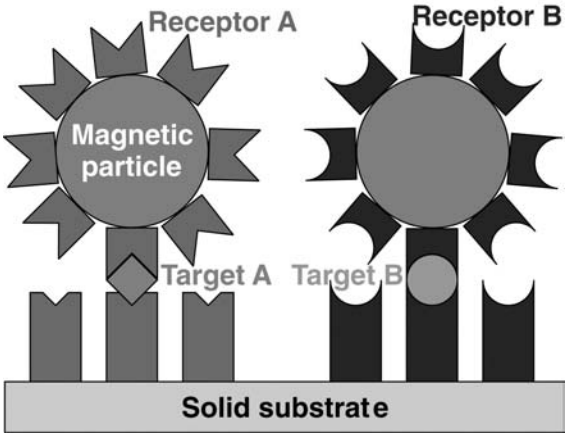

*Figure 1*
Generic illustration of magnetic labeling of targets captured onto a solid substrate in a "sandwich" configuration using specific biomolecular ligand–receptor recognition.

Because magnetic particles experience a force in the presence of a magnetic field gradient, they may be manipulated by magnets. This phenomenon can be used to apply a controlled force that selectively pulls off only those labels not bound to the surface by specific binding (Lee *et al.* 2000). Such a force discrimination assay increases the sensitivity of detection by greatly reducing the background signal and thereby permitting very low signal levels to be detected with confidence.

## 2. Magnetic Particle Detection

The detection of magnetic particles can be accomplished by a number of methods, as mentioned above. Here we will focus on the use of solid-state magnetic field sensors embedded in the substrate, a method that illustrates many of the advantages of magnetic labeling for biomolecule detection. For example, such an approach has the potential to eliminate the requirement for an external detection system, thereby reducing the size, cost, and power of the sensor system.

One of the simplest solid-state magnetic field sensors to incorporate into a microelectronic substrate is a giant magnetoresistive (GMR) wire (Baselt *et al.* 1998). GMR materials are multi-component thin films with alternating magnetic and nonmagnetic layers (see *Giant Magnetoresistance*). The relative orientation of the magnetic moments of these layers is altered in the presence of a magnetic field, changing the electrical resistance of the wire. When a magnetic particle is present above a GMR sensor, the resistance of the sensor changes; the larger the number of particles present, the larger the change. The availability of suitably sensitive GMR sensors was made possible by recent advances in magnetic materials for high-density data storage, including magnetic disk drive read-out sensors and nonvolatile magnetic memory elements (Prinz 1998).

When paramagnetic microbeads are used, such as those commercially available, GMR sensors have been designed that are only sensitive to a planar component of the dipolar magnetic field induced in the particles, as illustrated in Fig. 2. As discussed by Miller *et al.* (2001), when an external magnetic field is applied normal to the plane of the GMR sensor, the field strength at the sensor is given by

$$B \sim m/z^3 \tag{1}$$

where $m$ is the magnetic moment of the bead and $z$ is the distance from the center of the bead to the sensor.Therefore, the resistance change in the sensing wire is roughly proportional to the number of magnetic particles present above it, a signal that can be easily measured. For maximum signal, the particle should have as large a magnetization as possible and be as close to the sensor as possible.

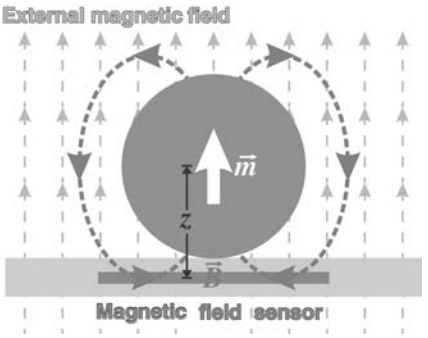

*Figure 2*
Schematic of the magnetic field induced around a paramagnetic microbead on top of a magnetic field sensor when an external field is applied normal to the substrate.

### 3. *Detection with a GMR Sensor Microarray*

A well-developed system that uses a GMR microarray to detect different DNA sequences in a sample is the bead array counter (BARC) sensor (Baselt *et al*. 1998, Edelstein *et al*. 2000, Miller *et al*. 2001). In this system, the test is performed inside a small, quartz flow cell mounted over the sensor chip. The chip itself is wire bonded to a printed circuit board housed in a disposable plastic cartridge that contains the required liquid reagents. The cartridge plugs into an automated electronic controller and connects to a miniature pumping system (Tamanaha *et al*. 2002).

Before assembly, the surface of the sensor chip is coated with a biocompatible polymer film (polyethylene glycol (PEG)) and an array of single-stranded DNA capture probes (Fig. 3(a)). Note that the GMR sensors and associated interconnects must be protected from the reactive and conductive salt solution used in the biochemical test, in this case by a film of

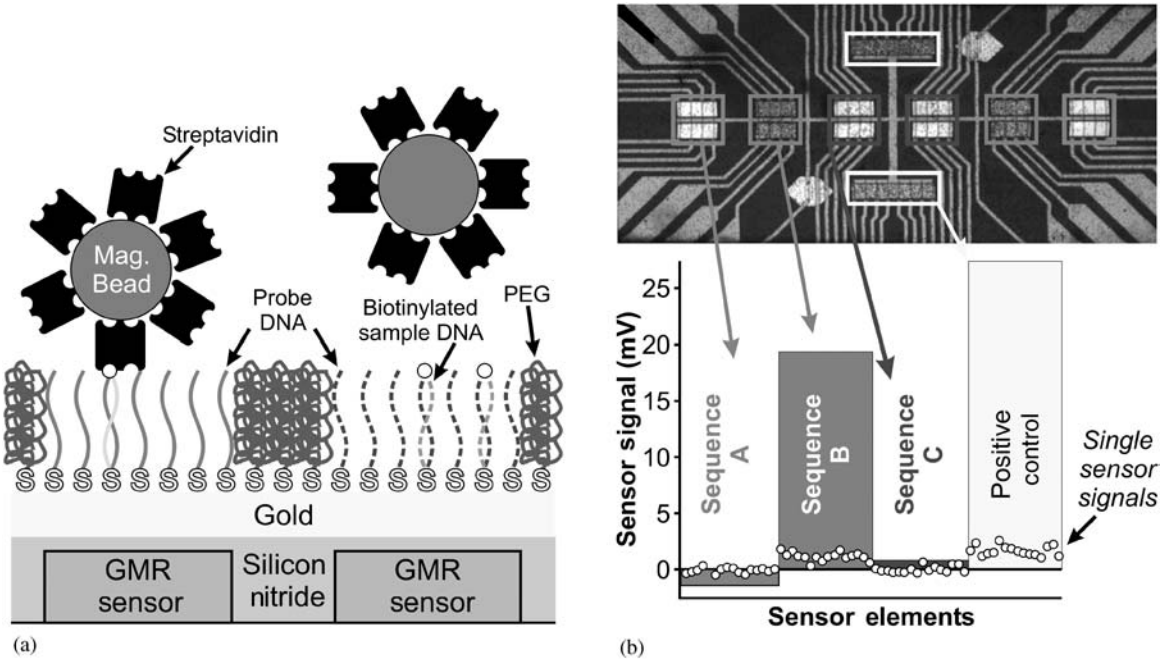

*Figure 3*
(a) An illustration of the BARC biosensor approach. Note that the elements are not to scale; in particular, the beads and sensors are much larger in proportion to the biomolecules. (b) A micrograph of a BARC chip after a DNA test, with the eight sensing zones outlined. For each of the probe zones, the graph shows the measured signals from the individual sensing elements (open circles) and the integrated signal for all 16 elements (colored bar). The assay for sequence "B" was performed with 10 nM DNA hybridized for 30 min. The total test required about $\sim$60 min.

silicon nitride. The chip is also coated with a thin gold layer so that the DNA probes and PEG can be attached to the surface by strong gold–sulfur bonds. Each sensor zone is covered with strands of DNA complementary for a different target strand. The PEG film inhibits undesirable, nonspecific, sticking of target DNA and magnetic particles in the areas outside of the DNA probe spots.

To test for the presence of specific target DNA sequences, the sample is introduced into the flow cell and allowed to hybridize with the capture probes. In the illustrated example, the target strands have been pre-modified to have biotin molecules attached at one end. Therefore, the presence of target in the sample will result in double-stranded, biotin-tagged DNA bound above a sensor. The captured targets are then labeled with streptavidin-coated magnetic microbeads. Beads just resting on the surface can be removed by a magnetic force, and the remaining beads detected by the underlying GMR sensors.

The results of an actual experiment performed in this way are shown in Fig. 3(b) on a chip with eight sensor zones (Miller *et al*. 2001). A micrograph shows the surface of the chip after the test. In this test, each of the three different DNA sequences and the positive control (a probe with biotin already on it) were each applied to two zones. Introducing a sample containing only sequence "B" results in the complementary zones and the positive control being covered with beads (appearing dark). The presence of the beads is accurately detected by the eight GMR sensors in each zone.

## 4. Summary

Magnetic labeling and detection holds great promise for sensing biomolecules. As demonstrated by the BARC system, advances in microelectronics and materials can be adapted to analytical applications in the biosciences with great success. Magnetic particles, magnetic force manipulation, and magnetoelectronic detection can be combined to create relatively simple, compact, sensor systems. Such technology promises to fulfill the need for ever faster, more sensitive, and more portable systems in fields as diverse as homeland defense, clinical diagnostics, genomics, proteomics, and forensics.

## Electrodynamics of Superconductors: Flux Properties

The "mixed state" of type II superconductors occurs when magnetic flux penetrates the material in the form of flux lines (vortices) without destroying the superconducting ground state (Tinkham 1996). Above the field of first flux penetration, $H_p$, the repelling flux lines spontaneously order into a triangular (Abrikosov) lattice with sixfold symmetry. The state of zero resistivity is destroyed by vortex motion, which, however, is retained up to a critical current density, $J_c$, when the flux lines are pinned by crystalline defects. Vortex motion can also be driven by thermal fluctuations. When they are sufficiently large, the vortex lattice melts to a vortex liquid and the superconducting ground state is destroyed.

### 1. Flux Line Lattice

Thermodynamically, a flux line is stable above the lower critical field, $H_{c1}$ (Abrikosov 1957). The flux line (or vortex) consists of a "normal" core in which the density of Cooper pairs decreases to zero over a length scale $\xi(T)$, the Ginzburg–Landau (GL) coherence length. Around the core superconducting screening currents circulate, which generate a local magnetic field of about $2\,\mu_0 H_{c1}$, where $\mu_0$ is the magnetic permeability of vacuum. Away from the core both the field and the screening currents decay over a length scale $\lambda(T)$, the GL penetration depth. The line energy of a flux line per unit length is given by

$$\varepsilon = \varepsilon_0 \ln \kappa \equiv (\Phi_0^2/4\pi\mu_0\lambda^2) \ln \kappa \qquad (1)$$

where $\Phi_0$ is the flux quantum, which is also the magnetic flux carried by a flux line. The GL parameter $\kappa$ is the ratio $\lambda/\xi$.

Usually, the first penetration of flux occurs at a field $H_p$, which is considerably different from $H_{c1}$, because the flux line has to enter through the surface or across the edges of the superconductor. This means that $H_p$ is determined by surface and geometrical barriers which depend on sample shape and field orientation.

Well above $H_p$ the flux lines form a triangular Abrikosov lattice with lattice parameter $a_\Delta = (2/\sqrt{3})^{1/2} a_0$, where $a_0 = (\Phi_0/B)$ and $B$ is the flux density. Because of the electromagnetic origin, the range of the vortex interactions is $\lambda$, which is generally much larger than $a_0$. Elastic deformations of the Abrikosov lattice are described by elasticity moduli for uniaxial compression ($c_{11}$), for tilt deformations ($c_{44}$), and for shear deformations ($c_{66}$). Both $c_{11}$ and $c_{44}$ strongly depend on the wavelength of the deformation fields. Especially for small wavelengths the effect of the deformations is considerably reduced by averaging over the vortex interaction range $\lambda$, i.e., the flux line lattice is very soft on scales smaller than $\lambda$.

For very anisotropic materials, such as high-temperature superconductors, the flux lines caused by a magnetic field perpendicular to the $CuO_2$ planes break up into pancake vortices located in the superconducting layers (Blatter *et al*. 1994). The tilt modulus is now reduced by a factor equal to the anisotropy parameter, $\Gamma$, which can be as large as $10^5$. Above a crossover field $B_{cr} = \Phi_0/\Gamma s^2$ ($s$ is the interlayer distance) the tilt deformations become irrelevant and a quasi two-dimensional interaction results in which only compression and shear modes between pancake vortices in the same layer survive. When the magnetic field is parallel to the $CuO_2$ plane it penetrates in the form of Josephson vortices (Bulaevskii 1973), which possess no normal core. For arbitrary field directions crossing lattices of Abrikosov pancake vortex stacks and Josephson vortices may coexist (Koshelev 1999).

### 2. Thermodynamics

Usually the mixed state is represented by the magnetization curve $M(H)$ which in principle consists of five regimes: up to $H_{c1}$ in the Meissner state $M = -H$, just above $H_{c1}$ it drops exponentially, for $H_{c1} < H < H_{c2}$ it is characterized by $M \propto \ln(H_{c2}/H)$, near $H_{c2}$ it is linearly proportional to $H_{c2} - H$, and above $H_{c2}$ $M = 0$. Because of surface and geometrical effects there may occur deviations from this ideal behavior. In this picture it was believed that the phase transition to the superconducting state takes place at the upper critical field, $H_{c2}(T)$. It is now generally accepted that the real thermodynamic phase transition occurs at the melting line, $H_m(T)$. In pure single crystals of high-temperature superconductors the melting transition is of first order. It manifests itself by a jump in $B$, the flux liquid is slightly denser than the solid (Zeldov *et al*. 1995). In the presence of quenched disorder the transition becomes of second order.

Melting occurs when thermal fluctuations generate elastic modes in the lattice that are strong enough to destroy its shear strength (Nelson 1988). In a three-dimensional lattice both shear and tilt deformations determine the mean square displacement $\langle u^2 \rangle^{1/2}$. According to the Lindemann criterion the lattice melts when this quantity is a significant fraction of the lattice parameter, i.e., $\langle u^2 \rangle^{1/2} = c_L a_0$, where $c_L$ is the Lindemann number ($c_L = 0.1$–$0.3$). This criterion gives a good description of the melting line. For thin films in a perpendicular field the tilt modes of the flux lines do

not contribute to the thermal disorder and the system should be considered as a two-dimensional solid consisting of rigid flux bars. Thermal fluctuations in two dimensions give rise to the formation of edge dislocation pairs, which unbind at a second-order melting line in accord with the Kosterlitz–Thouless theory for two-dimensional melting.

In very anisotropic materials the low-temperature phase consists of a solid of flux lines (stacked pancake vortices) which at the first-order transition line decays to a plasma of decoupled pancake vortices. In all situations the state of true superconductivity is destroyed at the melting line and ohmic behavior is recovered.

### 3. Flux Pinning and the Critical Current

A moving flux line lattice (FLL) dissipates energy. When this motion is driven by a transport current with density $J$, a steady state with velocity $v$ is reached when the driving force, $J\Phi_0$, on each vortex is compensated by a frictional force $\eta v$. An illustrative model for the friction coefficient, $\eta$, is that of Bardeen and Stephen in which the vortex core is treated as a moving cylinder of normal metal. The ratio between flux flow resistivity, $\rho_f$, and normal state resistivity, $\rho_n$, is then simply represented by the normal fraction, i.e., $B/B_{c2}$, which leads to $\eta = \Phi_0^2 \rho_n^{-1}/2\pi\xi^2$.

A moving FLL should thus be considered as a normal metal with a (much) smaller resistivity $\rho_f$. Obviously, for applications, the flux flow state should be suppressed. In practice, most materials can be made with a high density of inhomogeneities acting as pinning centers which trap the flux lines up to a critical force $J_c\Phi_0$, where $J_c$ is the critical current density. Defects deviate from the background material by a different local density, elasticity, electron–phonon coupling, electron mean free path $P$, etc. The first three properties give rise to a local change in $T_c$, whereas the latter leads to a variation in $P$. Consequently, one may distinguish between $\delta T_c$ pinning and $\delta P$ pinning, each with its characteristic temperature and field dependence (Kes 1991).

The collective action of the pinning centers breaks up the FLL in domains of average size $L_c$ parallel to the field and transverse size $R_c$ perpendicular to the field. Its volume is $V_c \approx R_c^2 L_c$. The critical current density follows from the statistical average over distributions of pinning centers with pinning strength $W = n_p \langle f^2 \rangle$, where $n_p$ is the concentration of pins and $\langle f^2 \rangle$ the squared average of the pinning force of a single defect. This leads to the well-known collective pinning relationship (Larkin and Ovchinnikov 1979)

$$J_c B \approx (W/V_c)^{1/2} \tag{2}$$

In the original theory the domain sizes were determined by the balance of pinning energy and the energy of the *elastic* deformations in the FLL. However, when the pinning is strong, the local strains in the FLL may grow beyond the elastic limit so that topological defects such as edge dislocations are created. These now determine the positional disorder in the FLL and the domain size $V_c$. Optimal pinning occurs when the transverse order is totally destroyed, i.e., $R_c \approx a_0$, and individual flux line segments of length $L_c$ make up the average domain size. In anisotropic high-temperature superconductors this length can be as small as the height, $s$, of a single pancake vortex. The transition from elastic to plastic disorder may be seen as a peak effect in $J_c$. It usually happens near $H_{c2}$ or near the melting line. Interesting finite size effects may occur in thin films in a perpendicular field leading to two-dimensional collective pinning.

When the pinning is weak, as is the case in amorphous thin films, $L_c$ can be larger than the film thickness. Now only shear deformations are relevant, which makes the analysis conveniently transparent (Kes and Tsuei 1983).

### 4. Thermal Effects, Depinning, and Creep

The FLL in the presence of pinning centers may be seen as an elastic medium in a disorder potential with each domain sitting in a local potential minimum. With increasing temperature thermal fluctuations will give rise to positional fluctuations of the domains and thermal smearing of the potential roughness. When the mean square displacement is of the order of the range, $r_f$, of the disorder potential, this effect (called thermal depinning) is large enough to cause a considerable decrease of the pinning force and of $J_c$. The corresponding depinning or irreversibility line in the temperature–field diagram separates a strong pinning regime at low temperatures from a weak pinning regime at high temperatures.

Thermal fluctuations also make the FLL domains jump over energy barriers between different potential minimums of almost equal energy. In the presence of a driving force this process leads to a unidirectional creep of the FLL with an average velocity $\sim \exp(-U_p/k_B T)$, where $U_p$ is the typical height of the energy barrier and $k_B$ is the Boltzmann constant. For relatively small values, $U_p/k_B T \leqslant 10$, one thus gets linear resistivity at small $J$, called thermally assisted flux flow (TAFF):

$$\rho_{TAFF} = \rho_f \exp(-U_p/k_B T) \tag{3}$$

Although $\rho_{TAFF}$ may be extremely small, TAFF does not describe a true superconducting state with zero resistance at small $J$, but rather a normal metal with ohmic resistance. The reason is that $U_p$ is supposed to be finite and independent of $J$. It has been shown, however, that for collective creep of an elastic

medium in random disorder the domain size, the distance between available metastable states, and the corresponding energy barriers should grow when $J$ decreases in order to maintain the balance between deformation energy and work done by the driving force. In fact, $U_p \sim (J_c/J)^\mu$ with $\mu$ of order one, which leads to true zero resistance for $J \to 0$, according to $\rho \sim \rho_f \exp[-c(J_c/J)^\mu]$. A similar result is obtained in the vortex glass model where the flux flow is supposed to be triggered by the motion of topological defects in the FLL. It shows once more that the mixed state with strong pinning not only is a very practical phenomenon, but that it is a rich area of research for solid-state and statistical physics.

## Electrodynamics of Superconductors: Weakly Coupled

Systems consisting of two superconducting samples connected by a weak electrical contact possess several unusual properties. First, the net current flowing across the contact—the Josephson junction (see *Josephson Junctions: Low-$T_c$*; *Josephson Junctions: High-$T_c$*)—contains a supercurrent $I_S$. If $I_S$ is smaller than the critical current of a junction, $I_C$, then its flow does not lead to a voltage drop across the structure. The supercurrent depends on the phase difference $\varphi = \chi_1 - \chi_2$ of the superconductor order parameters $\Delta_1 \exp(i\chi_1)$ and $\Delta_2 \exp(i\chi_2)$ of the samples (stationary Josephson effect). This function is exactly $2\pi$ periodic and, in the simplest cases, is sinusoidal:

$$I_S(\varphi) = I_C \sin(\varphi) \tag{1}$$

The critical current, $I_C$, is a constant determined by the transport parameters of the contact material and the shape of the Josephson junction. At $I_S > I_C$ there is a voltage drop, $V$, across the junction, which is related to $\varphi$ by the fundamental law (nonstationary Josephson effect)

$$\frac{d\varphi}{dt} = \frac{2e}{\hbar} V \tag{2}$$

where $e$ is the electron charge and $\hbar$ is Planck's constant.

The physical origin of the stationary Josephson effect lies in the specific form of electron reflection from a superconducting interface. Electrons with energy $\varepsilon$ smaller than the superconducting gap, $\Omega$, of the electrodes are trapped in a contact material. They cannot penetrate into an electrode since there is a gap in the density of states near the Fermi level of a superconductor. However, if the energy $\varepsilon$ of an electron is in the interval $0 \leqslant \varepsilon \leqslant \Omega$, its interaction with an electrode results in the creation, with a probability equal to one, of an extra pair of correlated electrons (Cooper pair) in the superconductor and a hole with energy $-\varepsilon$ in the contact material. The latter moves in the direction opposite to that of the initial electron (so-called Andreev reflection). This hole, in turn, interacts with another electrode and causes annihilation of a pair of correlated electrons and the creation of an electron with energy $\varepsilon$, which moves in the same direction as that of the initial particle. As a result of this cycle, a pair of correlated electrons transfers from one superconductor to another leading to a supercurrent flow across a junction, i.e., to the stationary Josephson effect.

The nonstationary Josephson effect is a direct consequence of the Schrödinger equation. In the stationary state the wave function of correlated electrons has the form $\psi(r, t) = \psi(r) \exp(iEt/\hbar)$, and the Schrödinger equation for the phase of the wave function reduces to $\hbar \partial \chi_{1,2}/\partial t = -E_{1,2}$, where $E_{1,2}$ is the energy of the superconducting condensate in the samples. Thus $\hbar \partial \varphi/\partial t = E_2 - E_1$ and this latter difference should be equal to the difference $E_{F2} - E_{F1}$ of the electrochemical potentials $E_{F2}$ and $E_{F1}$ across the junction, which is exactly equal to 2 eV.

## 1. Current Components

In the general case, the net current, $I$, across a Josephson junction has several components in addition to $I_S(\varphi)$:

$$I = I_S(\varphi) + I_N(V) + I_D(V) + I_F(t) \tag{3}$$

where $I_N$ is the normal (quasiparticle) current, $I_D$ the displacement current, and $I_F$ the fluctuation current.

### 1.1 Supercurrent

In accordance with Eqn. (1) a d.c. supercurrent in the range

$$-I_C \leqslant I_S(\varphi) \leqslant I_C \tag{4}$$

can flow across the junction as a result of a constant phase difference $\varphi$. An external system supporting this phase difference represents work on the supercurrent and, thus, stores potential energy in the junction given by

$$U(\varphi) = E_C[1 - \cos(\varphi)] + \text{const}, \; E_C = \frac{\hbar I_C}{2e} \tag{5}$$

Since the energy is conserved in the form of persistent current, the Josephson junction can be considered as having a nonlinear inductance

$$L_S^{-1} = L_C^{-1}\cos(\varphi), \; L_C = \frac{\hbar}{2eI_C} \tag{6}$$

This means that for weak signals the supercurrent is equivalent to an inductance $L_S$ dependent on $\varphi(t)$ and on the critical current of the junction.

The most impressive property of a supercurrent is its ability to oscillate (*Josephson oscillations*) with a frequency

$$f_J = \frac{\omega_J}{2\pi} = \frac{2e}{h}\bar{V}, \; \frac{2e}{h} \approx 483 \text{ MHz}\mu\text{V}^{-1} \tag{7}$$

if a nonzero d.c. voltage, $\bar{V}$, is fixed across the junction. At typical voltages ($10^{-6}$–$10^{-2}$ V) the oscillation frequency, $f_S$, is of the order of $10^9$–$10^{13}$ Hz.

### 1.2 Normal Current

The scale of the normal current is given by the normal conductance of a junction $G_N$. Independent of transport properties of the contact material at voltages larger than $(\Delta_1 + \Delta_2)/e$, the $I_N(V)$ dependence of the junction is close to Ohmic at all temperatures:

$$I_N = G_S V + \delta I \tag{8}$$

The voltage-independent factor $\delta I$ in Eqn. (8) is the so-called "excess" ($\delta I \propto (\Delta_1 + \Delta_2)$) or "deficit" ($\delta I \propto -(\Delta_1 + \Delta_2)$) current observed if the contact material has a metallic type of conductivity (*SNS weak links*). In structures with transparent interfaces between the contact material and superconducting samples there is excess current on $I_N(V)$. Andreev reflection of electrons is responsible for this effect. Owing to a gap in the density of states, an electron with energy $\varepsilon$ in the interval

$$E_{F2} + eV - \Omega_2 \leqslant \varepsilon \leqslant E_{F2} + eV + \Omega_2 \tag{9}$$

cannot penetrate into the superconductor as an electron, as in the normal case. Instead, in accordance with the Andreev process, it creates a pair of correlated electrons and a hole in the contact material. Thus, in this energy interval, (as in the normal case) two electrons instead of one are injected into the electrode leading to an "excess" current.

In structures with small transparent interfaces between the contact material and superconducting samples (*SINIS double barrier structures*) there is a current "deficit" on $I_N(V)$. The probability of Andreev reflection for an electron with energy defined by Eqn. (9) is proportional to $D^2$, where $D \ll 1$ holds for the transparency of an interface. Thus, in contrast to the normal case, there is no electron injection into the superconductor if the electron energy is in the range given by Eqn. (9) and, therefore, a current deficit should be observed on $I_N(V)$.

In junctions with tunneling-type conductivity of the contact region (*SIS tunnel Josephson junction*), $\delta I = 0$.

### 1.3 Displacement Current

For most practical Josephson junctions the displacement current is defined by

$$I_D = CV = C\frac{dV}{dt} \tag{10}$$

where the junction capacitance, $C$, has the same value as in the normal state and depends on both the junction type and its size. The effect of the capacitance on the processes in the junction is characterized by the dimensionless parameter

$$\beta = \frac{2e}{\hbar} I_C R_N^2 C \tag{11}$$

introduced by McCamber (1968) and Steward (1968). It compares the normal and displacement currents. Junctions with $\beta \ll 1$ have small capacitance or *high damping* ($I_N \gg I_D$), and junctions with $\beta \gg 1$ have large capacitance or *low damping* ($I_N \ll I_D$).

### 1.4 Fluctuation Current

The necessity of taking fluctuations ("noise") into account often arises in an analysis of the sensitivity of

superconducting devices. In most cases this is carried out by including some fluctuation current, $I_F(t)$, in the whole current across the junction. There are several sources of current fluctuation. These are *external noise sources*, *1/f noise*, *thermal noise*, and *shot noise*.

Usually, in experimental setups the intensity of an external noise is effectively suppressed to a level that is negligibly small compared to that provided by other sources.

The cutoff frequency of $1/f$ noise is relatively low. In a low-temperature Josephson junction it scales from 1 Hz to 10 Hz, while in high-temperature junctions it is in the range 100–1000 Hz. This means that at typical Josephson frequencies $\omega \approx \omega_J$ the net effect of this noise is very small. Nevertheless, in some practical devices (e.g., see *SQUIDs: Biomedical Applications*) the useful signal is contaminated with $1/f$ noise and special techniques such as signal or bias modulation are used for suppression of this noise component.

Thermal noise and shot noise are two types of classical fluctuations which exist since there is a dissipative current, $I_N$, across a junction. The relative intensity of the thermal fluctuations can be characterized by the ratio of the thermal energy, $k_B T$, to the Josephson energy, $E_C$:

$$\gamma = \frac{k_B T}{E_C} = \frac{I_T}{I_C} = \frac{2e}{\hbar}\frac{k_B T}{I_C}, I_T[\mu A] \approx 0.0417[K] \quad (12)$$

Thus, if the critical current of the junction is much larger than $I_T$ the influence of thermal fluctuations should be small.

Shot noise is important if the voltage across the junction is large compared to $\hbar\omega/e$ and $k_B T/e$ and can be characterized by the spectral density

$$S_I(\omega) = \frac{1}{2\pi} e I_N = \text{const} \quad (13)$$

Equations (2) and (3) form the system of the basic equations for the Josephson junction. The concrete expressions for the current components in Eqn. (3) depend on the type of conductivity of the contact material and the geometry of the junction. The problem of finding the relationship between the current and voltage was solved in solid-state theory (Werthamer 1966, Larkin and Ovchinnikov 1966) only for structures with tunnel-type conductivity of the contact material. For this reason, even now the majority of dynamics problems in systems with Josephson junctions are solved in the framework of phenomenological models, which provide approximations of the real properties of various junctions. The resistively shunted junction (RSJ) model introduced by McCamber (1968) and Steward (1968) is the simplest and the most widely used tool for studying the processes in junctions.

## 2. RSJ Model

The RSJ model is based on Eqns. (1) and (8) with $\delta I = 0$, on Eqn. (10) for the current components in Eqn. (3)

$$I = I_C \sin(\varphi) + G_N V + C\frac{dV}{dt} + I_F(t) \quad (14)$$

and on the Josephson relationship (Eqn. (2)).

Quantitatively this model is valid for SIS and SNS Josephson junctions only in a narrow temperature interval in the vicinity of the critical temperature of the superconductor. At lower temperatures $G_N$ becomes a nonlinear function of voltage and often the $I_S(\varphi)$ relationship is no longer sinusoidal.

Nevertheless, this model is widely used for describing the processes in Josephson junctions of any type, if they are shunted by a conductance $G_e \gg G_N$. A shunted junction can be considered as a new Josephson contact with linear normal conductance, $G_e$, which should replace $G_N$ in Eqn. (14). A real form of the $I_S(\varphi)$ relationship can be taken into account by representing a junction as a junction with $I_S(\varphi) = I_C \sin(\varphi)$ and effective inductance connected in series (Zubkov *et al*. 1981).

The RSJ model is of great importance, since it provides the possibility of studying the processes in a variety of devices employing Josephson junctions without having the exact solutions of solid-state physics problems for the current components in Eqn. (3).

There are two experimental tests that are generally used to verify how close the behavior of real Josephson contacts are to the predictions of the RSJ model. These are the specific reactions of the structure to external magnetic and microwave fields.

## 3. Josephson Junctions in a Magnetic Field

In an external magnetic field, $B$, the phase difference, $\varphi$, across a junction depends on a space coordinate, $x$, along the junction and is a solution of the equation

$$\lambda_J^2 \frac{d^2\varphi}{dx^2} = J(x,t) \quad (15)$$

where $J$ is the local value of a current (Eqn. (3)) through the junction and $\lambda_J$ is the Josephson penetration depth given by

$$\lambda_J^2 = \frac{\Phi_0}{2\pi\mu_0(d + \lambda_1 + \lambda_2)J_C} \quad (16)$$

where $d$ is the distance between the superconducting samples, $\Phi_0$ the magnetic flux quantum, $\mu_0$ the vacuum magnetic constant, and $\lambda_{1,2}$ the London penetration depths of the superconducting samples.

Solution of Eqns. (14) and (15) essentially depends on the relationship between the length of the junction, $L$, and $\lambda_J$.

In a long Josephson junction with $L \gg \lambda_J$ the magnetic field penetrates inside the structure in the form of a Josephson vortex. This is a region with a length of the order of $\pi\lambda_J$, filled by magnetic flux lines, which are screened by the supercurrent, $J$, circulating around:

$$B = \frac{\pm\Phi_0}{\pi d\lambda_J}\cosh^{-1}\left(\frac{x - x_0}{\lambda_J}\right),$$

$$J = \frac{\pm 2J_C \sinh[(x - x_0)/\lambda_J]}{\cosh^2[(x - x_0)/\lambda_J]}$$

In a short junction with $L \ll \lambda_J$ the phase difference is a linear function of $B$:

$$\varphi(x) = \frac{Bd}{\Phi_0}x + \eta,\ \eta = \text{const} \tag{17}$$

The critical current of a junction

$$I_C = \max_{\eta}\left\{\int_0^W J_C \sin[\varphi(x)]\mathrm{d}x\right\} = I_{C0}\left|\frac{\sin(\pi\Phi/\Phi_0)}{(\pi\Phi/\Phi_0)}\right| \tag{18}$$

depends in this case on the magnetic flux, $\Phi$, inside the junction and exactly equals zero at $\Phi = n\Phi_0$. The form of $I_C(\Phi)$ dependence is similar to the pattern of Fraunhofer diffraction of waves passing through a slit and has been termed the "Fraunhofer pattern."

### 4. Josephson Junctions in a Microwave Field

In his original paper Josephson (1962) also predicted the appearance of a set of vertical current steps on the current–voltage characteristics of short Josephson junctions under the influence of microwave radiation, $V(t) = V_1\cos(\omega t)$.

If the normal current component across the junction is large compared to the supercurrent, then the solution of Eqns. (2) and (3) has the simple form

$$\varphi = \frac{2e}{\hbar}\bar{V}t + \frac{2e}{\hbar\omega}V_1\sin(\omega t) + \alpha \tag{19}$$

Substituting Eqn. (19) into the expression for $I_S$ (Eqn. (1)) of the RSJ model gives

$$I_S = I_C\sum_{m=-\infty}^{\infty} J_m\left(\frac{2eV_1}{\hbar\omega}\right)\sin\left[\left(m + \frac{\omega_J}{\omega}\right)\omega t + \alpha\right] \tag{20}$$

where $J_m(x)$ are Bessel functions of the first kind. It is clear from Eqn. (20) that synchronization of the $n$th harmonic of the external radiation with the frequency of the Josephson oscillation ($n\omega = \omega_J$) should result in formation of steps, which look like "spikes" in the current–voltage characteristic and have amplitude $I_C J_m(2eV_1/\hbar\omega)$. According to the well-known properties of Bessel functions, as the signal amplitude increases the $n$th step first increases, reaches a maximum, and then slowly decreases, oscillating with a period approximately equal to $2\pi$.

These oscillating steps were first observed by Shapiro (1967) and are referred to as Shapiro steps.

Both effects discussed above (Fraunhofer pattern, Eqn. (18), and Shapiro steps, Eqn. (20)) are the direct consequence of the sinusoidal relationship between supercurrent and phase difference $\varphi$. It is for this reason that they are used as a standard experimental test for the applicability of the RSJ model for the description of the properties of a Josephson junction of any type and configuration.

## 5f Electron Systems: Magnetic Properties

5f electron systems are characteristic of actinides, i.e., elements between actinium, atomic number $Z = 89$, and lawrencium, $Z = 103$. These elements

are characterized by a gradual filling of the 5*f* electronic shell, in analogy to the 4*f* shell filling in lanthanides. The filling tendencies for free-ion states with increasing $Z$ resemble strongly those in lanthanides, but as part of a solid the behavior of the 5*f* electrons resembles 3*d* materials more. The reason is the spatial extent of the 5*f* wave functions, being larger compared with the 4*f* states in lanthanides. Therefore the magnetism of most 5*f* electron systems is more similar to the *d*-band magnetism than to the localized 4*f* magnetism of lanthanides. This is particularly true for light actinides (up to plutonium), whereas for the heavier actinides (from americium onwards) 5*f* localization has been documented for the pure elements. More systematic information on magnetism of heavy-actinide compounds is missing.

The specific characteristics of the 5*f* electron magnetism are manifest in systems based on elements up to plutonium. The higher actinides behave in an analogous way to the corresponding 4*f* systems. The main characteristics of the 5*f* magnetism comprise strong spin-orbit interaction, leading to large orbital moments formed even in the case of band-like states, exchange interactions mediated or assisted by the hybridization of the 5*f* states with the ligand states, and enormous magnetic anisotropy arising from the anisotropy of the hybridization (bonding anisotropy). Another characteristic is a high sensitivity of magnetic properties to external variables, such as pressure and magnetic field, and to fine details of composition.

## 1. General Features of Electronic Structure and Magnetism of Light-actinide Systems

The fundamental difference between the character of the 4*f* electron states in lanthanides (see *Localized 4f and 5f Moments: Magnetism*) and 5*f* states in light actinides can be attributed to a much larger spatial extent of the 5*f* wave functions, and thus a much stronger interaction with the metallic environment, compared to the 4*f* case. The 5*f* electrons are, as a rule, delocalized due to their participation in bonding, which leads to a considerable hybridization of the 5*f* states with the valence states of neighboring atoms (5*f* ligand hybridization). The delocalization of the 5*f* electrons has serious consequences. The most important one is, that the 5*f* states form a more or less narrow 5*f* band intersected by the Fermi energy $E_F$ (the bandwidth $W_{5f}$ is of the order of several eV) rather than discrete energy levels. Consequently, the magnetic moments due to the itinerant 5*f* electrons are much smaller than expected for a free ion, and magnetic moments can disappear in a broad-band limit leading to weak (Pauli) paramagnetism.

This situation resembles to a certain extent the 3*d* transition metals. The strength of magnetic coupling in cases of existing 5*f* moments is typically much larger than for the 4*f* moments interacting via the RKKY interaction. The impact on magnetic excitations is even more dramatic, no crystal-field excitations could be observed by inelastic neutron scattering in a vast majority of systems studied so far. Instead, one observes typically a rather broad quasielastic response reflecting the 5*f* moment's instability in analogy to, for example, cerium mixed valence materials. However, the high density of states at $E_F$ is projected into high $\gamma$-values of the low temperature specific heat (which are further renormalized by strong *e–e* correlations), and into highly anomalous transport properties, resulting from the hybridization of such ''heavy'' electron states with the non-*f* states carrying the electrical current.

## 2. Pure Actinide Elements

The small separation of the ions in the pure elements leads to large overlap of the 5*f* wave functions of nearest neighbors, formation of a broad 5*f* band and weakly paramagnetic behavior. With increasing 5*f* occupation the value of the Pauli-type susceptibility increases due to the increase of $N(E_F)$, the density of states at the Fermi level, which is corroborated by a similar increase of the low-temperature electronic specific heat coefficient $\gamma$ (see Table 1). This tendency

***Table 1***
Overview of essential properties of elemental actinides, summarizing available data on the $\gamma$-coefficient of the low-temperature specific heat, temperature independent susceptibility $\chi_0$, Néel temperature $T_N$ and Curie temperature $T_C$.

| | Th | Pa | U | Np | Pu | Am |
|---|---|---|---|---|---|---|
| $\gamma$ (mJ mol$^{-1}$ K$^{-2}$) | 4 | 6.6 | 10 | 14 | 22 | 2 |
| $\chi_0$ ($10^{-8}$ m$^3$ mol$^{-1}$) | 0.12 | 0.34 | 0.48 | 0.68 | 0.64 | 0.85 |
| | Cm | Bk | Cf | Es | | |
| $T_N$ (K) | 64 | 34 | 51($T_C$) | | | |
| $\mu_{eff}$ ($\mu_B$) | 7.55 | 9.7 | 9.7 | 11.3 (?) | | |

is interrupted between plutonium and americium, where the 5*f* states localize, and do not contribute to bonding for heavier actinides. The reason for the localization (and loss of the 5*f* bonding energy) can be found qualitatively in the gain of electron correlation energy for atomic-like 5*f* states (which is partly lost in the 5*f* band case). For details see Johansson and Brooks (1993).

Thus the Stoner criterion (see *Itinerant Electron Systems: Magnetism (Ferromagnetism)*) is not fulfilled in light actinides because of too small $N(E_F)$ and the Coulomb interaction parameter $U$. But these materials can lower their electron energies by forming different open crystal structures, sometimes of a very low symmetry (in analogy to Jahn–Teller effect). The best example of this phenomenon is plutonium, having six allotropes, with the ground-state allotrope, α-plutonium, showing a complicated monoclinic structure. A similar situation occurs in α-uranium, the structure of which is orthorhombic, but an incommensurate charge-density wave is formed below $T = 43$ K (Lander *et al*. 1994).

Due to the weakly magnetic character, superconductivity can appear at the beginning of the actinide series. The critical temperatures $T_c$ are 1.368 K for thorium, 1.4 K for protactinium, 0.68 K for α-uranium. For heavier actinides, superconductivity was found for americium ($T_c = 0.625$ K).

Plutonium, the element on the verge of localization, exhibits the most complex behavior. Its room temperature phase, α-plutonium, is monoclinic with 16 atoms per unit cell. At $T = 395$ K it undergoes a phase transition to an even more complicated monoclinic β-phase with 34 atoms per unit cell. From the remaining phases, most of the data is on the f.c.c. δ-phase with four atoms per unit cell, which has its atomic volume expanded by 26% compared to the α-phase, and which can be stabilized by several percent by doping with aluminum, cerium, or gallium. Comparing to the data for α-plutonium given in Table 1, $\gamma$ is strongly enhanced to $53 \pm 10\,\mathrm{mJmol^{-1}\,K^{-2}}$. For details see Méot-Reymond and Fournier (1996), where the properties of δ-plutonium are discussed in terms of a Kondo effect with the characteristic Kondo temperature $T_K$ higher than the room temperature.

The elements behind plutonium behave rather similar to the lanthanide series. The analogy starts with crystal structures. Americium, curium, berkelium, and californium all have d.h.c.p. structures, but the structures change and the 5*f* states delocalize under external pressure, yielding low symmetry structures of the light-actinides type (Benedict and Holzapfel 1993).

The nonmagnetic ground state of americium (exhibiting low $\gamma$ and quite high Van Vleck susceptibility), can be understood in the framework of either *L–S* or *j–j* coupling for the $5f^6$ configuration. Most information on curium was obtained on a fast decaying isotope $^{244}$Cm (half-life 18 years), which is available in large amounts (milligrams) but displays high self-heating and radiation damage. A maximum magnetic susceptibility indicating antiferromagnetic (AF) ordering was observed at $T = 52$ K for this isotope, and a simple AF order was indeed confirmed by neutron diffraction. For $^{248}$Cm, which has longer half-life, but is available in smaller amounts only, the AF order was indicated at $T = 64$ K. Values of effective moment are compatible with $\mu_{eff} = 7.55\,\mu_B$ expected for the intermediate coupling model. Besides the ground-state d.h.c.p crystal structure, a high temperature f.c.c phase can occur in a low-temperature metastable state. Its magnetic ordering temperature is enhanced to $T = 205$ K. Berkelium and californium could be studied only in submilligram quantities. For berkelium, AF ordering was deduced below $T = 34$ K; californium is probably ferromagnetic below approx. 51 K. Both materials display $\mu_{eff}$ values compatible with free-ion theoretical values in the paramagnetic state. Einsteinium, which could be studied in submicrogram quantity only, yields a moment of $11.3\,\mu_B$, which is even somewhat higher than the theoretical value (Huray and Nave 1987).

## 3. *Magnetic Properties of Actinide Intermetallic Compounds*

Similar to the pure actinide elements, the magnetic properties of the compounds also reflect the gradual filling of the incomplete 5*f* shell. In thorium compounds the very small filling of the 5*f* states cannot give rise to 5*f* magnetic moments, and compounds are typically Pauli paramagnets with a susceptibility $\chi_0$ of the order of $10^{-9}$–$10^{-8}\,\mathrm{m^3mol^{-1}}$ for intermetallic compounds, where its value reflects the density of states at $E_F$. The ground state is frequently superconducting. Exceptions are compounds such as $Th_2Fe_{17}$ ($T_C = 295$ K) and $Th_2Co_{17}$ ($T_C = 1035$ K), in which magnetism is dominated by transition-metal components.

In the compounds of uranium, neptunium, and plutonium, magnetic ordering can appear in those cases in which the actinide–actinide spacing is increased to such an extent, that the 5*f* band narrowing and consequent increase of the density of states at $E_F$ leads to the fulfillment of the Stoner criterion. The proximity of these elements to the boundary between the localized and itinerant character of the 5*f* electronic states makes them very sensitive to variations of the environment. In the first approximation the width of the 5*f* band can be taken as a function of the overlap of the 5*f* atomic wave functions centered on nearest neighbors, and the increase of the overlap can be taken as a principal delocalizing mechanism of the 5*f* electrons. The situation is best documented for uranium compounds, where the inter-uranium spacing $d_{U\text{-}U} = 340$–$360$ pm, called the Hill limit, is an

approximate boundary value of the spacing, corresponding to the critical 5*f*–5*f* overlap. For smaller spacings most of the compounds are nonmagnetic (often superconducting). For $d_{U\text{-}U}$ larger than the Hill limit they incline to a magnetically ordered ground state. The value of the Hill limit should be taken as very approximate; the width of the 5*f* band is naturally affected also by the coordination number.

For compounds with $d_{U\text{-}U}$ larger than the Hill limit, the principal control parameter is not the U–U spacing, but the hybridization of the 5*f* states with electronic states of other components. In particular, in compounds with transition metals it is mainly the overlap of the 5*f* states with the *d* states of the transition metal component in the energy scale which affects the strength of the hybridization. The 5*f* states remain pinned at the Fermi level in most cases, whereas the late transition metals (as well as noble metals), being much more electronegative, have particular *d* states shifted towards higher binding energies thus leaving the 5*f*–*d* overlap in energy scale small. The reduced 5*f*–*d* hybridization leads to the onset of 5*f* magnetism, whereas the *d*-states are occupied more than in the pure *d*-element. Even if the *d*-element itself is magnetically ordered (cobalt, nickel, iron), in the compound with uranium it behaves essentially as nonmagnetic (a similar effect appears in thorium compounds).

Exceptions are compounds with very high content of the transition metal component, in which the *d*-magnetism can prevail. In compounds with earlier *d*-metals such as iron or ruthenium the *d*-states appear closer to the Fermi energy and the 5*f*–*d* overlap increases, leading typically to a nonmagnetic ground state (as in UFeAl). But in some cases magnetic moments appear both on uranium and transition-metal ions. Prominent examples are Laves phases with iron, all ordering ferromagnetically. Relatively high $T_C$ values ($UFe_2$ 162 K, $NpFe_2$ 492 K, $PuFe_2$ 564 K, $AmFe_2$ 613 K) point to the dominance of the iron–sublattice exchange interactions, but actinide magnetic moments are non-negligible, reaching 1.1 $\mu_B$ per neptunium or 0.45$\mu_B$ for plutonium. The tiny total moment in the case of uranium in fact consists of orbital (0.23 $\mu_B$) and spin (0.22 $\mu_B$) component, nearly canceling each other.

In compounds with non-transition metals, it is mainly the size of ligand atoms that affects the hybridization. Compounds with larger ligands are typically magnetic (e.g., $UIn_3$), whereas those where smaller ligands make the hybridization stronger form broad bands with low $N(E_F)$ and are weakly paramagnetic ($USi_3$). Several characteristic groups of uranium compounds can thus be distinguished in Table 2.

The last group, heavy-fermion materials, comprises those having a substantially enhanced $\gamma$-coefficient of specific heat, showing a coexistence of magnetic ordering and superconductivity of an unconventional type (see *Heavy-fermion Systems*). In all uranium compounds mentioned, the 5*f* states remain essentially band-like, i.e., contributing to the bonding, and therefore appearing at the Fermi level. The only exception known (at least from binary compounds) is $UPd_3$, for which the 5*f* localization has been confirmed by microscopic methods. Photoelectron spectroscopy exhibits in this case the 5*f* spectral intensity displaced from the Fermi level to higher binding energies. Neutron scattering shows clear crystal electric field (CEF) excitations, normally absent in spectra of

***Table 2***
Overview of the most characteristic groups of uranium intermetallics.

| Characteristics | Examples |
|---|---|
| Very high U content, small $d_{U\text{-}U}$, weakly paramagnetic, superconducting | $U_6Fe$, $U_6Co$, $U_6Ni$ |
| Higher U content, small $d_{U\text{-}U}$, weakly paramagnetic, normal ground state | $UCo_2$, $U_3Si_2$ |
| Low $d_{U\text{-}U}$ (< 340 pm), magnetic order of 5*f* moments (very weak itinerant magnetism) | rare case ($UNi_2$) |
| Intermediate $d_{U\text{-}U}$ (340–360 pm), typically ferromagnetic ground state, itinerant magnetism, typically $T_C < 100$ K | URh, UPt |
| Low U content, large $d_{U\text{-}U}$, low 5*f*-ligand hybridization, ferromagnetic ground state | rare case ($UGa_2$) |
| Low U content, large $d_{U\text{-}U}$, weak 5*f*-ligand hybridization, AF ground state | $UIn_3$, $UGa_3$ |
| Low U content, large $d_{U\text{-}U}$, strong 5*f*-ligand hybridization, normal ground state | $USi_3$, $UNi_5$, $UPt_5$ |
| Low U content, large $d_{U\text{-}U}$ spacing, heavy-fermion behavior with different types of ground state | $UPt_3$, $UBe_{13}$, $URu_2Si_2$, $UPd_2Al_3$, $U_2Zn_{17}$, $UCu_5$, $UCd_{11}$ |

uranium intermetallics, and the coefficient $\gamma$ reaches only $5\,\mathrm{mJ\,mol^{-1}\,K^2}$.

Besides binary compounds there exist large groups of ternary compounds, often including a transition metal T and a non-transition metal X (UTX, $U_2T_2X$, $UT_2X_2$), which follow the tendencies of the 5*f* ligand hybridization mentioned above. The advantage of studies of the 5*f* magnetism in such groups is that both the transition and the non-transition metal component can be varied, while the structure type, i.e., the symmetry of environment of actinide atoms, is preserved. This makes it possible to trace out in more detail the cross-over from a nonmagnetic to magnetic ground state.

Materials which are in the boundary region (i.e., nearly or weakly magnetic) show a variety of spin-fluctuation features. Those with nonmagnetic ground state exhibit Curie–Weiss behavior of magnetic susceptibility at high temperatures, but at low temperatures a broad maximum in $\chi(T)$ appears (e.g., URuAl, UCoAl). Other types of spin fluctuators are characterized by a plateau in $\chi(T)$ below a characteristic temperature, and a low-temperature upturn as in URuGa (see Sechovský and Havela 1998).

High ordering temperatures can be achieved, for example, in ternary compounds of the $UT_{10}Si_2$ type ($ThMn_{12}$ structure type), in which both uranium and the transition metal T (iron, cobalt) carry magnetic moments. The highest $T_C = 750\,\mathrm{K}$ was recorded for $UFe_5Co_5Si_2$.

The occurrence of magnetic ordering in neptunium-based compounds is dominated by mechanisms analogous to their uranium counterparts. Important information is obtained using $^{237}$Np Mössbauer spectroscopy, which allows determination of microscopic parameters of neptunium magnetism. In particular, the magnetic hyperfine field $B_{\mathrm{hf}}$ on the neptunium nuclei was found to be approximately proportional to the local neptunium magnetic moment $\mu_{\mathrm{Np}}$ (Dunlap and Kalvius 1985): $B_{\mathrm{hf}}/\mu_{\mathrm{Np}} = 215\,(\mathrm{T}/\mu_B)$. The fact that the boundary between the magnetic and nonmagnetic behavior for different materials is not far from the uranium isotypes demonstrates that for neptunium compounds the mechanisms of the 5*f* delocalization play a comparable role. Thus the nonmagnetic behavior of neptunium in $NpGe_3$ and $NpRh_3$ has to be attributed to the 5*f*–*p* and 5*f*–*d* hybridization in analogy to $UGe_3$ and $URh_3$. However, differences exist, too. For example, $NpSn_3$ is an itinerant antiferromagnet, whereas $USn_3$ is a spin-fluctuator not undergoing magnetic ordering. Such differences can be generally attributed to a higher 5*f* count or weaker 5*f* delocalization.

However, $Np_2Rh_2Sn$ is a nonmagnetic spin fluctuator, whereas $U_2Rh_2Sn$ undergoes AF order ($T_N = 24\,\mathrm{K}$). $^{237}$Np Mössbauer spectroscopy under high pressure has been a convenient tool to distinguish different types of magnetically ordered compounds. For those with more stable 5*f* moment the neptunium moment does not decrease with pressure in the gigapascal range while the ordering temperature increases (e.g., $NpCo_2Si_2$), whereas a pronounced decrease of both parameters points to a stronger 5*f*-moment instability e.g., in neptunium Laves phases $NpOs_2$ or $NpAl_2$.

## 4. *Magnetic Properties of Other Actinide Compounds*

A large majority of actinide compounds, even with nonmetallic elements, has a metallic character. The magnetic behavior is dominated by the *f*–*p* hybridization, which plays a dual role. It leads to a delocalization of the 5*f* states and mediates the exchange interaction. The metallic character appears in most of the rocksalt type of compounds, monopnictides AnX (An = U, Np, Pu; X = P, As, Sb, Bi) and monochalcogenides AnY (An = U, Np; Y = S, Se, Te), which are magnetically ordered and reach appreciable magnetic phase transition temperatures e.g., $T_N = 213\,\mathrm{K}$ in USb or 285 K in UBi. However, plutonium monochalcogenides are semimetallic and nonmagnetic. Carbides, which are slightly under-stoichiometric ($AnC_{1-x}$), are weakly magnetic for An = Th, Pa, U. $NpC_{1-x}$ is ferromagnetic below $T = 225\,\mathrm{K}$, whereas AF ordering is found up to about 300 K, depending on the $x$ values. $PuC_{1-x}$ undergoes AF ordering with $T_N$ ranging between 100 K and 30 K, depending on the stoichiometry. A large data set exists for nitrides AnN. Whereas ThN and AmN are weakly magnetic, magnetic ordering appears for UN ($T_N = 53\,\mathrm{K}$), NpN ($T_C \approx 90\,\mathrm{K}$), presumably also in PuN ($T_N = 13\,\mathrm{K}$) and CmN ($T_C = 109\,\mathrm{K}$), and data exist even for BkN ($T_C = 88\,\mathrm{K}$). Of the other compounds, a high magnetic ordering temperature can be found, for example, in $U_3As_4$ ($T_C = 196\,\mathrm{K}$), $U_3Sb_4$ ($T_C = 146\,\mathrm{K}$), even 400 K for AF ordering in $U_2N_2As$. $USb_2$ and $UAs_2$ are antiferromagnets with $T_N = 205\,\mathrm{K}$ and 273 K, respectively.

Of the numerous oxides, the dioxides are the most common. $UO_2$ and $NpO_2$ are antiferromagnets ($T_N = 31\,\mathrm{K}$ and 25 K, respectively). These systems are examples of the 5*f* localized magnetism, with attributes such as crystal-field excitations and spin waves, but the latter exhibits certain mysterious features as tiny magnetic moments $< 0.1\,\mu_B/\mathrm{Np}$. For further discussion see *Localized 4f and 5f Moments: Magnetism*. $PuO_2$ is a weak paramagnet, presumably due to a singlet crystal-field ground state for the $5f^4$ ionic state. With hydrogen, uranium forms a trihydride known as a ferromagnet ($T_C = 180\,\mathrm{K}$). AF order was found in $PuH_2$ ($T_N = 30\,\mathrm{K}$), whereas $PuH_3$ is ferromagnetic ($T_C = 100\,\mathrm{K}$). Neptunium hydrides are weakly paramagnetic, which can be understood as being due to CEF effects in the case of the $5f^4$ ionic state (for details see Wiesinger and Hilscher 1991). Hydrogen can be absorbed also by a number of

binary and ternary intermetallic compounds. Similar to elemental light actinides, it strongly supports the tendency to form local 5*f* magnetic moments and to give rise to magnetic order. This can at least partly be attributed to 5*f*-band narrowing due to enhanced inter-actinide spacing.

## 5. Orbital Moments in Light Actinides

Although the majority of the light actinides and their intermetallic compounds is characterized by itinerant 5*f*-states, an important difference with 3*d* magnetics is the energy of the spin-orbit coupling $\Delta_{S\text{-}O}$ and the width of the 3*d* (5*f*) band $W_{3d}$ ($W_{5f}$). Whereas $\Delta_{S\text{-}O} \ll W_{3d}$, the respective values in the light actinides become of comparable magnitude because $\Delta_{S\text{-}O}$ is of the order of eV. Due to the strong spin-orbit interaction, typically a large orbital magnetic moment $\mu_L$ is induced. It is antiparallel to the spin moment for uranium, in analogy with the light lanthanides and the third Hund's rule stating that the total angular momentum is given by $\boldsymbol{J}=\boldsymbol{L}-\boldsymbol{S}$. The existence of such orbital moments for the 5*f*-band systems was first revealed from band structure calculations involving a spin-orbit interaction term coupling the spin and orbital moment densities (see *Density Functional Theory: Magnetism*). Experimentally this was confirmed by studies of the neutron form-factor, which adopts a very specific shape with a maximum, especially if spin and orbital moments are of the same size. Such a case, at which the total moment is close to zero, but the spatial extent of spin and orbital moment densities is different, was observed, for example, in $UNi_2$ or $UFe_2$. In the latter case the uranium moment consists of the orbital part $\mu_L = 0.23\,\mu_B$ and a spin part $\mu_S = -0.22\,\mu_B$. Recently, orbital moments became accessible also in x-ray scattering studies using synchrotron radiation (see *Magnetism: Applications of Synchrotron Radiation*).

A different sensitivity of spin or orbital moments to external variables led to the assumption that the ratio of orbital and spin moment should reflect the degree of the 5*f*-delocalization. Indeed, as seen from Fig. 1, the compounds showing the least delocalized nature of the 5*f* states ($UO_2$, USb, $NpAs_2$, PuSb) are located on the line representing values of $-\mu_L/\mu_S$ of a free $5f^n$ ion. On the other hand, magnetically ordered materials with presumably the most itinerant 5*f* states ($UFe_2$, $UNi_2$, $NpCo_2$, $PuFe_2$) have this ratio close to 1.

Relatively large orbital moments induced by magnetic field exist probably even in weakly paramagnetic materials such as uranium metal. Surprisingly, in an external magnetic field the spin and orbital magnetic moments orient parallel, as shown by a simple balance of the Zeeman and spin-orbit energy in the case of weak susceptibility (for details see Sechovský and Havela 1998).

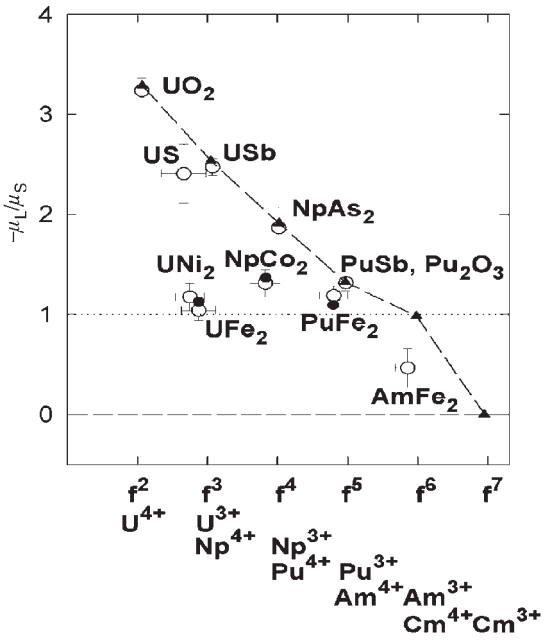

***Figure 1***
Ratio of the orbital $\mu_L$ and spin $\mu_S$ moments in a number of magnetically ordered materials plotted as a function of the number of the 5*f* electrons. The triangles, connected by a dashed line, are the values derived from single-ion theory including intermediate coupling. Experimental results are shown by open circles. Results of band structure calculations are shown by solid circles. For details see Sechovský and Havela 1998.

## 6. Exchange Interactions and Magnetic Anisotropy

Exchange interactions in materials with localized 5*f* states can be seen as being analogous to regular lanthanides, for which the indirect exchange of the RKKY type is a good approximation. The other limit, systems with strongly itinerant 5*f* states, can be understood in terms of the Stoner–Edwards–Wohlfarth theory for itinerant magnets (see *Itinerant Electron Systems: Magnetism (Ferromagnetism)*), in which the ordering temperature is proportional to the ordered moment. For intermediate delocalization, when the direct 5*f*–5*f* overlap is negligible, a dual role of the 5*f* ligand hybridization has to be taken into account. It is a primary mechanism of destabilizing the 5*f* magnetic moments, but because the spin information is conserved in the hybridization process, it leads to an indirect exchange coupling. Maximum ordering temperatures can consequently be expected for a moderate strength of hybridization, because a strong hybridization completely suppresses magnetic moments, whereas a weak one leaves the moments intact, but their coupling is weak.

A model leading to realistic results have been worked out by Cooper *et al.* (1985) on the basis of the Coqblin–Schrieffer approach. The mixing term in the hamiltonian of the Anderson type is treated as a perturbation, and the hybridization interaction is replaced by an effective *f*-electron-band-electron resonant exchange scattering. Considering an ion-ion interaction as mediated by different covalent-bonding channels, each for particular magnetic quantum number $m_l$, the strongest interaction is for those orbitals that point along the ion–ion bonding axis, which represents the quantization axis of the system. The two 5*f* ions maximize their interaction by compression of the 5*f* charge towards the direction to the nearest 5*f* ion. This has serious impacts on magnetic anisotropy, because it means a population of the 5*f* states with orbital moments perpendicular to the bonding axis. This interaction prefers a strong ferromagnetic coupling of the actinide moments along the bonding direction. There is no special general tendency to ferro- or antiferromagnetism in the perpendicular direction, where the interaction is much weaker, and can be of a size comparable to that of the "background" isotropic exchange interaction of the standard RKKY type.

Unlike such two-ion hybridization mediated anisotropy, crystal electric field (single-ion) effects control the type and strength of magnetic anisotropy for materials with the localized 5*f* states, in analogy to lanthanide systems.

The two-ion anisotropy, for which orbital moments are necessary prerequisite, has been observed especially in numerous uranium compounds, for which single-crystal magnetization data exist. The tendency for moments to orient perpendicular to the U–U bonding links leads to a uniaxial anisotropy in crystal structures with uranium atoms organized in planes with a short in-plane U–U spacing and larger inter-plane spacing. The case of uranium linear chains leads to a planar type of anisotropy (see Fig. 2). The strength of the anisotropy, which is well observable both in magnetically ordered and paramagnetic phases, can be estimated in some cases from the difference of the paramagnetic Curie temperatures (see *Magnetism in Solids: General Introduction*) when the susceptibility is studied with the magnetic field along different crystallographic directions. Another estimate can be obtained from the anisotropy field, at which the extrapolated magnetization curves along different directions would intersect each other. Typically values of $10^2$–$10^3$ K or $10^2$–$10^3$ T are obtained in this way (see Figs. 3 and 4).

For large groups of isostructural compounds, the same type of anisotropy is, as a rule, found irrespective of the non-actinide components. Examples are the strong uniaxial anisotropy of UTX compounds (with hexagonal structure of the ZrNiAl type) or tetragonal $UT_2X_2$ compounds, both with strong uranium bonding within planes perpendicular to the

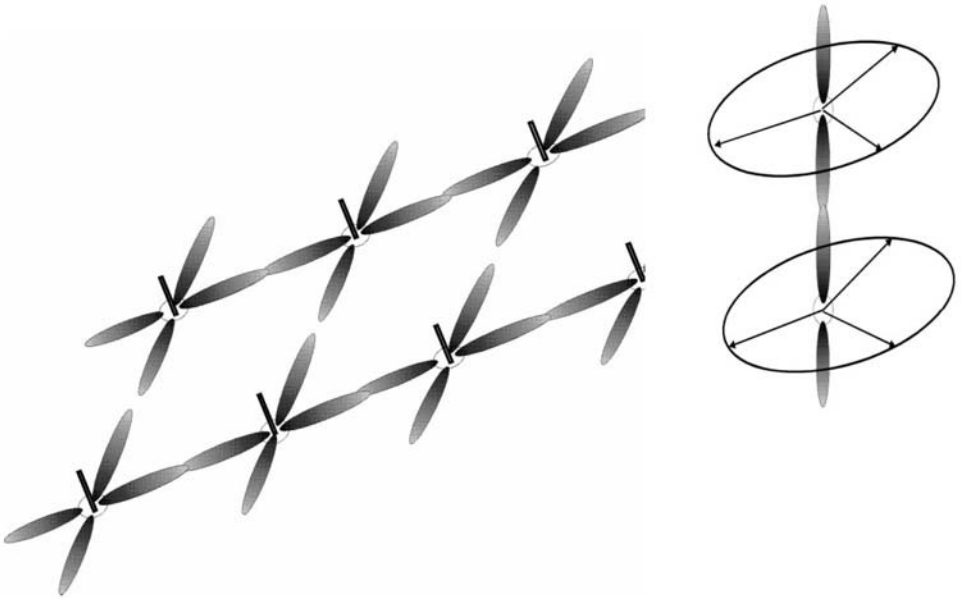

***Figure 2***
Schematic view illustrating how the bonding and easy-magnetization directions are related in light actinides. On the left, the easy-axis anisotropy for planar bonding; on the right, the easy-plane anisotropy for columnar bonding.

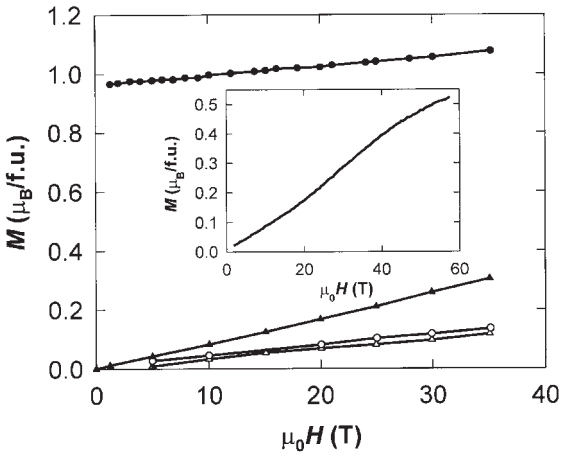

*Figure 3*
Illustration of the strong uniaxial anisotropy observed in the hexagonal UTX compounds (ZrNiAl structure type), in particular in URhAl–ferromagnet, $T_C = 27$ K (circles), and URhAl–paramagnet (triangles). Magnetization at $T = 4.2$ K was measured as a function of magnetic field applied along the *c*-axis (filled symbols) and *a*-axis (open symbols). The comparison shows that the response along the *a*-axis is practically the same, unaffected by ordered magnetic moments oriented along the *c*-axis in URhAl. The inset shows a similar experiment on field-oriented powder of URuAl extending the field range. The noticeable S-shape is attributed to the suppression of spin fluctuations in high magnetic fields (see Sechovský and Havela 1998).

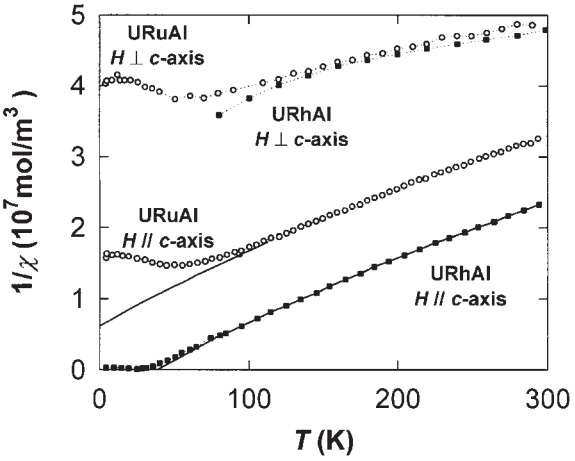

*Figure 4*
Temperature dependence of inverse magnetic susceptibility for the same materials as shown in Fig. 3, illustrating the same type of anisotropy of the paramagnetic behavior.

hexagonal (tetragonal) axis, and uranium moments (or higher susceptibility) along this axis.

## 7. Magnetic Structures

Both specific mechanisms in light-actinide materials, the magnetic anisotropy and exchange interactions, affect their magnetic structure types. Strong anisotropy frequently leads to collinear modulated structures (spin-density waves), which are preferred over noncollinear equal moment structures. The reason is that the anisotropy energy is typically stronger than the exchange coupling energies. Noncollinear magnetic structures are stable if the easy-magnetization directions on different sites are noncollinear, as in $U_2Pd_2Sn$, where they are orthogonal. Also in cases in which the lattice symmetry imposes no special requirements on the moment's directions (see Sandratskii 1998), noncollinear equal-moment structures appear (e.g., UPtGe). Types of magnetic structures are also affected by the strong ferromagnetic coupling along strong bonding directions (see the hybridization-induced exchange model, above). For example, UTX compounds with hexagonal structure of the ZrNiAl type, form magnetic structures consisting of ferromagnetic basal-plane sheets, whereas the inter-sheet exchange interaction is weaker and can be of ferro- or antiferro-type, leading to a variety of stacking sequences along the hexagonal axis. In this case, ferromagnetic-like alignment can be obtained in moderate magnetic fields applied along the AF stacking direction.

# Electron Systems: Strong Correlations

The physics of strongly correlated electron systems originates primarily from the presence of an inner d or f shell in one of the atoms embedded in the system considered. The d electrons in transition elements and the 4f or 5f electrons in rare earths or actinides are generally well localized and correlated. The physics of strongly correlated electron systems is the subject of many experimental and theoretical studies and we will summarize here the main points.

The correlations tend firstly to favor the existence of magnetism which is because of open inner d or f shells, as observed in pure iron, cobalt, or nickel in the 3d series, in the rare-earth metals, and in actinide metals after americium. Magnetism is also observed in many ionic, insulating, or metallic systems containing these magnetic elements.

The generic term of strongly correlated electron systems is mostly reserved to metallic systems where there exists a strong interaction or hybridization between the inner d or f electrons and the conduction electrons. This type of physics started from the experimental observation of the resistivity minimum in dilute alloys such as CuFe, CuMn, LaCe, or YCe, the theoretical concept of ''virtual bound state'' introduced by Friedel (1956), 1958), the derivation of the hybridization Anderson (1961) model, and the explanation by Kondo (1964) of the resistivity minimum. After the exact solution of the Kondo effect at low temperatures for a single impurity (Wilson 1975), there are many topics involved in the physics of strongly correlated electron systems. The main topic concerns the so-called ''heavy-fermion'' behavior observed in many cerium or other anomalous rare-earth compounds, after its first observation in $CeAl_3$ (Andres *et al*. 1975). In the ''Kondo lattice,'' there exists a strong competition between the Kondo single impurity behavior and the magnetism, and the behavior around the quantum critical point of the Doniach (1977) diagram has been extensively studied.

The metal–insulator transition, introduced by the work of Mott (1974), and the study of compounds such as manganites are also a very important part of this type of physics. The discovery of superconductivity in the $CeCu_2Si_2$ compound by Steglich *et al.* (1979), and in some cerium compounds at high pressure and uranium compounds at normal pressure is also a very noteworthy result. Strong correlations appear to be the origin of the high $T_c$ superconductivity, which was discovered by Bednorz and Muller (1986), but this question is still not answered. Finally, the study of strongly correlated electron systems has considerably contributed to the development of new experimental techniques, such as high-accuracy photoemission or related experiments, neutron scattering, and NMR or muon spectroscopy, as well as to all kinds of magnetic and transport measurements at extremely low temperature and high pressures, and under very large magnetic fields.

## *1. The Series of Rare-earth and Actinide Metals*

The first systems studied that could be considered as strongly correlated electron ones were dilute alloys with 3d transition element impurities embedded in a host such as copper; now the most studied systems contain rare earths and actinides.

Most of the rare-earth metals have a magnetic moment given by Hund's rules (see *Magnetism in Solids: General Introduction* and *Localized 4f and 5f Moments: Magnetism*), corresponding to the $4f^n$ ($n$ an integer) configuration. For example, gadolinium, in the middle of the series, has a $4f^7$ configuration with a magnetic moment equal to $7\,\mu_B$ in the ferromagnetic phase below the Curie temperature of 293 K, and there is no change in the number of 4f electrons under pressure, even a very high one. It follows that the ''valence,'' taken here as equal to the number of conduction electrons, remains constant and equal to 3. Thus, most of the rare-earth metals have a stable valence of 3 and are called ''normal'' (Coqblin 1977).

However, some rare-earth metals undergo a change of valence under different experimental conditions (pressure, temperature, or relative composition in the case of alloys and compounds containing these metals) and they are called ''anomalous.'' The best example of the series is cerium, the first element after lanthanum, which varies or fluctuates between the two configurations $4f^0$ and $4f^1$. Cerium metal has a very peculiar phase diagram with several phases,

which is discussed below. However, dilute cerium alloys such as LaCe or YCe, which are magnetic with a magnetic moment corresponding to the $4f^1$ configuration, show at low temperatures a resistivity minimum which was first accounted for by Kondo (1964). This Kondo effect, which has since been observed in many alloys and compounds containing cerium or other anomalous rare earths, has been the subject of many studies.

The actinide series (see *5f Electron Systems: Magnetic Properties*) corresponds to the filling of the 5f inner shell, but clearly the 5f electrons are less localized than the 4f electrons of the rare-earth metals. In fact, the degree of localization of the 5f electrons lies between that of the 4f electrons and that of the d electrons of the transition elements. The actinide metals of the first series up to americium are not magnetic and magnetism arises only in the middle of the series for curium. Thorium and protactinium, at the beginning of the series, are not magnetic. Uranium, neptunium, and plutonium are close to being magnetic, and most of the properties of neptunium and plutonium can be accounted for by the classical model of spin fluctuations. Finally, the ionic model becomes valid for americium and the following actinides; americium is not magnetic because of the presence of the $5f^6$ configuration, while the following two actinides have magnetic moments corresponding to the $5f^7$ and $5f^8$ configurations. A strong hybridization between the 6d and 5f electrons, which yields an effective broadening of the 5f band and gives a nonmagnetic situation, has been proposed to explain this phenomenon (Jullien *et al*. 1972). Many compounds of uranium, neptunium, and plutonium have been studied and various physical situations have been observed, from a clear magnetic situation with a magnetic order at low temperatures to a nonmagnetic, heavy-fermion situation. Moreover, some uranium compounds are both magnetically ordered, with a heavy-fermion behavior, and superconducting at low temperatures.

## 2. *The Friedel Sum Rule and the Anderson Hamiltonian*

As previously explained, transition or rare-earth elements in dilute alloys can be magnetic and in an ionic configuration, but many dilute alloys or compounds contain d or f elements that are in an intermediate situation. This is typically the case for CuMn alloys or cerium compounds. There is a strong interaction between the localized electrons (d or f) on the impurity sites and the conduction electrons that are almost free in the lattice and are generally scattered by the localized electrons. Localized magnetism on the impurity comes from the Coulomb integral, $U$, and the criterion for the occurrence of localized magnetism is $U\rho(E_F) > 1$, corresponding, therefore, to strong electron correlations and a large density of states, $\rho(E_F)$, at the Fermi energy. Pioneering work discussing this problem provided the "Friedel sum rule" (Friedel 1954), which connects the difference of charge, $Z$, between the localized electrons on the impurity and the conduction electrons to the phase shifts introduced by the scattering of the conduction electrons. For example, in CuMn dilute alloys, $Z$ represents the difference of charge between copper and manganese and corresponds to essentially the difference in occupation of the 3d shell.

The Friedel sum rule gives a relationship between $Z$ and the phase shifts, $\delta_l$, at the Fermi energy corresponding to the different partial wave functions scattered by the impurity:

$$Z = \frac{1}{\pi}\sum_{l,\sigma}(2l+1)\delta_l^\sigma \tag{1}$$

The phase shifts correspond to the different $l$ values of the orbital momentum. Friedel (1956, 1958) developed the model of "virtual bound state" to describe the case of dilute aluminum- or copper-based alloys with 3d impurities. The only nonzero (or multiple of $\pi$) phase shift is that of $l=2$ and $\delta_2$ increases from 0 to $\pi$ when the 3d shell fills up, passing roughly through a maximum value of $\pi/2$ for manganese. Since the residual resistivity varies as $\sin^2\delta_2$, this derivation explains the maximum of the residual resistivity observed in the 3d series for aluminum-based dilute alloys with 3d impurities. The same type of derivation explains the two maxima observed in the case of copper-based alloys that are magnetic, because there are two different phase shifts for the two spin directions.

Anderson (1961) introduced a Hamiltonian given by

$$H = \sum_{k,\sigma}\varepsilon_k n_{k\sigma} + E_0\sum_\sigma n_{f\sigma} + U n_{f\uparrow}n_{f\downarrow} + \sum_{k,\sigma}(V_{kf}c^*_{k\sigma}c_{f\sigma} + V_{fk}c^*_{f\sigma}c_{k\sigma}) \tag{2}$$

where the 3d (or 4f or 5f) level located at the energy $E_0$ is hybridized with the conduction electrons by the hybridization parameter $V_{kf}$. The Coulomb integral, $U$, for the localized electrons is generally taken as very large, corresponding, therefore, to the case of strong correlations. For a single impurity, the density of states for the localized electrons has a Lorentzian shape with a width of $\Delta = \pi\rho_s V_{kf}^2$ (where $\rho_s$ is the density of states of the conduction band at the Fermi energy), which leads to a nonintegral number of localized electrons. The Hamiltonian is self-consistently solved within the Hartree–Fock approximation and this model has also been applied to describe the occurrence of magnetism in transition element-based alloys. For example, CuMn alloys are magnetic while AlMn alloys are not, because the density of states at

the Fermi energy, $E_F$, for the localized electrons hybridized with the conduction electrons is larger in copper than in aluminum.

### 3. The Kondo Effect

The starting point of the history of the Kondo effect is the first calculation performed by Kondo (1964) to account for the observed experimental evidence of a resistivity minimum in magnetic dilute alloys such as CuMn, CuFe, YCe, or LaCe. The first observed resistivity minimum in CuFe dates from 1931. In such dilute alloys, the transition element impurities are magnetic and the system is well described by the classical exchange Hamiltonian given by

$$H = -\boldsymbol{J}\boldsymbol{s}_c\boldsymbol{S}_f \tag{3}$$

where the localized spin, $\mathbf{S_f}$, on the impurity interacts with the spins, $\mathbf{s_c}$, of the conduction electrons coming from the host. The exchange constant, $J$, can be either positive (corresponding to a ferromagnetic coupling) or negative (antiferromagnetic coupling). It follows that a localized spin, $\mathbf{S_f}$, on site $i$ interacts with another localized spin on site $j$ by an indirect mechanism involving the conduction electrons through the exchange interaction given by Eqn. (3). This indirect interaction between two localized electron spins is called the "Ruderman–Kittel–Kasuya–Yosida" (RKKY) interaction (Ruderman and Kittel 1954). The RKKY interaction (see *Magnetism in Solids: General Introduction*) decreases as a function of the distance, $R$, between the two sites $i$ and $j$ as $\cos(k_F R)/(k_F R)^3$.

Kondo computed the magnetic resistivity, $\rho_m$, up to third order in $J$ (or in second-order perturbation) and found the following:

$$\rho_m = A|J|^2 S(S+1)\left[1 + J\rho\log\left(\frac{k_B T}{D}\right)\right] \tag{4}$$

where $\rho$ is the density of states for the conduction band at the Fermi energy, $A$ is a constant, and $S$ is the value of the spin for the localized electrons. We see that, for a negative $J$ value, the magnetic resistivity decreases with increasing temperature. Thus, the total resistivity, which is the sum of the magnetic resistivity and the phonon resistivity which increases with temperature, passes through a minimum (Kondo 1964, 1969). A negative $J$ value corresponds to an antiparallel coupling between the localized and conduction electron spins and the preceding treatment is valid only at sufficiently high temperatures above the so-called "Kondo temperature," $T_k$, given by

$$k_B T_k = D\exp\left(-\frac{1}{|J\rho|}\right) \tag{5}$$

where $D$ is a cut-off corresponding roughly to the conduction band width. The magnetic susceptibility decreases above $T_k$ as $1/T$, as in a Curie–Weiss law (see *Magnetism in Solids: General Introduction*). The different transport, magnetic, and thermodynamic properties of a Kondo impurity have been extensively studied by perturbation in the so-called "high-temperature" regime (i.e., above $T_k$). It is clear that, below $T_k$, the perturbative treatment is not valid and the low-temperature behavior is completely different from the previously described high-temperature behavior.

At "low temperatures" ($T \ll T_k$), a so-called heavy-fermion behavior (see Heavy-fermion Systems) has been observed in many cerium Kondo compounds, such as $CeAl_3$, $CeCu_6$, or $CeCu_2Si_2$. This behavior was first observed experimentally in $CeAl_3$, where Andres *et al.* (1975) found an extremely large electronic specific heat constant $\gamma = 1.62\,\mathrm{J mol^{-1} K^{-2}}$ and an $AT^2$ law for the resistivity with a very large coefficient $A = 35\,\mu\Omega\mathrm{cm K^{-2}}$. An extremely high value of $\gamma = 8\,\mathrm{J mol^{-1} K^{-2}}$ has been obtained in the YbBiPt compound, which is the maximum observed $\gamma$ value (Lacerda *et al.* 1993).

The theoretical problem of a single Kondo impurity has been exactly solved at $T = 0$ by Wilson (1975) using the renormalization group technique on the exchange Hamiltonian (Eqn. (3)) with a negative $J$ value. Wilson was the first to show numerically that the exact $T = 0$ solution is a completely compensated singlet formed by the antiparallel coupling between the conduction electron spin, $s_c = 1/2$ , and the localized electron spin, $S_f = 1/2$. An analytical exact solution of the single Kondo impurity problem has been obtained by the Bethe–Ansatz method for both the classical exchange and the Coqblin–Schrieffer Hamiltonians (Andrei *et al.* 1983, Schlottmann 1982, Tsvelick and Wiegmann 1982). The exact solutions have given a clear description of the Kondo effect, but since it is difficult to use them for computing the different physical properties, sophisticated mean field-type methods have been introduced, such as the "slave boson" method (Read and Newns 1983, Coleman 1984) or the method using correlators (Lacroix and Cyrot 1979). A dynamical mean-field theory that takes the limit of infinite dimension (or a very large lattice coordination number) has been introduced because this limit can yield an exact mapping of lattice models onto quantum impurity models (Georges *et al.* 1996). We can also mention many works describing dynamical effects or spectroscopic properties and both the impurity Kondo and Anderson problems including dynamical properties have been solved by different theoretical techniques, in particular by the renormalization group technique (Allen *et al.* 1986). There is a tremendous literature on this subject and the reader can find very interesting reviews in Hewson (1992) or Bickers (1987).

The low-temperature (i.e., $T \ll T_k$) properties of a Kondo impurity are those of a "Fermi liquid" and can be summarized as follows:

- The electronic specific heat constant, $\gamma$, and the magnetic susceptibility, $\chi$, are much larger than those corresponding to normal magnetic behavior, but the Wilson ratio, $R = \gamma/\chi$, remains constant between 1 and 2 in suitable units. The values of $\gamma$ are typically of the order of $1000\,\mathrm{mJmol^{-1}K^{-2}}$ in the case of compounds that remain nonmagnetic at low temperatures and of the order of $100\,\mathrm{mJmol^{-1}K^{-2}}$ in the case of compounds which order magnetically. The term "heavy fermions" originates from these high values of $\gamma$ and $\chi$, and Table 1 gives some examples of heavy-fermion systems (see *Heavy-fermion Systems*).
- Direct evidence of the heavy-fermion behavior has been obtained by de Haas van Alphen effect experiments in many Cerium compounds, such as $CeCu_6$, $CeB_6$, and $CeRu_2Si_2$, and some uranium compounds. An effective mass up to roughly $100m_e$ (where $m_e$ is the electron mass) has been observed in cerium compounds (Onuki and Hasegawa 1995).
- The transport properties of cerium Kondo compounds are described by the Fermi liquid formalism at low temperatures. In particular, the electrical resistivity follows a $T^2$ law and the coefficient, $A$, of this term is particularly large in heavy-fermion systems.

The exchange Hamiltonian (Eqn. (3)) describes well the case of a magnetic impurity embedded in a normal matrix. The Anderson Hamiltonian (Eqn. (2)) is in fact richer, because it can describe different situations, such as the nonmagnetic and the magnetic case or the intermediate valence (see *Intermediate Valence Systems*) and the almost integer valence. However, in the special case of a magnetic impurity with a valence close to an integer (3 in the cerium case), Schrieffer and Wolff (1966) have shown that the Anderson Hamiltonian is equivalent to a Kondo Hamiltonian with a $J$ value given by

$$J = -\frac{|V_{kf}|^2}{|E_0 - E_F|} \tag{6}$$

and we immediately see that the $J$ value is negative. Thus, this so-called Schrieffer–Wolff transformation allows one to show that the Anderson Hamiltonian in the almost ionic limit yields automatically a negative $J$ value and, therefore, the Kondo effect.

***Table 1***
Some examples of heavy-fermion compounds.

| Compound | Crystal structure (ground state) | CEF splitting (K) | $T_N$ (K) | $\gamma$ ($\mathrm{mJmol^{-}K^{-2}}$) |

### *4. The Case of Cerium Metal and Compounds: The Introduction of Spin and Orbital Magnetism*

The Anderson and the exchange Hamiltonians have been used to describe the situation of magnetic systems with only a spin magnetic moment and a quenched orbital magnetic moment, as in the alloys with 3d transition elements, where we deal with $S = 1/2$ or $S = 5/2$ spins. However, the physical situation of rare earths is more complicated, because the magnetic moment has both spin and orbital components and the states are labeled according to the $z$-components of the total angular momentum $J = L + S$. For example, in magnetic cerium systems, the spin–orbit is sufficiently large to split the $4f^1$ configuration into a ground state $J = 5/2$ and an excited state $J = 7/2$. Then, the six-fold degenerate level $J = 5/2$ is split by the crystalline field effect which has a typical energy splitting of the order of 100 K and, therefore, of the same order as the usual temperature of the experiment. Thus, both the orbital degeneracy and the crystalline field effect are important in the study of anomalous rare earths like cerium or ytterbium, which have the configurations $4f^1$ and $4f^{13}$, respectively (see *Localized 4f and 5f Moments: Magnetization*).

Thus, it is necessary to include the orbital degeneracy owing to the seven orbitals corresponding to $l = 3$ and $m = l_z = -3, -2, -1, 0, +1, +2, +3$. The Anderson Hamiltonian including the orbital degeneracy is given by

$$H = \sum_{k,\sigma} \varepsilon_k n_{k\sigma} + E_0 \sum_{m,\sigma} n_{m\sigma} + \sum_{k,m,\sigma} (V_{km} c^*_{k\sigma} c_{m\sigma} + V_{mk} c^*_{m\sigma} c_{k\sigma}) + \frac{1}{2} \sum_{m,m',\sigma(m \neq m')} (U_{mm'} - J_{mm'}) n_{m\sigma} n_{m'\sigma} + \frac{1}{2} \sum_{m,m',\sigma} U_{mm'} n_{m\sigma} n_{m'-\sigma} \quad (7)$$

This Hamiltonian has been used to explain the phase diagram of cerium metal, which provides a very fascinating example of many features of strong correlations. Cerium, the first element in the series after lanthanum, varies or fluctuates between the two configurations $4f^0$ and $4f^1$. The phase diagram of cerium metal, shown in Fig. 1, is very peculiar and has several phases (Jayaraman 1965). The phase occurring at normal temperature and pressure is the $\gamma$ phase, which is paramagnetic with a magnetic moment of roughly 2.5 $\mu_B$ corresponding to a valence of 3 and a $4f^1$ configuration. The $\alpha$ phase which exists at high pressure is not magnetic and has a valence larger than 3, and is an "intermediate valence" phase. The $\gamma$–$\alpha$ transition is of first order at room temperature, but the intensity of this transition decreases with increasing pressure and tends to zero at a critical point, $C$, of the order of 600 K and 20 kbar. Thus, the existence of a critical point is unique in pure metals and looks like that of the liquid–vapor diagram. At low temperatures, the $\beta$ phase orders antiferromagnetically at roughly 12 K, while at very high pressures above 50 kbar, cerium undergoes another phase transition to the $\alpha'$ phase, which becomes superconducting at very low temperatures. At high temperatures, the $\delta$ phase has a transition temperature that decreases with increasing pressure.

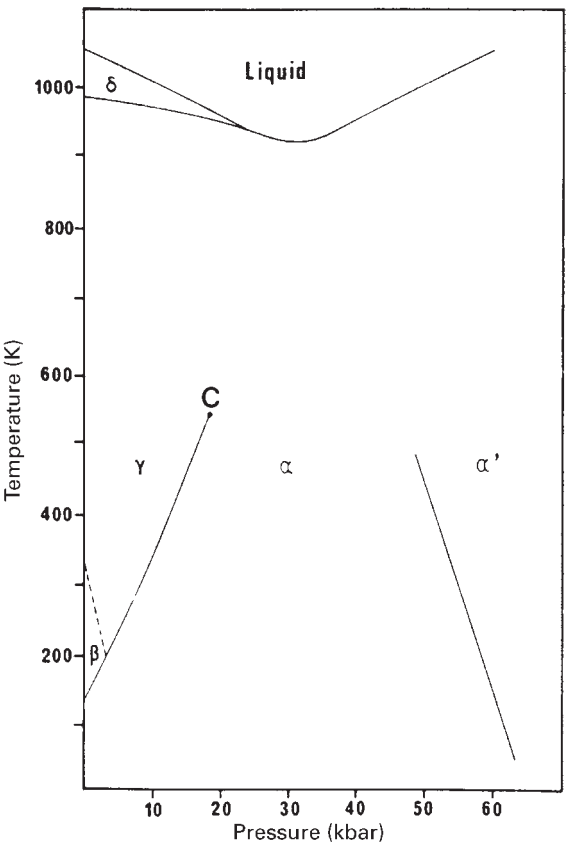

***Figure 1***
Phase diagram of cerium metal.

The theoretical explanation of the $\gamma$–$\alpha$ transition of cerium with the existence of a critical point has been the subject of several explanations and many discussions. One explanation of the $\gamma$–$\alpha$ transition is based on a Hartree–Fock treatment of the Hamiltonian of Eqn. (7) and yields a first-order transition accompanied by a change of valence from the magnetic trivalent $\gamma$-cerium to the nonmagnetic $\alpha$-cerium that has an intermediate valence of the order of 3.5 (Coqblin and Blandin 1968). Another explanation is based on the Kondo effect with a very large Kondo temperature for the $\alpha$ phase (Allen and Martin 1982, Lavagna *et al.* 1983) and sophisticated band calculations have been performed to account for the phase diagram of cerium (Svane 1996). There have also

been many experiments, in particular those yielding spectroscopic data, that give an estimate of the valence change in cerium.

In the so-called "Kondo limit," i.e., when the number of 4f electrons (or holes) is close to 1, corresponding to the $4f^1$ configuration of cerium (or the $4f^{13}$ configuration of ytterbium), an effective Hamiltonian has been derived using the Schrieffer–Wolff transformation (Coqblin and Schrieffer 1969). We start from the Anderson Hamiltonian with orbital degeneracy and a large spin–orbit coupling. Thus, we define the operators $c_M$ that destroy a localized 4f electron in the $l=3$, $s=1/2$, $j=5/2$ for cerium ($j=7/2$ for ytterbium), and $j_z=M$ state. Then, the only conduction electrons that are hybridized with the 4f electrons correspond to the partial waves with the same quantum numbers, because the hybridization parameter mixes only localized and conduction electrons with the same values of $l$, $s$, $j$, and $j_z$. Thus, the resulting so-called "Coqblin–Schrieffer" Hamiltonian can be written as follows:

$$H = -\sum_{k,k',M,M'} J_{MM'} c^*_{k'M'} c_{kM} c^*_M c_{M'} + \sum_{k,k',M} V_{MM} c^*_{k'M} c_{kM} \tag{8}$$

with the exchange parameters given by

$$J_{MM'} = \frac{1}{2} |V_{kf}|^2 \left( \frac{1}{E_M} + \frac{1}{E_{M'}} \right) \tag{9}$$

When the crystalline field effect is not considered there is a unique exchange parameter corresponding to the unique value, $E_0$, of the 4f level compared to the Fermi level, $E_F$. However, $J_{MM'}$ are not equal to a unique value when the crystalline field is considered; for example, a cubic crystalline field splits the $j=5/2$ state into a doublet $\Gamma_7$ of energy $E_1$ and a quartet $\Gamma_8$ of energy $E_2$ and there are three different exchange integrals $J_{11}$, $J_{22}$, and $J_{12}$.

The Coqblin–Schrieffer Hamiltonian including crystalline field effects has been extensively used to derive many transport and magnetic properties of cerium Kondo compounds. The magnetic resistivity (Cornut and Coqblin 1972), calculated by perturbation theory at "high temperatures," i.e., for $T > T_k$, for a cubic crystalline field of energy splitting $\Delta$, shows a maximum at a temperature roughly equal to $\Delta$ and two log $T$ behaviors above and below $\Delta$. The slopes of these log $T$ behaviors are characteristic of the respective degeneracies, $\alpha_i$, of the levels:

$$\frac{d\rho_i}{d\log T} = A_0 \rho J^3 \frac{\alpha_i^2 - 1}{4j(j+1)} \tag{10}$$

where $A_0$ is a constant independent of $\alpha_i$.

Figure 2 shows the log $T$ plot of the magnetic resistivity, $\rho_m$, of the $CeAl_2$ compound (Nicolas-Francillon *et al.* 1972). At low temperatures, $CeAl_2$ becomes antiferromagnetic at $T_N = 3.85$ K and the magnetic resistivity drops rapidly below $T_N$. Figure 2 also shows the large effect of pressure: the absolute value of the log $T$ slopes increases rapidly with pressure, which is accounted for by a decrease of $|E_M|$ and an increase of $|J_{MM'}|$ with pressure. Although the results of Fig. 2 were obtained some time ago, they are worth presenting here because they were probably the first to show very well the effects of both the crystalline field and the pressure. These effects have been observed subsequently in other transport and magnetic properties and have been found in many cerium compounds (Coqblin *et al.* 1993).

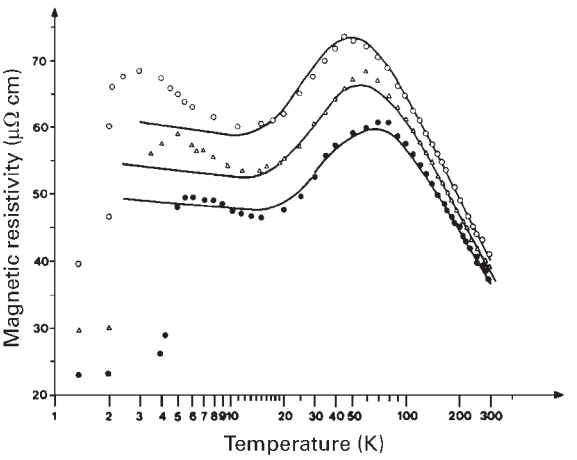

***Figure 2***
Magnetic resistivity of $CeAl_2$ vs. log $T$ at normal pressure (•), 8 kbar (△), and 16 kbar (○). The lines correspond to the theoretical calculations according to Nicolas-Francillon *et al.* (1972).

The decrease of the magnetic resistivity in log $T$ is considered as a clear signature of the Kondo effect in magnetic cerium compounds and has been observed in more than 100 compounds (Coqblin *et al.* 1996). The increase of the absolute value of the log $T$ slope is also characteristic of the pressure effect in cerium Kondo compounds. Moreover, the available highest pressures are now much larger and there exist new experiments on such cerium or ytterbium compounds. In fact, the values of $|J_{MM'}|$ first increase with pressure, then at very high pressures they pass through a maximum and then decrease, finally yielding a nonmagnetic state at very high pressures, as for example in YCe alloys (Maple and Wittig 1971).

## 5. *Heavy-fermion Compounds*

In the series of rare-earth metals, three are anomalous in the sense that they do not have a stable valence of 3. Cerium has a very peculiar phase diagram with intermediate valence phases, while europium and

ytterbium metals are divalent under normal conditions of temperature and pressure. Thus, as discussed below, many cerium and ytterbium alloys or compounds and only a few europium-based systems have an anomalous behavior.

An anomalous behavior has also been observed in alloys or compounds containing three other rare earths which are trivalent normal metals: praseodymium ($4f^2$), samarium ($4f^5$), and thulium ($4f^{12}$). However, no anomalous behavior has been detected and consequently the normal trivalent character remains very stable even at very high pressures in systems with the other rare earths and in particular with the heavy ones (gadolinium, terbium, dysprosium, holmium, and erbium) (Coqblin 1977).

Examples of anomalous behavior are known for systems containing praseodymium, samarium, or thulium. For example, $PrSn_3$ and TmS show a decrease of the magnetic resistivity characteristic of the Kondo effect. SmS shows, under pressure, a metal–insulator transition that is accompanied by a valence change. TmSe, which is insulating at low temperatures in the antiferromagnetic domain, has an intermediate valence, roughly equal to 2.5 at stoichiometry and varying with the departure from stoichiometry. A semiconducting or low carrier behavior has also been observed in other compounds, such as CeNiSn, $SmB_6$, and cerium or ytterbium pnictides.

We now discuss cerium and ytterbium compounds that have a Kondo or heavy-fermion behavior. In fact, there are more than 100 of such compounds, which are reviewed elsewhere (Coqblin *et al.* 1996). Moreover, there are several types of cerium and ytterbium systems, depending on the valence (i.e., intermediate valence and Kondo systems have clearly different behaviors), on the existence of a magnetic moment (yielding a Curie–Weiss law at sufficiently high temperatures), and on the existence of a magnetic order at low temperatures. For example, when $x$ increases, the compound $CeSi_x$ passes through several situations: first a Kondo system which orders antiferromagnetically at low temperatures, then the Néel temperature tends to zero and the compound is no longer magnetically ordered but still magnetic at high temperatures, and finally a nonmagnetic intermediate valence state is reached (Lee *et al.* 1987).

We now discuss the case of Kondo systems that have a heavy-fermion behavior. Table 1 gives some examples of heavy-fermion compounds of cerium, ytterbium, and uranium, with the corresponding values of the crystalline field splittings deduced from the high-temperature behavior, the Néel temperatures when the compounds order, and the very low-temperature values of $\gamma$. In fact, it is difficult in some cases to estimate the values of $\gamma$, which are not really constant at low temperatures. In spite of these possible difficulties, the values of $\gamma$ given in Table 1 are very large and characteristic of the heavy-fermion behavior. The cerium compounds that order magnetically at low temperatures generally show an antiferromagnetic order and only some of them (such as $Ce_3Al_{11}$ in Table 1) order ferromagnetically.

A similar behavior is observed in ytterbium compounds, except that the effect of pressure is reversed. When pressure is applied, the system goes from a nonmagnetic to a magnetically ordered state, and the Néel temperature increases with pressure, as, for example, observed in $YbCu_2Si_2$ (Jaccard *et al.* 1999). There are also examples of heavy-fermion compounds of uranium. Table 1 includes the compound $U(Pt_{0.95}Pd_{0.05})_3$ that orders antiferromagnetically at 6 K because the parent compound $UPt_3$ seems to have a very peculiar short-range magnetic order, as observed by sophisticated neutron scattering or muon spectroscopy experiments (Koike *et al.* 1999). The three uranium compounds listed in Table 1 have a fascinating behavior, because they combine a heavy-fermion behavior with an antiferromagnetic order and a superconducting state; this last point is discussed in Sect. 7. Finally, very large values of $\gamma$ have been found in the two compounds $YMn_2$ and $LiV_2O_4$ containing 3d transition elements. Table 1 gives the corresponding values of $\gamma$ for these compounds as well as, for example, for the actinide compound $NpSn_3$, which orders antiferromagnetically at low temperatures. The heavy-fermion character of actinide systems is also a very interesting subject that can be connected to the multichannel Kondo effect (see also *Heavy-fermion Systems*).

## 6. *Competition Between the Kondo Effect and Magnetism: The Doniach Diagram*

The competition between the Kondo effect on each atom, which tends to suppress the magnetic moment with decreasing temperature, and the RKKY interaction, which, on the contrary, tends to give a magnetic ordering between different rare-earth atoms is described by the well-known "Doniach diagram" (Doniach 1977), as shown in Fig. 3. Let us call $T_{\mathrm{ko}}$ the Kondo temperature for a single impurity and $T_{\mathrm{No}}$ the Néel (or Curie in a few cases) temperature as if there were no Kondo effect. For the exchange Hamiltonian (Eqn. (3)), $T_{\mathrm{ko}}$ is proportional to $\exp(-1/|J\rho|)$ and $T_{\mathrm{No}}$ to $|J\rho|^2$, where $\rho$ is the density of states for the conduction band at the Fermi energy. Thus, for small $|J\rho|$ values, $T_{\mathrm{No}}$ is larger than $T_{\mathrm{ko}}$ and the system tends to order magnetically, often with a reduction of the magnetic moment owing to the Kondo effect. On the contrary, for large $|J\rho|$, $T_{\mathrm{ko}}$ is larger than $T_{\mathrm{No}}$ and the system tends to become nonmagnetic and does not order magnetically. The real ordering temperature, $T_{\mathrm{N}}$, therefore increases initially with increasing $|J\rho|$, then passes through a maximum, and tends to zero at a critical value, $|J\rho|_{\mathrm{c}}$, corresponding to the so-called "quantum critical point" (QCP) I of Fig. 3.

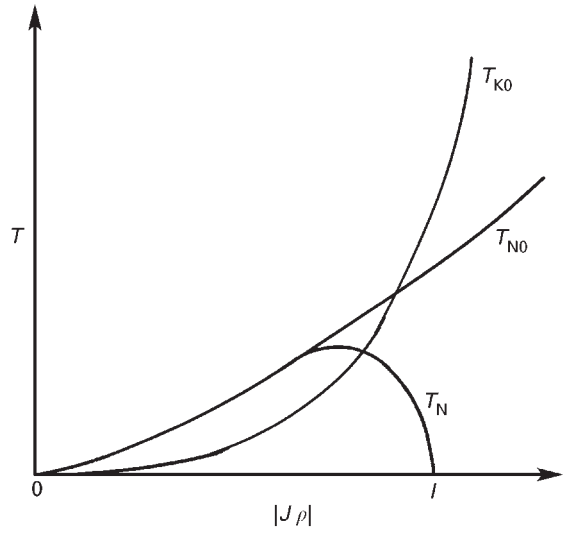

***Figure 3***
The Doniach diagram.

Such behavior of $T_N$ has been experimentally observed with increasing pressure in several cerium Kondo compounds, such as $CeAl_2$, CeAg, $CePd_2Al_3$, CePtGa, $CeIn_3$, $CePd_2Si_2$, $CeAu_2Si_2$, $CeCu_2$, and $CeRh_2Si_2$. A maximum in the ordering temperature has been observed in some of them, such as CeAg, which is ferromagnetic, or $CePd_2Al_3$, but in all these compounds, the Néel temperature decreases and tends to zero at high pressures. A similar variation of $T_N$ has been observed in $Ce(Ru_xRh_{1-x})_2Si_2$ with a variation of the relative concentration $x$. In the compounds mentioned above there is no change of valence, but another type of transition to an intermediate valence and eventually to a nonmagnetic state has been observed in the systems $CeSi_x$, $CeNi_xPt_{1-x}$, and $Ce(Cu_xPd_{1-x})_2Si_2$.

Above the QCP corresponding to the magnetic–nonmagnetic instability (or to the disappearance of the Néel temperature, $T_N$), several behaviors have been observed: a departure from the Fermi liquid (FL) behavior, called "Non-Fermi liquid" (NFL), has been observed experimentally in many cerium compounds under high pressure, such as $CeCu_{6-x}Au_x$ or $Ce_7Ni_3$ (see *Non-Fermi Liquid Behavior: Quantum Phase Transitions*). For example, $CeCu_{5.8}Au_{0.2}$ alloys (Löhneysen *et al*. 1997) are magnetic with a Néel temperature equal to 0.25 K at normal pressure and become nonmagnetic above 3.2 kbar. Above this critical pressure, the electronic specific heat constant, $\gamma$, decreases logarithmically vs. temperature and the slope of $\gamma$ vs. log $T$ decreases with pressure, i.e., when one goes farther away from the QCP. A similar behavior is observed in the compound $Ce_7Ni_3$ (Umeo *et al*. 1996), which shows successively a magnetic ordering up to roughly 3 kbar, then a NFL behavior up to roughly 6–7 kbar, and finally a FL behavior at higher pressures with a coefficient of the resistivity $T^2$ law decreasing rapidly with pressure and disappearing above 12 kbar. The NFL behavior of the Kondo lattice near the magnetic instability has been theoretically studied within the scaling theory of critical phenomena (Continentino *et al*. 1989) and within the self-consistent renormalized theory of spin fluctuations (Moriya and Takimoto 1995). This latter theory predicts a log $T$ law for $\gamma$ and a $T^{3/2}$ law for the magnetic resistivity, $\rho_m$, just at the QCP. As one goes farther away from the QCP, the behavior tends to return to FL behavior, with a decrease of the log $T$ slope of $\gamma$ and a power law for $\rho_m$ approaching the $T^2$ law.

In fact, the FL behavior exists above the QCP in some cerium compounds, such as $CeRh_2Si_2$, and the real Kondo temperature has been found to remain roughly constant with $|J|$ or with pressure in the nonmagnetic domain. A theoretical model taking into account both the intrasite Kondo interaction and an additional intersite Heisenberg-type interaction can explain the observed decrease of the real Kondo temperature with respect to the one-impurity Kondo temperature, as a function of the increase of the intersite interaction (Iglesias *et al*. 1997) and of the decrease of the number of conduction electrons (Coqblin *et al*. 2000). The latter result corresponds to the idea of "exhaustion" (Nozieres 1999), which yields a decrease of the Kondo effect when there are not enough conduction electrons to screen the localized electrons. The separation between the FL and the NFL behaviors above the QCP, which depends on the cerium compounds considered, is still a subject of research, but it has been proposed that the FL–NFL separation temperature increases with $|J|$ above the QCP (Continentino *et al*. 1989).

There are in fact several different NFL behaviors, in contrast to the obviously unique FL behavior, and also several theoretical explanations for such experimentally observed NFL behaviors. In addition to the NFL behavior directly connected to the proximity to the QCP described above, a second observed NFL behavior is because of an effect of the disorder. A simple model of a disordered Anderson lattice has been proposed and the disorder introduces a distribution of Kondo temperatures. This simple mechanism leads to logarithmic behaviors in thermodynamic properties and a linear temperature dependence of the resistivity (Miranda *et al*. 1997), as experimentally observed in some cerium and uranium alloys.

The third case of NFL behavior observed in cerium and uranium compounds arises from the so-called "multichannel Kondo model" (Nozieres and Blandin 1980). The regular Kondo effect corresponds to a complete screening of the localized electrons by the conduction electrons, while the multichannel Kondo effect corresponds to either an underscreening or to an overscreening of the localized electrons by the

conduction electrons. The multichannel Kondo model for a single impurity has been completely solved analytically by the Bethe–Ansatz method and numerical solutions have been obtained to describe the different physical properties (Schlottmann and Sacramento 1993).

In the "underscreened" Kondo effect with $2S > n$ (where $n$ is the number of channels for conduction electrons), a part, $n/2$, of the impurity spin is compensated, while the part $S' = S - n/2$ is not compensated. It follows that the magnetic susceptibility is diverging in $1/T$, as for a Curie law, which is obviously different from the constant magnetic susceptibility obtained at low temperatures for the regular screened Kondo effect ($2S = n$). A ferromagnetic coupling between the resulting spin $S'$ and the conduction electron spin is finally obtained in the underscreened Kondo model.

In the "overscreened" Kondo effect with $2S < n$, there remain $(n - 2S)$ uncoupled conduction electrons and the spin, $S' = n/2 - S$, is antiparallel to $S$. The magnetic susceptibility, $\chi$, and the electronic specific heat constant, $\gamma$, have been numerically computed (Schlottmann and Sacramento 1993). For $S = 1/2$, constant values of $\chi$ and $\gamma$ are obtained at low temperatures for the screened Kondo effect corresponding to $n = 1$. Conversely, for $S = 1/2$ and $n = 2$, a logarithmic dependence of $\chi$ and $\gamma$ is obtained, while for $S = 1/2$ and $n > 2$, the temperature dependence of $\chi$ and $\gamma$ is given by a power law in $T^n$. A particular model within the overcompensated case is the "quadrupolar Kondo effect" introduced by Cox (1987), corresponding to the two-channel case. A logarithmic dependence for $\gamma$, a linear dependence for the magnetic resistivity, and an unusual value for the entropy (corresponding to half the value of the entropy for the regular Kondo effect) have been obtained, and these theoretical results have been used to account for the NFL behavior observed in $Y_{1-x}U_xPd_3$.

In conclusion, at and above the QCP several different experimental and theoretical behaviors have been found. First, the FL behavior has been found in many compounds, but even there the real (i.e., for the lattice) Kondo temperature can be either roughly constant with $|J\rho|$ or pressure, as observed in $CeRh_2Si_2$, or can increase rapidly, as observed in some other cerium compounds. Second, a NFL behavior is obtained above the QCP for three possible cases, namely the proximity to the QCP, the disorder, and the overscreened Kondo effect. But, in fact, a given physical case can be relevant to two NFL features, as for example the proximity to the QCP and the disorder for disordered alloys or also the disorder and the multichannel Kondo effect for disordered uranium alloys. The questions of the relative stability of the FL and NFL phases and of the FL–NFL separation have not been solved. In the case of disordered alloys, there can also exist a spin glass state and the relative stability between the spin glass, the FL, and the NFL states is studied. Finally, a superconducting phase occurs in the proximity of the QCP and this, which will be discussed in the next section, is not really understood.

There has been a tremendous improvement in the experimental techniques used for the study of heavy-fermion compounds and more generally of strongly correlated electron systems. The conditions of transport, calorimetric, and magnetic experiments, using for instance SQUID magnetometry, have reached some millikelvin for temperature, several hundreds of kilobar for pressure, and at least 50 T for pulsed magnetic fields. Also, sophisticated new techniques have been developed: spectroscopic experiments, starting with photoemission, have contributed very much to the determination of the electronic structure of many cerium compounds and other systems; the de Haas van Alphen effect has determined the heavy-fermion character in many cerium and uranium compounds; neutron scattering and muon spin relaxation spectroscopy have been able to determine very small magnetic moments and have been used to study complicated magnetic transitions, as, for example, in $U(Pt_{1-x}\ Pd_x)_3$ or $CeCoGe_{3-x}Si_x$ alloys (Krishnamurthy *et al.* 1999).

## 7. *Superconductivity and Strong Electron Correlations*

Superconductivity was discovered experimentally in 1911 by Kamerlingh Onnes (1911) in mercury metal below $T_c = 4.15$ K. The theoretical explanation of superconductivity was given by Bardeen *et al.* (1957) who explained the superconductivity by a collective pairing mechanism between electrons of opposite spins. The observed maximum $T_c$ values up to 1986 were 9.25 K for niobium at normal pressure, 12.9 K for lanthanum at 200 kbar, 20.3 K for bulk $Nb_3Ga$, and 23.2 K for a thin film of $Nb_3Ge$ (Vonsovsky *et al.* 1982, Tominez *et al.* 2000).

Since the mid-1980s there has been considerable interest and progress in the study of superconducting materials, after the discovery by Bednorz and Muller (1986) of "high $T_c$ superconductivity." There are several series of high $T_c$ superconducting materials: the $LaSrCuO_4$ systems are superconducting below roughly 40 K, the $YBaCu_3O_7$ systems have a $T_c$ larger than 90 K, and the mercury-based compounds show the maximum $T_c$ value of 133 K at normal pressure. The origin of superconductivity in cuprates is attributed to the $CuO_2$ planes and $T_c$ appears to increase with the number of such planes. The alloys $HgBa_2Ca_{n-1}Cu_nO_{2n+2+\delta}$ are superconducting at 94 K, 129 K, 133 K, and 126 K for, respectively, $n = 1$, 2, 3, and 4 layers of $CuO_2$, showing an increase of $T_c$ with $n$ that unfortunately stops above $n = 3$. The $n = 3$ system Hg-1223 shows, under pressure, a very large increase of $T_c$, which reaches the

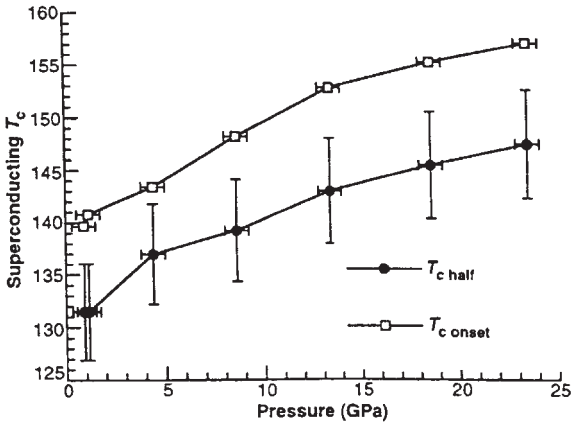

***Figure 4***
Pressure dependence of the superconducting transition temperature in the Hg-1223 compound. $T_{c\ onset}$ is defined as the temperature at which the resistance turns visibly away from the high-temperature behavior. $T_{c\ half}$ corresponds to the temperature halfway between 80% and 20% of the resistive transition.

value of 157 K at 235 kbar, as shown in Fig. 4 (Nunez-Regueiro *et al.* 1993). Thus, the experimental value of $T_c$ has increased from a value of 23 K in 1986 to more than 150 K in 1993, but is still roughly half the room temperature, the goal of many solid-state physicists. A theoretical explanation of this phenomenon has not yet been found, but there are several possibilities. Superconductivity comes from the $CuO_2$ planes and the most plausible explanation for the high transition temperature comes from strong magnetic correlations and several models have been built under this assumption. The two-dimensional character of the superconducting $CuO_2$ planes, which yields a large increase of the density of states, has also been invoked to account for the increase of $T_c$. There are many experimental works in the field of high-temperature superconductivity, in particular those attempting to increase $T_c$. Many theoretical studies are based on strong magnetic correlations.

The coexistence of magnetism and superconductivity occurs in several systems, such as the Chevrel phases $RMo_6S_8$ and $RMo_6Se_8$ (R being a rare earth Re or tin, lead, or mercury) (Fischer *et al.* 1975) or the borocarbides $ReRh_4B_4$ and $ReNi_2B_2C$ (Mazumdar *et al.* 1993, Tominez *et al.* 2000), but in these cases magnetism comes from the rare earths and superconductivity from the other atoms of the complex chemical structure of these compounds.

Another remarkable and unsolved problem is the "heavy-fermion" superconductivity occurring at low temperatures around the QCP in several cerium compounds. The discovery of superconductivity at $T_c = 0.6$ K in $CeCu_2Si_2$ at normal pressure (Steglich *et al.* 1979) is very fascinating. It is known that the compound $CeCu_2Si_2$ is very close to being magnetic and that a small departure from stoichiometry yields a magnetic phase. Superconductivity has been found at very high pressures around the QCP in several cerium compounds, namely $CeCu_2Ge_2$ at $T_c = 0.6$ K above 77 kbar, $CePd_2Si_2$ at $T_c = 0.5$ K above 23 kbar, $CeRh_2Si_2$ at $T_c = 0.4$ K above 9 kbar, $CeCu_2$ around 60 kbar, $CeIn_3$ below 0.2 K at 25 kbar, and $CeNi_2Ge_2$ below 0.1 K at normal pressure (Mathur *et al.* 1998, Gegenwart *et al.* 1999). The two compounds $CeCu_2Si_2$ and $CeNi_2Ge_2$ are nonmagnetic at normal pressure, but in fact they are very close to being magnetic. Thus, we can say that, in all these cerium compounds, this peculiar heavy-fermion superconductivity occurs around the QCP when the Néel temperature disappears but when the heavy-fermion character is very large. (For more details see *Non-Fermi Liquid Behavior: Quantum Phase Transitions*.)

Thus, both the high $T_c$ and the heavy-fermion superconductivities appear to be closely connected with the occurrence of strong electron correlations and further work is necessary to understand better this fascinating subject.

Superconductivity has also been observed in some uranium compounds at low temperatures. The compound $UPt_3$ is interesting since it undergoes, below 5 K, a transition to a kind of short-range magnetic order and becomes superconducting below $T_c = 0.5$ K, while heavy-fermion behavior characterized by a large electronic specific heat constant, $\gamma = 0.4\ J\ mol^{-1}K^{-2}$, and a $T^2$ term of the resistivity is observed at low temperatures. A real long-range antiferromagnetic ordering occurs when the concentration, $x$, increases in alloys $U(Pt_{1-x}Pd_x)_3$ and the Néel temperature is equal to 6 K for $x = 0.05$, as given in Table 1. Some uranium compounds show, when the temperature decreases, first a transition to an antiferromagnetically ordered state at $T_N$ and then a transition to a superconducting state at $T_c$. The values of $T_N$ and $T_c$ are, respectively, 8.8 K and 0.85 K in $UBe_{13}$, 17.5 K and 0.8 K in $URu_2Si_2$, 4.6 K and 1 K in $UNi_2Al_3$ (Geibel *et al.* 1991b), and 14 K and 2 K in $UPd_2Al_3$ (Geibel *et al.* 1991a). The physics of such uranium compounds is difficult to understand. We can invoke the underscreened Kondo effect in order to understand better the apparent coexistence observed in such compounds of the heavy-fermion character owing to the Kondo effect and a weak magnetic order resulting from the RKKY interaction, but clearly the occurrence of superconductivity at low temperatures is not yet explained.

## 8. Manganites

A rapidly developing subject is the experimental and theoretical study of mixed-valence manganites with the perovskite structure. Typical examples are given

by compounds $(La_{1-x}T_x)MnO_3$ or $(Pr_{1-x}T_x)MnO_3$, with T being calcium or strontium. The magnetic phase diagrams show, with varying $x$, many magnetically ordered phases that are insulating or metallic. In these systems, manganese can be in the two configurations $3d^4$ (corresponding to $Mn^{3+}$) or $3d^3$ (corresponding to $Mn^{4+}$). When divalent calcium replaces trivalent lanthanum, the valence of manganese changes from $Mn^{3+}$ to $Mn^{4+}$ resulting in the system being a mixed-valence one. The crystallographic and magnetic structures for the $(La_{1-x}Ca_x)MnO_3$ compounds have been determined in a neutron and x-ray diffraction study as a function of $Mn^{4+}$ (Wollan and Koehler 1955). The system is found to be antiferromagnetic and insulating for $x$ close to 0 and 1, while it is metallic and ferromagnetic with a Curie temperature of 220 K for $x = 0.3$. Zener (1951) presented an explanation of the behavior of such compounds by considering the indirect magnetic exchange between manganese atoms of different charges via an oxygen ion and Goodenough (1955) studied the role of covalence. The ''double exchange'' corresponding to a simultaneous transfer of an electron from the $Mn^{3+}$ to the oxygen and from the oxygen to the neighboring $Mn^{4+}$ and the classical superexchange that involves a virtual electron transfer were both considered to account for the different magnetic structures, because the double exchange is always ferromagnetic and the superexchange is frequently antiferromagnetic.

Thus, the interest in the study of this quite ''old'' subject arises from both the discovery of new phenomena such as the so-called ''colossal magnetoresistance'' which presents interesting new applications in magnetoelectronic devices and the formulation of important physical concepts such as the double exchange and the Jahn–Teller polaron. Excellent reviews are available (Coey *et al*. 1999). Considerable progress has been achieved in several directions: the study by different experiments (transport, magnetic, optical, etc.), the availability of single crystals, the study of systems such as $La_{2-x}T_{1+x}Mn_2O_7$ (with T = Ca, Sr), the development of possible applications, and the important progress in the development of theoretical models treating the magnetic polaron and the metal–insulator transition. (See also *Transition Metal Oxides: Magnetism*.)

## 9. Conclusion

There has been considerable improvement in the development of the field of strongly correlated electron systems since the pioneering works of Mott, Friedel, Anderson, and Kondo. Alloys and compounds of cerium or other anomalous rare earths and obviously heavy-fermion systems are relevant to this field. Manganites also have a strongly correlated electron behavior. The explanation of the high $T_c$ and heavy-fermion superconductivity has certainly to be looked for in strong electron correlations. Spin-ladder compounds, such as $(Sr,Ca)_{14}Cu_{24}O_{41}$, and low-dimensional systems, such as the ruthenate $Sr_2RuO_4$ or the compound $CuGeO_3$, can show superconducting and magnetic properties and strong correlations are certainly important in such systems.

Finally, very interesting reviews on strongly correlated electron systems (SCES) have been given at SCES Conferences (SCES Conference Proceedings 1997, 1999, 2000).

# Electronic Configurations of 3*d*, 4*f*, and 5*f* Elements: Properties and Simulation

The development of crystalline spectroscopy of the transition elements and more particularly of the rare earths was strongly connected to the chemical purity of the rare earth elements and of their compounds as well as to their availability on the market. This problem was partially resolved around the 1950s and a litany of works appeared from that time when scientists like Dirac, Bethe, Racah, Stevens, Wybourne, Judd, and others published the works which constitute the basis of this specialty.

From a theoretical point of view, the rare earth elements are one of the most convenient fields for the elaboration and testing of the quantum theories of atomic spectroscopy and their application to an ion included in a crystal. These techniques allow the energy level scheme, deduced from experiment, to be simulated. Moreover, knowledge of the associated wave-functions extends the technique towards the reproduction of other physical properties, mainly involving the magnetic operator (see *Crystal Field and Magnetic Properties, Relationship Between*).

The ability to perform such simulations is entirely due to the great development in computer technology, particularly PCs which make possible sophisticated calculations in a short time at a reduced cost. This rather recent tool, but largely generalized in modern science, has transformed the traditional *Theory–Experiment–Calculation* triptych into a new *Theory–Experiment–Simulation* one in which the physical phenomenon is always accompanied by its image.

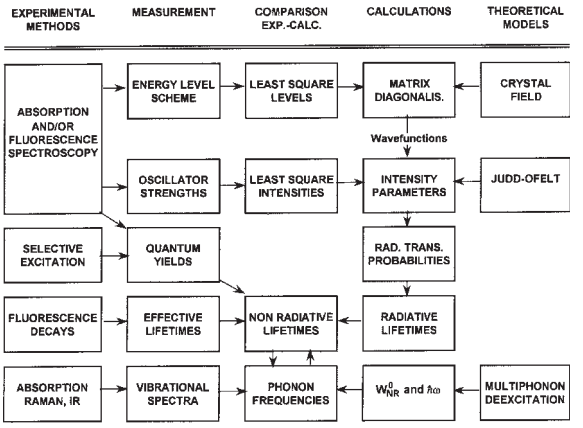

***Figure 1***
Organigram of the rare earth spectroscopic properties. From Delsart C 1973 Thesis, University of Orsay (ref: CNRS-AO8332), reprinted with the permission of the author.

In such a concept, the crystalline spectroscopy of transition elements can be summarized in an organigram (Fig. 1) illustrating how the steps of the triptych are connected. The present article is devoted to the simulation of the energy level positions.

The experimental part of the "static" optical spectroscopy that is presented in this article constitutes an energy level scheme deduced from transitions between states of the electronic configuration. It is mainly deduced from absorption and/or emission measurements performed in the wavelength range from the infrared to the ultraviolet. Other techniques, like inelastic neutron scattering, specific heat measurements, etc., can also yield some of the lowest energy levels. The quantum mechanics technique provides the basic theory for the models developed in the case of an ion located in a chemical neighborhood. This is also connected to the nature of the chemical bonding, knowledge of which is so important for the solid-state chemist.

## *1. Electronic Configurations of the Transition Elements*

Simulation of the rare earth (or 3d) elements' electronic configurations is based on the one-center model. In this analytical approach the central ion is submitted to various interactions, quantified, and parameterized according to the perturbation methods. All interactions are considered together in a

unique secular determination. The diagonalization gives the energy levels, which have to be compared with the experimental ones. On the basis of the intermediate coupling, the interactions are formally divided into free ion and crystal field interactions. The framework of the description is the Racah algebra (Judd 1963, Wybourne 1965) which permits a quantitative description of the coupling between angular moments, whereas the qualitative rules are a consequence of the elegant use of group theory.

All trivalent rare earth ions have the $[Xe]4f^N$ configuration as a ground configuration, in which [Xe] represents the filled electronic layers of the rare gas xenon. They are usually considered as isolated from other configurations located at a distance in the energy level energy scale, which is not necessarily a good approximation for other transition elements. The influence of the excited configurations on the ground state is small, but included in the simulation technique through effective operators. This assumption appears to be rather realistic with an energy gap between the ground configuration and the first excited state of $(4f^{N-1}5d$ for $RE^{3+})$ ca. 120 000 $cm^{-1}$. The description is based on the $|\eta SLJM\rangle$ kets, in which $\eta$, S, L, J, and M are the quantum numbers of the intermediate coupling description. The number of kets is equal to the degeneracy of the configuration, i.e., the number of possible elementary states according to the Pauli exclusion principle. In the group theory aspect, each momentum is associated to a reducible representation of the $R_{3i}$ rotation group (or of the $R_{3i}$' double group for odd number of electrons), $D_S$, $D_L$, and $D_J$. It is noteworthy that some differences often appear when $4f^N$ and $3d^N$ are compared, the latter being traditionally described on the $|\eta SM_S LM_L\rangle$ basis, in which the total angular momentum (spin–orbit coupling) is not included. This parametric model gives an approximate solution of the Schrödinger equation, each electron being supposed to move independently in an explicit central field replacing the Coulombian potential. In the perturbation theory framework various interactions of decreasing importance are then introduced to correct that approximation. Judd (1963) and Wybourne (1965) have standardized the formalism generally employed.

### *1.1 Electrostatic Repulsion*

This interaction representing the Coulombian repulsion between pairs of electrons is the most important among the free ion interactions:

$$H_{El} = \frac{1}{2}\sum_{i\neq j}^{n}\frac{e^2}{r_{ij}}$$

The corresponding matrix element is written as a linear combination of products between a radial integral (expressed as the Slater integrals, $F_k$, or as the Racah parameters, $E^k$) and of an angular part, tabulated by Nielson and Koster (1964):

$$\langle \alpha SLJM|H_{El}|\alpha' S'L'J'M'\rangle = \delta(S,S')\delta(L,L')\delta(J,J') \times \delta(MM')\sum_{k=0}^{3} f_k F_k \qquad (1)$$

This interaction is diagonal in S,L,J,M except when the principal quantum numbers are different. It creates the $^{2S+1}L$ terms of the configuration, associated to the $D_L \otimes D_S$ irreducible representation products of the $R_{3i}$ rotations group. Their degeneracy is $(2S+1)(2L+1)$ (Table 1). The energy difference between two terms is ca. 20 000 $cm^{-1}$. Values of the $F_2$ Slater integral for various configurations are reported in Table 2.

### *1.2 Two- and Three-body Interactions*

In addition to the electrostatic repulsion operating between the states of the ground configuration (intraconfiguration), correcting interactions are usually added in order to reproduce electrostatic coupling with states of excited configurations (interconfigurations) through effective operators. The two-electron operators (for $4f^N$ with $N \geqslant 2$), are the Tree parameter $\alpha$ operating on the angular momentum L and $\beta$ and $\gamma$

***Table 1***
Number of terms, levels, and degeneracy of the $d^N$ and $f^N$ configurations.

| Configurations $nd^N$ | | | |
|---|---|---|---|
| Nb Electrons | Nb Terms $^{2S+1}L$ | Nb Levels $^{2S+1}L_J$ | Nb States $^{2S+1}L_{JM}$ |

| $4f^N$ | 70 000 | 1500 | 500 |
| $5f^N$ | 50 000 | 2500 | 2000 |

parameters associated to the Casimir operators for the Lie groups $G_2$ and $R_7$. When interactions between three electrons (for $4f^N$ with $N \geqslant 3$) are taken into account, the Judd parameters $T^k$ are associated to the $t_k$ operators, also transforming as the irreducible representations of the $G_2$ and $R_7$ groups.

### *1.3 Spin–Orbit Coupling*

The most important magnetic interaction is the coupling between the spin and the orbit of an electron. The radial part of the interaction defines the phenomenological spin orbit parameter, $\zeta$:

$$H_{SO} = \zeta_N \sum_{i=1}^{N} \vec{l}_i \cdot \vec{s}_i$$

This interaction is not diagonal in L and S and consequently the L–S coupling is broken and replaced by the intermediate coupling. The matrix element is written as:

$$\begin{aligned} \langle \alpha SLJM | H_{SO} | \alpha' S' L' J' M' \rangle &= \delta(J, J') \delta(M, M') \\ &\times [l(l+1)(2l+1)]^{1/2} \zeta_{Nl} (-1)^{L+S'+J} \\ &\times \begin{Bmatrix} L & L' & 1 \\ S & S' & J \end{Bmatrix} \times \langle \alpha SL | V^{11} | \alpha' S' L' \rangle \end{aligned} \quad (2)$$

in which $l$ is the orbital quantum number ($l = 2$ for 3d elements and $l = 3$ for 4f elements), $V^{11}$ is a double tensor whose doubly reduced values are tabulated by Nielson and Koster (1964), and {} represents the 6j symbol for the coupling between three angular moments. The triangular rules of the 6j symbols are that L and S cannot differ by more than one unit. In group theory that interaction is associated to the explicitly direct product $D_S \otimes D_L = \sum_{J=|L-S|}^{J=L+S} D_J$. That interaction creates the $^{2S+1}L_J$ levels associated with the $D_J$ irreducible representation, whose remaining degeneracy is $2J + 1$. The energy separation between two terms is about $500\,cm^{-1}$ for the rare earths whereas the coupling constant varies from $\sim 700\,cm^{-1}$ for $Ce^{3+}$ to $\sim 3000\,cm^{-1}$ for $Yb^{3+}$ (from $\sim 200$ to $\sim 800\,cm^{-1}$ for 3d elements).

### *1.4 Other Interactions*

Other interactions of minor importance can be included. They have essentially a magnetic origin just like the spin–orbit coupling:

(i) the spin–other–orbit and spin–spin interactions, parameterized by the Marvin integrals $M^k$ ($k = 0, 2, 4$);

(ii) the electrostatically correlated spin–orbit interaction, parameterized by two-body pseudomagnetic operators $P^k$ ($k = 2, 4, 6$).

These interactions are considered practically for the $nf^N$ configurations only when the number of experimental levels is large. They have a significant action on the $4f^2$ and $5f^2$ configurations and on those at the end of the series. Usually only $M^0$ and $P^2$ vary freely, while the other parameters keep the Hartree–Fock ratios with $M^0$ and $P^2$.

## *2. Crystal Field Interaction*

When embedded in a crystalline matrix the rare earth ion is submitted to an internal electric field due to the ligands, assimilated to point charges in the first approximation. Thus, in the original conception, the crystal field has a purely electrostatic origin (Garcia and Faucher 1995, Görller-Wallrand and Binnemans 1996).This is the point charge electrostatic model (PCEM). For one ligand the potential is written as:

$$V = \frac{1}{4\pi\varepsilon_0} \frac{ge}{|r - \rho|}$$

The potential is developed in Legendre polynomials

$$V = \frac{ge}{4\pi\varepsilon_0} \sum_{k=0}^{\infty} \frac{r^k}{\rho^{k+1}} P_k(\cos\Omega) \quad (3)$$

then in spherical harmonics:

$$P_k(\cos\Omega) = \frac{4\pi}{2k+1} \sum_{q=-k}^{q=k} Y_q^{k*}(\alpha, \beta) Y_q^k(\theta, \phi) \quad (4)$$

The hamiltonian of the systems sums over all ligands and electrons involved

$$H_c = -e \sum_i V(r_i, \theta_i, \phi_i) \quad (5)$$

in Eqns. (3) and (4), the ligand and electron parts are separated

$$H_c = -\frac{e^2}{4\pi\varepsilon_0} \sum_{i,k,q} A_q^k r_i^k Y_q^k(\theta_i, \phi_i) \quad (6)$$

with

$$A_q^k = \frac{4\pi}{2k+1}\sum_j \frac{g_j}{\rho_j^{k+1}} Y_q^{k*}(\alpha_j, \beta_j) \tag{7}$$

where $A_q^k$ is the lattice sum depending on the spherical coordinates of the ligands and $g_j$ is the electric charge of the jth ligand. Using perturbation theory, the energy is written as:

$$E_{cc}^{(1)} = \langle \Phi^{(0)} | H_c | \Phi^{(0)} \rangle \tag{8}$$

$\Phi^{(0)}$ being the nonperturbed state, and in that expression appear the radial integrals $\langle R_{4f} | r^k | R_{4f} \rangle = \langle r^k \rangle$. These integrals can be obtained directly from the routine package of Cowan. The crystal field parameters are defined as the product of an angular part by a radial part: $B_q^k = A_q^k \langle r^k \rangle$.

### 2.1 Limitations of the Crystal Field Potential

Equation (3) indicates a summation over k, an integer without any limitation and in Eqn. (4) a summation over q, also integer. In fact, the physical application to electronic configurations and the group theory rules reduce the possible values:

(i) there is a limitation on k due to the nature of the electrons. If the crystal field potential operates as in Eqn. (8) between states of to the same configuration (which is the case for most of the crystal field analysis), then k is even and $k \leqslant 2l$;

(ii) there is also a limitation on q connected to the symmetry of the point group, for instance:

(a) if there is an inversion center in the group symmetry like $O_h$, $S_6$, all odd $B_q^k$ vanish;

(b) if there is a $C_n$ or $S_n$ symmetry axis, q/n must be an integer;

(c) other rules are less evident but are a consequence of the application of the projection operators associated with the point group on the spherical harmonics.

An exhaustive list of nonvanishing $B_q^k$ vs. point symmetries is found in the work of Görller-Wallrand and Binnemans (1996).

### 2.2 Group Theory and Crystal Field

From the group theory point of view the irreducible representations $\Gamma_x$ of the point group G, associated with the atomic position occupied by the rare earth ligands are considered. G is a subgroup of the rotation group $R_{3i}$ for an even number of electrons and of the rotation double group $R_{3i}'$ for an odd number of electrons. The number and the type of irreducible representations of the subgroup G involved are determined by decomposition of the $D_J$ irreducible representation of $R_{3i}$ (or $R_{3i}'$) on the basis of the G symmetry operations. The list of the J level decomposition as a function of the J value and of point groups is found in Görller-Wallrand and Binnemans (1996) or Prather (1961).

### 2.3 Crystal Field Strength

It is often interesting to classify the compounds as a function of the crystal field strength. This parameter can cover the whole crystal field effect or partial effect as a function of the rank k of the parameters. This quantity is a rotational invariant, connected with the displacements of the centers of gravity of the levels from their free ion values. It allows a simple characterization of chemical bondings. It is written as (Chang *et al.* 1982):

$$S = \left[ \sum_{k=2,4,6} \frac{1}{2k+1} \sum_{q=-k}^{q=k} |B_q^k|^2 \right]^{1/2}$$

### 2.4 The Racah Algebra Formalism of the Crystal Field

Equation (3) supposes that the crystal field potential has a pure electrostatic origin. Except for cases involving ionic ligands, this model is unable to represent the reality. For a quantum mechanical treatment it is more realistic to keep only the symmetry aspect of the mathematical expression. The crystal field hamiltonian is then written as:

$$H_c = \sum_{i,k,q} B_q^k [C_q^k + (-1)^q C_{-q}^k]_i + i S_q^k [C_q^k - (-1)^q C_{-q}^k]_i \tag{9}$$

The summation runs over all electrons of the system, where $B_q^k$ and $S_q^k$ are the real and imaginary parts, respectively, of the phenomenological crystal field parameters and $C_q^k$ are tensor operators of rank k, connected to the spherical harmonics. The Wigner–Eckart theorem gives a simple expression of the coupling between two angular momentums in the $|\eta SLJM\rangle$ basis:

$$\langle \alpha SLJM \left| B_q^k C_q^k \right| \alpha' S' L' J' M' \rangle = \delta(S, S')(-1)^{\ell}(2\ell+1) \begin{pmatrix} \ell & k & \ell \\ 0 & 0 & 0 \end{pmatrix} \times (-1)^{J-M} \begin{pmatrix} J & k & J' \\ -M & q & M' \end{pmatrix} B_q^k \langle \alpha SLJ \| U^k \| \alpha SL'J' \rangle \tag{10}$$

where () are 3j symbols for two angular moment couplings. The second 3j symbol shows the possibilities of coupling between states of different J (J-mixing), which can never be neglected. $U^k$ is a unitary tensor. Equation (10) can be developed

further:

$$\langle \alpha SLJ \| U^k \| \alpha SL'J' \rangle = (-1)^{S+L'+J+k}[(2J+1)(2J'+1)]^{1/2} \begin{Bmatrix} J' & J & k \\ L' & L & S \end{Bmatrix} \langle \alpha SL \| U^k \| \alpha SL' \rangle \quad (11)$$

in which $\langle \alpha SL \| U^k \| \alpha SL' \rangle$ is a doubly reduced matrix element also tabulated by Nielson and Koster. The order of magnitude of the crystal field splitting is shown in Table 2.

### 2.5 *Correlated Crystal Field*

The concept of correlated crystal field corresponds to the two-electron part of the crystal field interaction. This interaction was formalized in the 1970s and implies a "scandalously high number of parameters" (Garcia and Faucher 1995). That interaction creates a term-dependent correction to the one-electron crystal field. It has been somewhat "simplified" by considering separately the spin- and orbital-correlated crystal field effects. Thus, the operators become orthogonal to the one-electron crystal field operators and are easier to manipulate. However, it has not been shown clearly if the simulation of the energy level scheme is significantly improved when these interactions are included. A clever overview on that problem is found in the work of Garcia and Faucher (1995).

## 3. *Simulation of the Rare Earth Electronic Configurations*

When all interactions are analyzed and described it is easy to write down the secular determinant. It comprises a great number of matrix elements, written as $\langle \alpha SLJM | H_{Tot} | \alpha' S'L'J'M' \rangle$ in which $H_{Tot}$ represents the sum of elementary hamiltonians previously described:

$$H_{Tot} = H_0 + \sum_{k=0,1,2,3} E_k e^k + {}_{4f}A_{SO} + L(L+1) + G(G_2) + G(R_7) + \sum_{k=2,4,6} P^k p_k + \sum_{k=0,2,4} M^k m_k \sum_{k=2,3,4,6,7,8} T^k t_k + \sum_{k,q,i} B^k_q C^k_q(i) \quad (12)$$

Each interaction follows its own rules, in particular as regards its nonzero values as a function of the quantum numbers $\eta SLJM$. $H_0$ represents the energy separation between the ground and excited configurations. The diagonalization done by standard techniques provides the energy levels and their associated wave-functions. An estimation of the phenomenological parameters is made by comparing calculated and experimental energy levels by minimization of the root mean square deviation taken as factor of merit (Porcher 1989, unpublished Fortran routines). For the rare earths the number of free ion parameters match 20 and the number of crystal field parameters can vary between two (for $O_h$ or $T_d$ point symmetry) and 27 (for $C_1$). This last number could be largely increased if the two-electron crystal field effect is included. Thus, it is very common to take into account some 20 parameters, which creates a problem concerning the real significance of the parameters and the reliability of the phenomenological simulation.

Fortunately, various models help in calculating many parameters whose values are considered as starting values in the refining processes. This is true for the free ion parameters as well as for the crystal field parameters (see Sect. 4).

- Free ion parameters calculated by the Hartree–Fock method (Cowan) reproduce the reality with a precision of $\sim 25\%$, which is reasonable.
- There is a smooth variation of free ion parameters vs. the number of f electrons, whatever the crystalline matrix (Fig. 2).
- If all free ion parameters cannot vary freely, some of them are fixed in predetermined ratios. This is often the case for the $M^k$ and $P^k$ integrals and sometimes for the $E^k$ (or $F^k$) parameters.
- There is also a smooth variation of the crystal field parameters with the ionic radius of the optically active rare earth embedded in a given matrix or when the crystalline matrices are isostructural (Fig. 3).
- In some cases, a descending symmetry procedure is applied for crystal field calculations, assuming the real point symmetry is close to a higher one involving less parameters.

In spite of the relative simplicity of these calculations, few works deal with the optical properties of all rare earth ions in a unique matrix, in single crystal

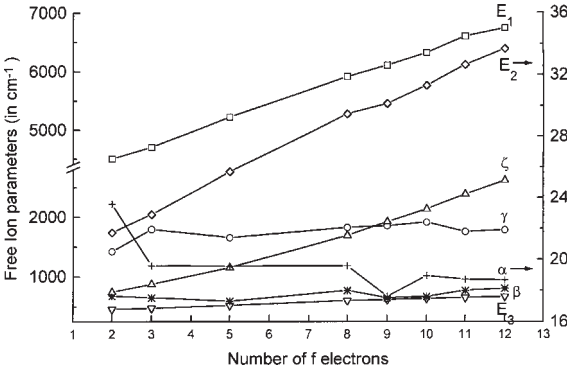

***Figure 2***

Variation of the crystal field parameters in the REOCl series. From Hölsä *et al*. (1998a), reprinted with the permission of the authors.

form. The most complete work was published by Carnall as early as 1977 for pure rare earth fluoride $REF_3$ or rare earth doping in lanthanum fluoride $LaF_3$. This particular matrix is transparent in the far-UV region and therefore gives a great number of experimental energy levels. Initially the simulations were performed with approximated symmetries for the lanthanum ($D_{3h}$ then $C_{2v}$), the last revision considering the real symmetry ($C_2$). Later, two other families were systematically studied,but in polycrystalline form, with all trivalent rare earth ions: the rare earth oxychlorides REOCl (Hölsä *et al*. 1998a) and the oxyfluorides REOF (Hölsä *et al*. 1998b), where the rare earth occupies a point site with higher symmetry—$C_{4v}$ for REOCl and $C_{3v}$ for REOF respectively—which means less crystal field parameters (five and six, respectively). The number of observed energy levels is large and SmOF could be added to the *Guiness Book of Records* for rare earth spectroscopy with 191 observed crystal field states! Many other matrices have been studied, not necessary with all rare earth ions, especially with $Nd^{3+}$, $Eu^{3+}$, and $Er^{3+}$ which are ions with potential industrial application. Most of the results concerning rare earth energy levels are available in books (Görler-Wallrand and Binnemans 1996, Kaminski 1996) and/or on web sites (NASA, Porcher 2000).

## 4. Semiempirical Calculation of the Crystal Field Parameters

Newmann (1971) noted that several different interactions should have to be taken into account: ligand point charges of first neighbors and of the rest of the crystalline network, dipolar and quadrulopar polarization of the ligand, exchange and overlap between the rare earth and the ligand, covalency, charge transfer ligand-to-rare earth and ligand-to-ligand, and triangular interaction. He was able to calculate the different contributions for $PrCl_3$, i.e., in the case of a relatively simple ligand. Others have estimated the influence of the polarizability for some simple covalent ligands (Garcia and Faucher 1995, Morrison and Leavitt 1982). The problem is more complicated when complex ligands, such as borates, molybdates, and sulfates, are involved. Increasing difficulties are presented by organic ligands. For these reasons it seems more realistic to consider semi-empirical calculations. A review of the different models is given by Porcher *et al*. (1999).

### 4.1 Angular Overlap Model

This model is an extension to the f electrons of the model proposed by Jørgensen (1963) and Schäffer (1969, 1972) for the d electrons. It was initially introduced for explaining the one-electron energy differences between the seven 4f orbitals in lanthanide chromophores, and forms the most "chemical" approach in the sense that the f orbitals are immediately considered. The model expresses the antibonding energy of the molecular orbital created between the central ion and the ligand. One interest of this model is to consider f orbital expressions directly as read on the character table of the point symmetry group, which allows the result to be related to the irreducible representation of a level and consequently to the $\sigma$, $\pi$, and $\delta$ classical bonding of the d elements plus the $\phi$ bonding specific to the f orbitals. However, difficulties arise when the phenomenological approach of a $4f^N$ configuration simulation is considered as a whole, which also includes the free ion interactions. This model has been applied, coupled with the superposition model in various series of rare earth compounds.

### 4.2 Superposition Model

Newmann (1971) proposed an empirical approach, where each ligand is characterized by an intrinsic parameter, giving its own contribution to the crystal field. The general expression of $B_q^k$ is:

$$B_q^k = \langle r^k \rangle \frac{4\pi}{2k+1} \sum_j Y_q^{k^*}(j) \bar{A}_k(R_j) \left(\frac{R_0}{R_j}\right)^{t_k} \quad (13)$$

In that expression only the first coordination sphere is considered. There is a distance dependence of $B_q^k$ according to a power law, the rare earth–ligand distance reference $R_0$ being the shortest in the crystalline network. This semi-*a priori* model is strictly identified with the PCEM if $t_k$ is equal to $2k+1$. $t_k$ could be calculated according to the number and the type of considered interactions. Practically they are considered as adjustable parameters, whose values

are not necessarily integers and can be far from the nominal ones. The interest of that model lies in the fact that each ligand gives its quantitative finger-print which in principle could be transported from one compound to another.

### 4.3 *Effective Charge Model*

In this model, the crystal field parameters are written as:

$$B_q^k = (1 - \sigma_k)\,\frac{\langle r^k \rangle}{\tau^k} A_q^k \qquad (14)$$

This equation differs in four ways from the PCEM of Eqns. (4) and (5) in the expression of the radial as well as in the angular parts.

(i) The radial integrals $\langle r^k \rangle$ are corrected by a spatial expansion parameter $\tau$, which varies linearly with the number of f electrons.

(ii) A shielding factor $\sigma_k$ is introduced into the multipolar expansion of the crystal field potential.

(iii) A degree of covalence is introduced through effective charges of atoms. These effective charges keep the electric neutrality of the compound.

(iv) A slight shift of the ligand position is introduced in order to take into account their polarizability effect.

The summation runs over all atoms of the crystalline network, which in practice means atoms included within a sphere of ca. 100 Å.

### 4.4 *The Simple Overlap Model*

This model developed by Malta retains only the first coordination sphere (Porcher *et al.* 1999). The covalence is represented by the overlap, $\rho$, between the rare earth and ligand orbitals. The crystal field parameters are written as:

$$B_q^k = \rho\left(\frac{2}{1 \pm \rho}\right)^{k+1} \langle r^k \rangle A_q^k \qquad (15)$$

In that expression the $\langle r^k \rangle$ radial integral is not corrected from the spatial expansion as for the ECM. Lattice sums, $A_q^k$, are calculated with an effective charge for the ligand. The overlap $\rho$ varies for each ligand as a function of the distance to the central ion and is referred to the closest ligand, as for the superposition model. Finally, this method involves only two adjustable parameters: the overlap and the effective charge of the ligand. The model which offers the possibility of considering the big molecules of coordination chemistry has been successfully applied to a great number of compounds. It was found that the overlap is between 0.05 and 0.08 for the rare earth ions and between 0.10 and 0.25 for 3d elements.

## 5. *The Convenient Case of the $Eu^{3+}$ Ion*

Although the $4f^6$ configuration possesses one of the greatest degeneracy (3003) of the trivalent rare earth configurations (Table 2), $Eu^{3+}$ is the most convenient case for characterizing the energy levels of a rare earth ion in a crystalline matrix. This characteristic is due qualitatively to the type of symmetry site analysis of the spectroscopy as well as quantitatively to the relatively simple way of performing crystal field calculations. To a lesser extent, this is also true for intensity calculations. The particular feature of this configuration is a $^7F$ ground septet and a first excited $^5D$ quintet relatively well isolated in the energy level sequence.

### 5.1 *$Eu^{3+}$ as a Structural Local Probe*

This analytical aspect is a consequence of the even number of electrons in the $4f^6$ configuration. The crystal field lifts more or less completely the degeneracies of $^7F_J$ levels, according to the endomorphism between crystal field levels and irreducible representations of the local point group, whereas the observability of electronic transitions is related to the electric/magnetic dipole rules, also connected to the point symmetry. Practically, a fluorescence spectrum of europium compounds consists of transitions originating from the $^5D_J$ levels, more particularly $^5D_0$, the final levels being $^7F_J$. Most of the transitions are located in the visible wavelength range. Neither $^5D_0$ nor $^7F_0$ are split by the crystal field, which means that the number of $^5D_0 \rightarrow {}^7F_0$ transitions corresponds to the number of sites occupied by $Eu^{3+}$. However, this is only true if the group is due to the $C_1$, $C_s$, $C_n$, $C_{nv}$ symmetry point groups, for which that transition is permitted by the electric dipole rules. From the number of observed lines and by application of the same rules on other $^5D_0 \rightarrow {}^7F_J$ ($J = 1,6$) transitions, the symmetry of the point group of the rare earth crystallographic site in the structure is deduced. Another practical consequence is that liquid helium temperature measurements are not necessary, whereas it is required for other rare earth levels to prevent the excited crystal field emitting levels being thermally populated. Thus, only liquid nitrogen measurements are usually performed.

Moreover, the $^5D_0 \rightarrow {}^7F_0$ transition is situated just in the middle of the Rhodamine 6G dye laser wavelength emission range. This low-cost dye can be used for site-selective excitation in the case of multisite compounds. When the excitation wavelength is accorded on a selected $^5D_0 \rightarrow {}^7F_0$ transition each site gives its own "finger-print", any fluorescence response from other sites being almost completely quenched. Figure 4 shows, as an example, the case of $La_2(CrO_4)_3.7H_2O{:}Eu^{3+}$ in which the rare earth occupies two point sites of low symmetry. The

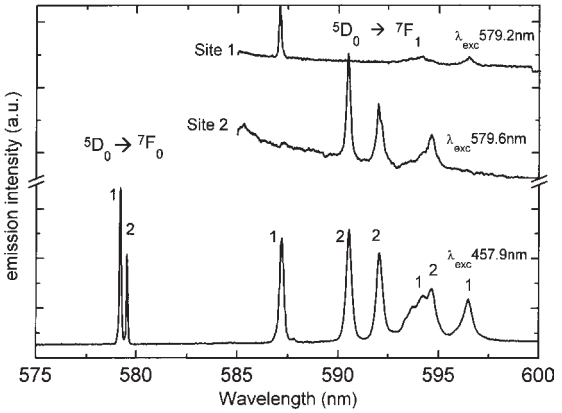

***Figure 4***

fluorescence spectrum excited by the blue lines of the cw-$Ar^+$ laser shows two lines for $^5D_0 \rightarrow {}^7F_0$ (bottom spectrum), whereas $^5D_0 \rightarrow {}^7F_{1,2}$ transitions exhibit more lines than expected for one point site. When selectively excited (Fig. 4, middle and top spectra), each site can be analyzed in terms of number and position of lines and the problem is nicely reduced to the case of a single site compound. If one of the sites is due to an impure phase the same result should be obtained. This structural probe aspect has been found to be of great importance in biochemistry.

### 5.2 *Crystal Field Calculations With $Eu^{3+}$*

The particular $^7F$ ground septet is convenient for fast crystal field calculation because: (i) this term is well isolated from the rest of the configuration with an energy gap of $\sim 12\,000\,cm^{-1}$ between $^7F_6$ and $^5D_0$; (ii) the crystal field operator is a spin operator which allows mixing only between terms of the same parity; (iii) the $^7F$ term only has this multiplicity; and (iv) the $^7F$ term wavefunctions are almost pure ($>95\%$) in $|{}^7F_{JM}\rangle$ states, the rest being small admixtures of $^5D$, $^5G$, $^3P$, $^3F$ ,and $^1S$ terms created only by the spin–orbit coupling. Instead, considering the entire configuration even reduced in submatrices according the crystalline quantum number properties, only a 49-square matrix (i.e., the $^7F$ degeneracy) is diagonalized, which means less than half a second of computation on a standard PC. In this case, the electrostatic repulsion and other interactions operating between terms are completely diagonal in $|{}^7F_{JM}\rangle$ states except for the spin–orbit coupling. Of course, if a precise knowledge of the wave-functions is necessary, as for paramagnetic susceptibilities and for transition intensity calculations, the full secular determinant has to be diagonalized (see *Crystal Field and Magnetic Properties, Relationship Between*).

### 5.3 *Intensity Calculations With $Eu^{3+}$*

Although it is not the purpose of this article we can mention how the europium ion permits an easier parameterization of the emission intensity, without the usual experimental complexities of absolute measurements. This is due to the simultaneous occurrence of magnetic and electric dipole transitions in the spectrum. Some of the transitions between crystal field states of $^5D_0 \rightarrow {}^7F_1$, $^5D_1 \rightarrow {}^7F_0$, $^5D_1 \rightarrow {}^7F_2$, $^5D_2 \rightarrow {}^7F_1$, $^5D_2 \rightarrow {}^7F_3$, etc., have a pure magnetic dipole character. The problem is then reduced to the measurements of relative intensities. However, a reference transition for each emitting level is necessary in order to take into account the nonradiative transition processes. When transitions between J levels are studied, $\Omega_2$ and $\Omega_4$, respectively, are deduced directly from the area ratios

$$\frac{^5D_0 \rightarrow {}^7F_2}{^5D_0 \rightarrow {}^7F_1}$$

and

$$\frac{^5D_0 \rightarrow {}^7F_4}{^5D_0 \rightarrow {}^7F_1}$$

# Elemental Rare Earths: Magnetic Structure and Resistance, Correlation of

The study of elemental rare earths spans several decades, and in this period there have been many reported studies of resistance and magnetoresistance. The results reveal many magnetic transitions as a function of temperature and applied field. However, as stated in *Boltzmann Equation and Scattering Mechanisms*, there are no general rules that may be applied for the magnetically ordered state, especially in the case of antiferromagnetism. This fact derives from the diversity of magnetic structures.

Electrical resistivity is a sensitive probe in magnetic systems and the construction of magnetic phase diagrams is possible. However, such constructions based on magnetoresistance alone must be made with caution, and this article will look at various aspects which are important in such determinations. The extent of the field is enormous, and in consequence the review will consider examples of heavy rare earths, with the cases being chosen to exemplify the effects of changing crystal field anisotropy and magnetic exchange interaction. Utilizing the results of elastic and inelastic neutron scattering, it is possible to establish canonical behavior in the resistance in response to changing magnetic structure.

## 1. Magnetic Order in Rare-earth Elements

As with all physical systems, it is possible to define a Hamiltonian. The spin Hamiltonian is composed of terms intended to represent the possibility of strong anisotropic behavior through crystal field and magnetic exchange. These terms are often linked to the crystal lattice through magnetoelastic coupling. Consideration of the spin Hamiltonian is beyond the scope of the current article, and the reader is referred to Jensen and Mackintosh (1991) and references therein.

The elements chosen for discussion are thulium and erbium. The crystal structure for each of these elements is hexagonal close-packed (h.c.p.), with the three orthogonal symmetry directions being the **a**, **b**, and **c** axes. The crystal field for each element is such that the preferred orientation of the magnetic moments is along different directions. In the case of thulium, the moment is constrained to the **c**-axis. In erbium, the moments are found to develop first along the **c**-axis, and then an additional moment develops along the **a**-axis. In each case, the propagation wave vector for the antiferromagnetic structures is parallel to the **c**-axis. The RKKY-exchange energy (Jensen and Mackintosh 1991) is found to increase going from thulium to erbium. The main consequences of this are an increase in the Néel temperature, and a decrease in the role played by the crystal field within the Hamiltonian.

### 1.1 Models Proposed to Understand Phenomena

In *Boltzmann Equation and Scattering Mechanisms*, Eqn. (68a) introduces the Matthiessen rule for electrical resistivity. For the systems considered in this article, the rule may be restated (see Eqn. (9) in *Intermetallic Compounds: Electrical Resistivity*) as:

$$\rho_{\text{total}} = \rho_{\text{residual}} + \rho_{\text{phonon}} + \rho_{\text{magnetic}} \qquad (1)$$

where $\rho_{\text{magnetic}}$ is the component derived from the elastic and inelastic magnetic scattering. This may be represented by the equation:

$$\rho_{\text{magnetic}} = \rho^0_{\text{magnetic}} \int_{-\infty}^{\infty} \mathrm{d}(\hbar\omega)\, \frac{\hbar\omega/k_{\text{B}}T}{4\,\sin\mathrm{h}^2(\hbar\omega/2k_{\text{B}}T)} \times \sum_{\alpha} \frac{1}{\pi} \langle \chi''_{\alpha\alpha}(\mathbf{q},\ \omega) \rangle_{\text{q}} \qquad (2)$$

where the weighted **q**-average of the susceptibility tensor components is given by

$$\langle \chi''_{\alpha\alpha}(\mathbf{q},\ \omega)\rangle_{\mathrm{q}} = \frac{3}{(2k_{\mathrm{F}})^4}\int_0^{2k_{\mathrm{F}}} q\mathrm{d}q \int \frac{\mathrm{d}\Omega_{\mathrm{q}}}{4\pi} \times (\mathbf{q}\cdot\hat{\mathbf{u}})^2\chi''_{\alpha\alpha}(\mathbf{q},\ \omega) \qquad (3)$$

The term $\rho_{\mathrm{magnetic}}$ may represent a number of different cases of excitations in the magnetic case, ranging from spin-wave scattering (Mackintosh 1963), crystal field (Hessel Andersen *et al.* 1974), and exchange dominated magnetic scattering (Hessel Andersen *et al.* 1980, Ellerby *et al.* 1998). In the high temperature limit, Eqn. (2) predicts the saturation of the spin-disorder scattering and is found to be proportional to the de Gennes factor (see *Intermetallic Compounds: Electrical Resistivity*).

In the heavy rare earths, measurement of the **c**-axis resistivity reveals a pronounced increase at the Néel temperature (Fig. 1). It was proposed (Mackintosh 1962) that this increase derives from a new periodicity along the **c**-axis, associated with the magnetic unit cell. This new periodicity results in additional zone boundaries (superzones), and produces further energy gaps which may appear at the Fermi surface. Watson *et al.* (1968) showed that, for the case of thulium, there was a number of such gaps with an energy of approximately 0.085 eV. Two groups (Elliott and Wedgwood 1963, Miwa 1963) developed a formalism to represent the effects of changing Fermi surface on the resistivity, and this is summarized by:

$$\rho^{uu}_{\mathrm{total}} = \frac{\rho^{uu}_{\mathrm{residual}} + \rho^{uu}_{\mathrm{phonon}} + \rho^{uu}_{\mathrm{magnetic}}}{1 - \Gamma_u M_1/M_1^0} \qquad (4)$$

Here $\Gamma_u$ is determined by the periodicity of the magnetic structure and for the ferromagnetic case, where ordering wave vector $\mathbf{Q}=0$ and $\Gamma_u=0$. $M_1^0$ and $M_1$ are the zero temperature saturation magnetic moment and temperature-dependent magnetic moment, respectively, which may be derived from neutron diffraction studies. The subscripts and superscripts, *uu* and *u* represent the axis under consideration. In the case of thulium, $\Gamma_{\mathbf{c}}=0.73$ and $\Gamma_{\mathbf{a}}=0$ (Ellerby *et al.* 1998). The influence of the denominator is to increase the resistivity parallel to the **c**-axis as a function of temperature.

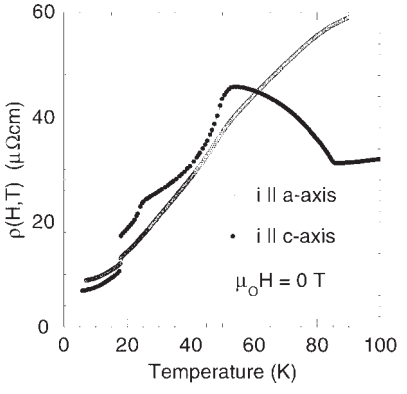

***Figure 1***
The temperature dependence of the longitudinal **c**(●) and **a**-axis (○) resistivity for erbium.

The magnetoresistance in magnetically ordered materials has been considered by Yamada and Takada (1973), and has been discussed in *Magnetoresistance: Magnetic and Nonmagnetic Intermetallics*. This model considers the effects, in an antiferromagnetic system, of scattering from enhanced transverse spin fluctuations resulting from an applied magnetic field. The authors also produce a schematic for the effect of spin-flop transitions on the resistivity, where the moments do not fully rotate parallel to the applied field in a single stage, but do so in a series of stages. This model for the magnetoresistance does not accommodate the affects of changing Fermi surface.

## 2. Discussion

The difference in anisotropy of thulium and erbium has already been alluded to in Sect. 1. The discussion begins in each section by outlining the main features for each of the magnetic phase diagrams shown in Figs. 2(a–c). In each of the phase diagrams, nomenclature is used to describe the magnetic phases and has been left as it appears in the references.

### 2.1 Thulium

The magnetic phase diagram for thulium (Ellerby *et al.* 1998) is presented in Fig. 2(a). There are five distinct magnetic phase regions. They are labeled as "ferromagnetic," "ferrimagnetic," "**c**-axis modulated" (CAM), "paramagnetic," and "A." The ferrimagnetic structure is such that all the moments are parallel to the **c**-axis with four moments pointing "up" and three moments "down" within the magnetic unit cell, with a wave vector of $\mathbf{Q}=2/7\mathbf{c}^*$ ($\mathbf{c}^*$ represents the reciprocal lattice vector of the **c**-axis). In the ferromagnetic phase, all the moments point "up" along the **c**-axis. The moments in the paramagnetic phase have no preferred orientation and may point in any direction. The CAM phase is a magnetic structure in which the moments all point along the **c**-axis, but the size of each moment varies from one position to next in a sinusoidal manner (modulation) within the magnetic unit cell. The nature of the phase marked by "A" remains undetermined at this time.

Having outlined the basic magnetic structures, the reader is now referred to Fig. 3. This figure presents two important measurement geometries, with the magnetic field applied parallel to the **c**-axis in both instances. On the left is the magnetoresistance

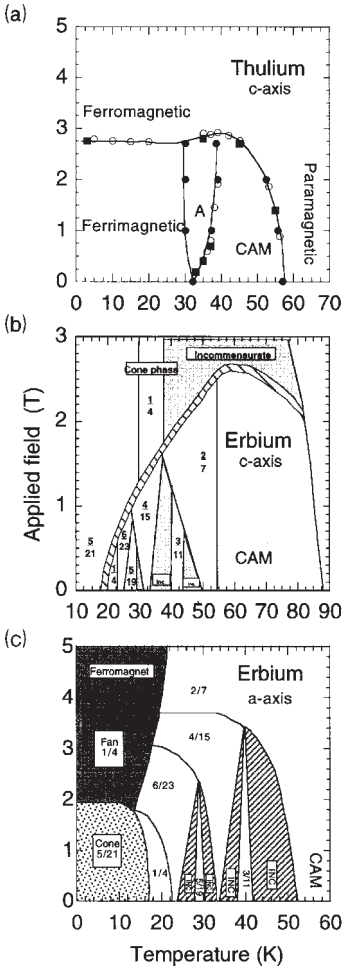

***Figure 2***
Magnetic phase diagrams for (a) thulium **c**-axis (Ellerby *et al.* 1998); (b) erbium **c**-axis (McMorrow *et al.* 1992); (c) erbium **a**-axis (Jehan *et al.* 1994).

measured along the **c**-axis (longitudinal magnetoresistance), and the magnetoresistance for the **a**-axis (transversal magnetoresistance) is on the right. For the longitudinal geometry at $T = 5\,\mathrm{K}$, the resistance shows no change with applied field and then a large decrease at 2.8 T, after which there is no change. This may be understood using the model of Fermi-surface modification (Mackintosh 1962, Elliott and Wedgwood 1963, Miwa 1963). The development of the ferrimagnetic structure results in the removal of large sections of the Fermi surface. As the field is increased, the ferrimagnetic structure becomes unstable, and at 2.8 T all the moments flip to form the ferromagnetic phase (see Fig. 2(a)). In doing so the modulation wave-vector changes from $\mathbf{Q} = 2/7\mathbf{c}^*$ to $\mathbf{Q} = 0\mathbf{c}^*$ (ferromagnetic). The additional potential is thus removed, resulting in an increase of available Fermi surface. In the transverse geometry ($\mu_0 H \| \mathbf{c}$-axis and $i \| \mathbf{a}$-axis) at $T = 5\,\mathrm{K}$, the features are different, with the resistivity increasing quadratically with field.

Then, as the structure changes, there is a sharp drop, followed by an almost linear increase. The quadratic and linear portion of this behavior is understood to be normal magnetoresistance (Pippard 1989) (discussed in *Magnetoresistance: Magnetic and Nonmagnetic Intermetallics*), and is associated with the Lorentz force acting at the conduction electron motion on the Fermi surface. The sharp decrease suggests that there is a small portion of the Fermi surface removed in the ferrimagnetic structure, which is replaced on entering the ferromagnetic phase. At $T = 45$ K (i.e., in the CAM region in Fig. 2(a)), the longitudinal measurement shows the same overall trend. However, before the large transition there is a smooth decrease. This is associated with the thermal activation of the moments along the **c**-axis. This activation results in fluctuations of the moment parallel and perpendicular to the **c**-axis, and results in spin-fluctuation scattering. The applied field acts to suppress these fluctuations, removing the scattering center and therefore reducing the resistivity until, at 2.7 T, the moments flip parallel to the **c**-axis. Above 2.7 T the applied field suppresses fluctuations of the moment away from the **c**-axis. The transverse magnetoresistance at $T = 45.1\,\mathrm{K}$ shows a smooth increase.

In this orientation, the field is perpendicular to the magnetic moments and thus, as the field increases, fluctuations transverse to the **a**-axis are enhanced, leading to additional scattering centers. This behavior is in accordance with the model (Yamada and Takada 1973). At the transition to the ferromagnetic state, the effects of fluctuations of the moment increase rapidly until full alignment at 2.7 T, after which the effect of the field is to suppress the fluctuations (Yamada and Takada 1973); at 3.2 T this becomes the dominant process. For $T = 53.0\,\mathrm{K}$, the application of a magnetic field results in a quadratic decrease in the resistivity for the longitudinal geometry. This may be seen as a flipping of the moments in a weak anisotropy field. The crystal field anisotropy has a temperature dependence (Jensen and Mackintosh 1991) which, at higher temperatures, allows the moments to rotate smoothly off the easy axis. The decrease in resistivity is attributed (Ellerby *et al.* 1998) to the replacement of Fermi surface. At $T = 53.0\,\mathrm{K}$, for the transverse geometry the resistivity is found to increase, and the process may be viewed as a continuous spin-flop process (Yamada and Takada 1973), with the moments eventually aligning parallel to the **c**-axis at 2.3 T. For larger fields, the fluctuations of the moments are systematically suppressed.

To summarize the case of thulium: the dominant influence for the magnetoresistance of the longitudinal geometry comes from the change in the Fermi

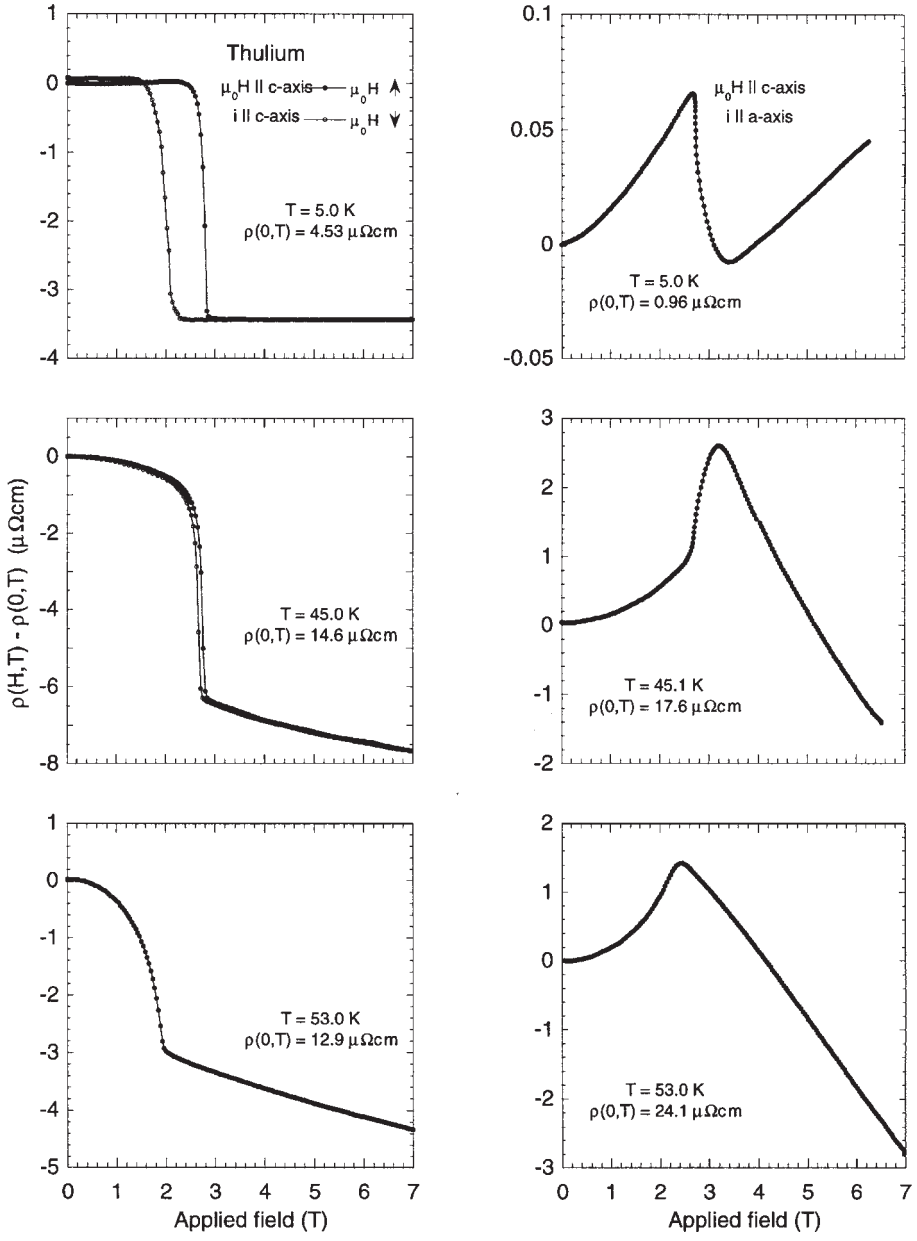

***Figure 3***
Magnetoresistance for thulium with B‖**c**-axis. Longitudinal **c**-axis on the left and transverse **a**-axis on the right.

surface (Mackintosh 1962, Elliott and Wedgwood 1963). As the temperature is increased, the anisotropy field decreases and spin-fluctuation scattering plays an increasing role. For the transverse geometry, the dominant scattering process derives from spin fluctuations becoming enhanced by the applied magnetic field; there is only a small effect due to the change in Fermi surface, and this can only be observed at very low temperatures. For the transverse geometry at low temperatures, the Lorentz force acting on the conduction electrons dominates. The temperature dependence of the thulium **c**-axis has been analyzed (Ellerby *et al.* 1998) for zero field and 4 T. From this analysis, Eqn. (4) has been found to provide a good model of the data. The features in Fig. 2(a) are all mapped using the longitudinal **c**-axis

magnetoresistance and temperature-dependent resistivity in fixed fields, and are found to agree with earlier studies.

### 2.2 Erbium

This introduction to the magnetic phase diagrams of erbium forms an overview, and the reader is encouraged to follow the references below for more detail of this fascinating element.

The magnetic phase diagrams for the **c** (McMorrow *et al*. 1992) and **a**-axes (Jehan *et al*. 1994) are presented in Figs. 2(b) and 2(c). When compared with thulium, it is clear that erbium has a greater number of magnetic structures and, unlike thulium, a moment develops parallel to the **a**-axis. However, as with thulium and other heavy rare earths, the structures are modulated along the **c**-axis. Where fractions appear in each of these figures, the denominator represents the fundamental periodicity. In the region marked CAM, the periodicity is similar to that observed for thulium of $\mathbf{Q} = 2/7\mathbf{c}^*$.

Referring to Fig. 2(b), there appears a region separated and marked by ''2/7''; this region of the phase diagram differs in that a moment has developed along the **a**-axis at these temperatures and fields, and this is also reflected in the **a**-axis phase diagram (Fig. 2(c)). In both figures there are regions marked ''INC,'' and these regions are described as incommensurate. This refers to the fact that the modulation wave vector parallel to the **c**-axis bears no simple relation to the crystal lattice. In the **a**-axis phase diagram (Fig. 2(c)) there are three other terms. These are ''cone,'' ''fan,'' and ''ferromagnetic.'' They all refer to the orientation of the moment parallel to the **a**-axis, since the moments parallel to the **c**-axis are aligned ferromagnetically. The ''cone'' phase refers to the structure in which the moments are parallel to both the **a**-axis and the **b**-axis. These moments are arranged in a helix about the **c**-axis, which, when projected onto a single lattice point, would appear as a ''cone.'' The term ''fan'' is used to describe a structure in which the moments on the **a**-axis have projected moments aligned parallel to the **a**-axis, but from one site to the next the angle of tilt away from the **a**-axis varies. When this arrangement of moments is projected onto a single lattice position, the moments appear to make a ''fan'' pattern parallel to the **a**-axis. The ''ferromagnetic'' phase has all the moments parallel to the **a**-axis.

For both phase diagrams there is a region between $T \sim 20\,\mathrm{K}$ and 55 K, and in this temperature range there is a host of structures. These structures are collectively known as ''cycloidal'' structures (Cowley and Jensen 1992), and may be ''viewed'' as moments modulated along the **c**-axis, forming an ellipse with the major axis parallel to the **c**-axis and the minor axis along the **a**-axis. This is an extremely difficult series of structures to visualize, and the reader is referred to Cowley and Jensen (1992), for a complete description.

Having outlined the magnetic phase diagrams obtained from neutron diffraction experiments, it is now possible to consider the results of magnetoresistance. There are two figures, presenting the effects of magnetic field for two crystal directions.

Figure 4 presents the results for the field parallel to the **c**-axis and measurement of the resistivity parallel to the **c**-axis (longitudinal **c**-axis on left) and parallel to the **a**-axis (transverse **a**-axis on right). For $T = 10\,\mathrm{K}$, erbium is in the ''cone'' phase, and for the longitudinal geometry there is a small decrease in the resistivity at low fields, associated with the removal of magnetic domains. As the field increases, there is a linear decrease associated with the suppression of spin fluctuations (Yamada and Takada 1973). In the transverse geometry at $T = 5\,\mathrm{K}$, the resistivity at first decreases as spin fluctuations are frozen. However, at approximately 2 T, the magnetoresistance increases linearly resulting from the Lorentz force (Pippard 1989) acting on the motion of the electrons in the applied magnetic field. At $T = 42.2\,\mathrm{K}$, the longitudinal measurement reveals several features. For fields less than 1.2 T, the magnetoresistance increases, revealing two regimes: $0 \rightarrow 0.4\,\mathrm{T}$ and $0.4 \rightarrow 1.2\,\mathrm{T}$. These regimes accord well with the passage through $3/11\mathbf{c}^*$ and $2/7\mathbf{c}^*$ phases.

The behavior in both may be viewed from the perspective outlined by Yamada and Takada (1973), in which the moments antiparallel to the applied field are being turned in the field. At 1.2 T there is a large decrease in the resistivity passing from the $2/7\mathbf{c}^*$ phase to the incommensurate phase (INC). This is interpreted as the removal of the superzone boundaries and the consequent replacement of Fermi surface (Elliott and Wedgwood 1963). Above 1.2 T, the moments of the incommensurate phase collapse smoothly about the **c**-axis, until at 6.2 T erbium enters the ferromagnetic phase. The transverse measurement at this temperature is interesting in that the behavior is very similar. This suggests that at this temperature there is strong coupling of the spin fluctuations along each axis. For $T = 64.3\,\mathrm{K}$, the magnetic structure is similar to that observed for thulium, with a CAM arrangement of the moments, and the dominant term in the anisotropy is that which ''prefers'' the **c**-axis. The behavior at this temperature is described by the same argument used for thulium at $T = 53\,\mathrm{K}$, and this represents the first appearance of ''canonical'' behavior in the magnetoresistance for these two different elements.

Figure 5 shows the influence of the magnetic field on the **a**-axis resistivity. The graphs on the left represent the longitudinal **a**-axis magnetoresistance, and those on the right represent the transversal **c**-axis resistivity. For the longitudinal magnetoresistance at $T = 4\,\mathrm{K}$, there is a steady increase of resistivity in the

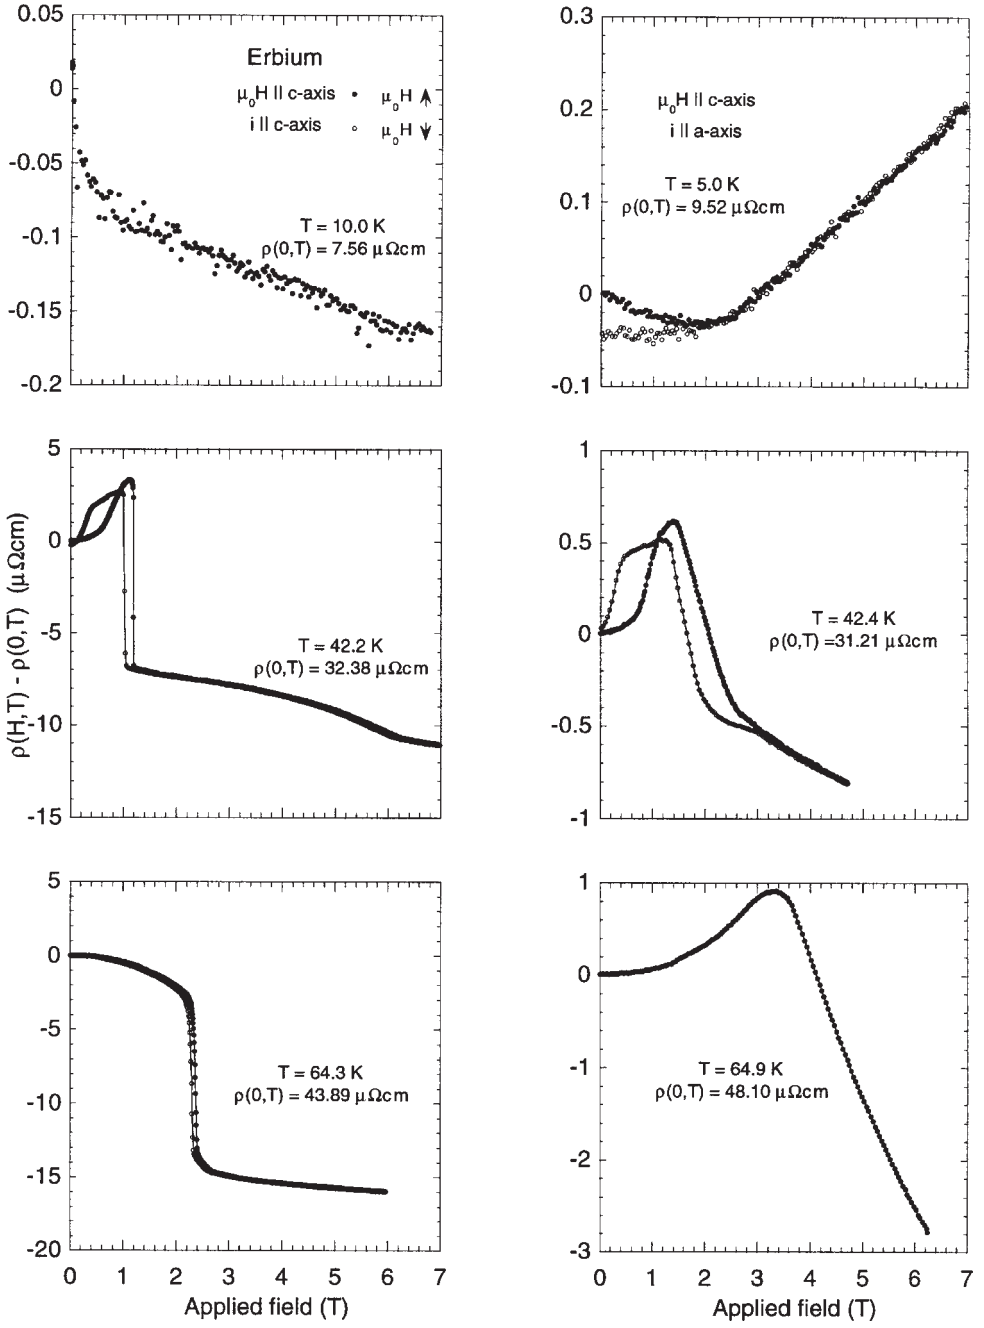

***Figure 4***
Magnetoresistance for erbium B‖**c**-axis. Longitudinal **c**-axis on the left and transverse **a**-axis on the right. The symbols (●) and (○) represent increasing field and decreasing field, respectively.

"cone" phase, consistent with the Lorentz force distorting the motion of the electrons (Pippard 1989). This is observed for both geometries. When the moments flip into the "fan" phase, there is a removal of Fermi surface. As the magnetic field increases there is smooth collapse of the "fan," formed by moments on the **a**- and the **b**-axes, onto the **a**-axis. There is no model for this process of moment collapse coupled

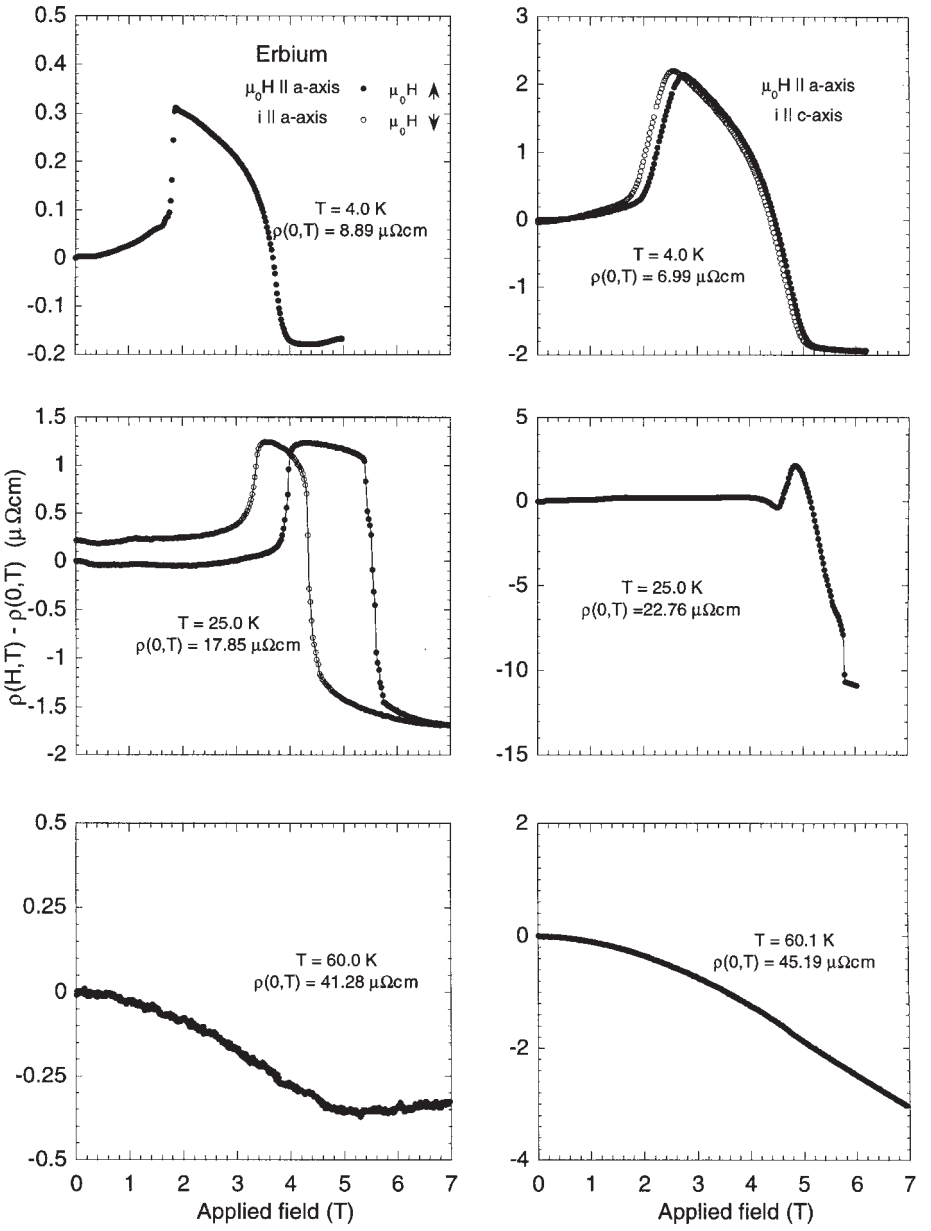

***Figure 5***
Magnetoresistance for erbium B‖**a**-axis. Longitudinal **a**-axis on the left and transverse **c**-axis on the right.

with a change in Fermi surface. Theoretical consideration of the results for erbium (Ellerby *et al.* 2000) has found that there are gaps in sections of the Fermi surface normal to both the **a** and **c**-axes, and this is certainly responsible for the decrease of the resistivity in the transverse **c**-axis above 5 T. This replacement of Fermi surface arises from the fact that a field parallel to the **a**-axis eventually drives erbium to a fully ferromagnetic state, as indicated in the phase diagram, and this in turn produces a modulation $\mathbf{Q} = 0\mathbf{c}^*$ and therefore $\Gamma_c = 0$.

The temperature-dependent resistivity for erbium in these two axes (Fig. 1) may be fitted, using Eqn. (4), with values for $\Gamma$ which have a temperature dependence (Ellerby *et al.* 2000), and values of $\Gamma_c^0 = 0.71$ and $\Gamma_a^0 = 0.14$ for $\mu_0 H = 0$ T. The value of $\Gamma_c$ is

similar to that found for thulium, where the structure is $\mathbf{Q} = 2/7\mathbf{c}^*$. At a temperature of $T = 25\,\mathrm{K}$, the magnetoresistance remains unaffected along both axes until 4 T, and thus the model of Yamada and Takada (1973), does not apply. The resistivity increases sharply at 4 T as erbium enters the $\mathbf{Q} = 2/7\mathbf{c}^*$ phase, this being in accordance with the removal of a portion of the Fermi surface. As the field is increased further, there is a sharp decrease in both geometries as erbium enters the ferromagnetic phase. As in the case at 4 K, there is no modulation of the magnetic moment, and consequently the superzone boundaries cease to exist abruptly at this boundary, whilst increasing the available Fermi surface. There is significant hysteresis at this transition, suggesting a first-order transition. The results at $T = 60\,\mathrm{K}$ can be understood through the model of Yamada and Takada (1973), in which erbium is paramagnetic along the **a**-axis, and therefore an applied field systematically suppresses the spin fluctuations along this axis. This is consistent with the dominance of the strong uniaxial anisotropy along the **c**-axis.

The summary of this section highlights the correspondence of magnetic phase diagrams with the magnetoresistance of erbium. The experimental results presented map well onto the magnetic phase diagrams; however, there are some differences worthy of note. The most prominent derives from the effects of the demagnetizing factor usually present in neutron diffraction studies, which can be of the order 0.5, whilst in longitudinal magnetoresistance the demagnetizing factor can be less than 0.1. The factor results in discrepancies of boundary position, and corrections for this effect can be determined (Stoner 1945). The low-temperature behavior of erbium is dominated by the motion of the conduction electrons in an applied field, with the effects of Fermi-surface modification superposed. A further aspect of phase diagrams concerns the nature of the phase transition. The observation of hysteresis at a transition is a strong indication of a first-order transition, and this can be important in some studies.

## 3. Concluding Remarks

The preceding sections presented a series of results for the rare earths, chosen to exhibit different anisotropy and exchange. In both cases it has been possible to apply some form of Eqn. (2), incorporating the superzone effects through Eqn. (4) as for the **c**-axis of thulium and erbium. There is, however, one proviso in the case of erbium. Eqn. (4) requires the inclusion of a temperature dependence in $\Gamma_u$ which represents the effects of the Fermi surface on the resistivity (Ellerby *et al*. 2000). In addition to this, the **a**-axis of erbium appears to lose a small portion of the Fermi surface in the cycloidal phase. This is recovered on entry into the cone phase at $T = 20\,\mathrm{K}$ (Fig. 1). Indeed, Eqn. (2) is particularly versatile in its ability to describe excitations in magnetic systems, and may also be used to analyze systems exhibiting gaps in the spin-wave spectrum.

There were two sets of canonical behavior observed in the magnetoresistance. The first concerned the prominent correlation for the **c**-axis modulated structures (CAM) of thulium and erbium. The second was found in the magnetoresistance for the ''fan'' phase in erbium and exhibited in the **a**-axis measurements a $T = 4\,\mathrm{K}$. This behavior has also been observed in the resistivity for the holmium **b**-axis in the ''fan'' phase, where there is quadratic collapse in the resistivity associated with the collapse of the ''fan.'' These responses may be added to the schema derived by Yamada and Takada (1973), to understand the magnetoresistance in spin-flop systems, and the influence of spin/moment fluctuations in ferromagnetic and paramagnetic materials. In both systems discussed, the influence of the magnetic superzones (Mackintosh 1962, Elliott and Wedgwood 1963, Miwa 1963) was found to be of prime importance in the study of the **c**-axis of these elements. This is true for many of the heavy rare-earth elements.

In comparing results of magnetoresistance with those of neutron diffraction studies, caution is required. In the neutron diffraction studies there is often a large contribution to the position of the phase boundary coming from the demagnetizing field. This can lead to ambiguities. Furthermore magnetoresistance, whilst being one of the most sensitive probes of magnetic systems, can often fail to reveal subtle changes in structural modulation; this is the case with incommensurate structures. Magnetoresistance can only assist in a qualitative fashion when composing magnetic phase diagrams, and will provide allusions as to the type of magnetic structure. However, accurate positions of the phase boundaries may be derived, particularly when using a longitudinal geometry.

## ESR Dosimetry: Use of Rare Earth Ions

The trapped electrons (or holes) that are produced in thermoluminescence (TL) phosphors owing to irradiation are thermally released and then recombined with emitting centers, resulting in TL. Therefore, the trapped electrons (or holes) reflecting an accumulated dose are completely released after measuring the TL.

The signal intensity of ESR owing to unpaired electrons produced in irradiated crystals is proportional to the exposure dose. The ESR signal intensity is hardly affected by the measurement because the dose reading with ESR does not require heating, essentially different from the case of TL. Thus, the memory of the irradiation is accurately retained in the crystal after the dose reading. The dose reading can be carried out repeatedly so that the signal/noise ratios are increased. Thus, ESR dosimetry is preferable as a low-dose method to TL dosimetry. Alanine (Regulla and Deffiner 1982), sucrose (Nakajima and Otsuki 1987), and gadolinium ion-doped $K_3Na(SO_4)_2$ (Ohta *et al.* 1997) are known as ESR dosimetry sensors, of which gadolinium ion-doped $K_3Na(SO_4)_2$ is the most sensitive.

ESR and TL properties have been described in $K_3Na(SO_4)_2$ doped with rare earth (Ln = Y, La, Pr, Nd, Sm, Eu, Gd, Tm, Lu) ions after x-ray irradiation. ESR and TL spectra of Ln ion-doped $K_3Na(SO_4)_2$ suggest that these dopants predominately substitute for sodium ions in the $K_3Na(SO_4)_2$ matrix, and the formation of $SO_3^-$ radicals is promoted by the cation vacancy that is produced by the charge compensation, owing to the presence of the trivalent ion. The $SO_3^-$ radical is isotropic and thermally stable. The absorption dependence on the ESR signal intensity of the $SO_3^-$ radical indicates that the ESR signal intensity is proportional to the absorbed dose of x rays from $10^{-4}$ Gy to $10^2$ Gy in yttrium ion-doped $K_3Na(SO_4)_2$ and from $10^{-5}$ Gy to $10^2$ Gy in gadolinium ion-doped $K_3Na(SO_4)_2$.

### 1. ESR Spectra

The typical ESR spectrum of Ln ion-doped $K_3Na(SO_4)_2$ after x-ray irradiation of about 70 Gy (Fig. 1) consists of a signal at $g = 2.003$, assigned probably to isotropic $SO_3^-$ radicals (Gromov and Morton 1966, Luthra and Gupta 1974). This $SO_3^-$ radical is thermally stable up to about 450 K. Furthermore, the fading of this radical at room temperature is less than 1% $yr^{-1}$ (Ohta *et al.* 1992a).

Figure 2 shows the effect of an amount of blended $Ln_2(SO_4)_3$ on the ESR signal intensity. The ESR signal intensity of $SO_3^-$ radical in stable trivalent yttrium, lanthanum, gadolinium, or lutetium ion-doped $K_3Na(SO_4)_2$ is higher than that in praseodymium, neodymium, or thulium ion-doped $K_3Na(SO_4)_2$, and much lower than that in samarium or europium ion-doped $K_3Na(SO_4)_2$ (Ohta *et al.* 1997).

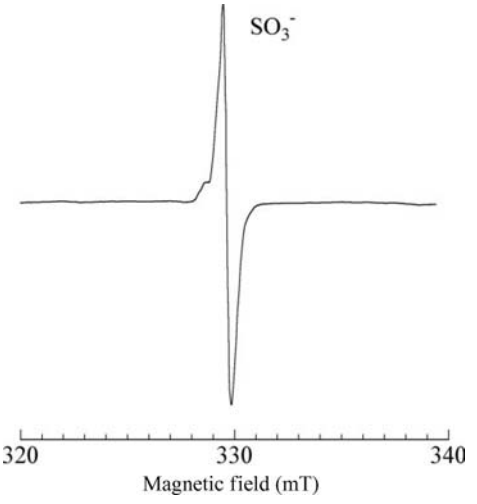

***Figure 1***

## 2. TL Spectra

TL spectra have been measured in order to investigate the valence of the Ln ion-doped $K_3Na(SO_4)_2$ matrix. The TL spectrum of yttrium, lanthanum, or lutetium ion-doped $K_3Na(SO_4)_2$ consists of a broad, weak peak (about 400 nm) owing to the $K_3Na(SO_4)_2$ matrix. In praseodymium, neodymium, gadolinium, or thulium ion-doped $K_3Na(SO_4)_2$, the TL spectrum consists of peaks assigned to the f–f transitions of each $Ln^{3+}$ ion, i.e., the $^1D_2 \rightarrow {}^3H_4$ transition of $Pr^{3+}$, the $^2G_{5/2} \rightarrow {}^4I_{13/2}$ and $^2H_{5/2} \rightarrow {}^4I_{9/2}$ transitions of $Nd^{3+}$, the $^6P_{7/2} \rightarrow {}^8S$ transition of $Gd^{3+}$, and the $^1D_2 \rightarrow {}^3H_6$, $^1D_3 \rightarrow {}^3H_4$, $^1G_4 \rightarrow {}^3H_6$, $^1G_4 \rightarrow {}^3H_4$, and $^1G_4 \rightarrow {}^3H_5$ transitions of $Tm^{3+}$. The TL intensity of the f–f transition peaks varies according to the following sequence: $Gd^{3+} \ll Pr^{3+}$, $Nd^{3+} < Tm^{3+}$. This is in contrast to the ESR signal intensity (Fig. 2).

The TL spectrum of samarium ion-doped $K_3Na(SO_4)_2$ is affected by the glow peak temperature, i.e., a broad peak owing to the $4f^5 5d \rightarrow 4f^6$ transition of $Sm^{2+}$ and three sharp peaks owing to the $^4G_{5/2} \rightarrow {}^6H_{5/2}$, $^4G_{5/2} \rightarrow {}^6H_{7/2}$, and $^4G_{5/2} \rightarrow {}^6H_{9/2}$ transitions of $Sm^{3+}$ are observed near 380 K and near 430 K, respectively. The TL spectrum of europium ion-doped $K_3Na(SO_4)_2$ consists of a broad, strong peak owing to the $4f^6 5d \rightarrow 4f^7$ transition of $Eu^{2+}$.

## 3. Formation Mechanism of $SO_3^-$ Radicals

The formation mechanism of $SO_3^-$ radicals can be interpreted on the basis of the ESR and TL characteristics (Ohta *et al*. 1992b, 1997). Ln ion-doped $K_3Na(SO_4)_2$ after x-ray irradiation reveals that the higher the ESR signal intensity, the lower the TL intensity. Since Ln substitutes mainly for potassium or sodium in Ln ion-doped $K_3Na(SO_4)_2$, cation vacancies are created. Consequently, the $SO_4^{2-}$ ion located in the neighborhood of the cation vacancy can easily capture the free hole released by x-ray irradiation, resulting in an $SO_4^-$ radical. Most of the unstable $SO_4^-$ radicals change immediately into $SO_3^-$ radicals, and some revert to $SO_4^{2-}$ ions with TL emission owing to the electron–hole recombination. The highest ESR signal intensity probably corresponds to a smaller distortion in the $K_3Na(SO_4)_2$ matrix when it is doped with yttrium or gadolinium, because the ionic radii of yttrium and gadolinium are close to that of sodium.

## 4. Application of $SO_3^-$ Radicals to ESR Dosimetry

Figure 3 shows the ESR signal intensity of $SO_3^-$ radical dependence on the absorption dose in yttrium and gadolinium ion-doped $K_3Na(SO_4)_2$. The net ESR signal intensity, which eliminates the intensity before x-ray irradiation, depends on the absorbed dose of x rays from $10^{-4}$ Gy to $10^2$ Gy in yttrium ion-doped $K_3Na(SO_4)_2$ and from $10^{-5}$ Gy to $10^2$ Gy in gadolinium ion-doped $K_3Na(SO_4)_2$ (Ohta *et al*. 1997).

## Faraday and Kerr Rotation: Phenomenological Theory

In 1845 Michael Faraday carried out a series of experiments to determine whether linearly polarized light, when passed though a transparent insulator, was influenced by strong electric fields. Despite Faraday's renowned experimental skills, he failed to observe any effects. Frustrated, he turned instead to the use of magnetic fields. After some initial failures, on the 13th of September he was able to detect a small, though dubious, change when using a poor-quality lead borate glass (Thomas 1991). Fortunately, some 20 years earlier, between 1825 and 1831, Faraday had carried out extensive research into the production of optical-grade glass. Although at the time Faraday considered his research into glasses tedious, his efforts were now to be handsomely repaid. Using one of his own optical-quality glasses he had a sufficiently perfect medium to demonstrate clearly the effect that bears his name to this day. The *Faraday effect* as it is known, demonstrates that the polarization state of electromagnetic radiation may be changed by its passage through an insulating medium when there is a strong magnetic field present (Faraday 1845).

Amazingly, 30 years later in 1875, John Kerr, a close collaborator of William Thompson (later Lord Kelvin), repeated Faraday's quest to demonstrate that electric fields can influence the polarization state of optical radiation as it passes through a transparent material. It is a tribute to the keen experimental skills of Kerr that, where Faraday had failed, he was successful. Using a variety of materials, including glass and later a number of liquids, he demonstrated the electrooptic effect. On the 26th August 1876, at the annual meeting of the British Association for the Advancement of Science held in Glasgow, UK, Kerr announced a further discovery of an effect that has since become known as the *Kerr magnetooptic effect* (Kerr 1877). Using linearly polarized light from a narrow paraffin flame, Kerr showed that a change in polarization state occurred on reflection from a polished, soft iron pole-piece of a strong electromagnet. Given that the changes produced by this effect are usually very small and are difficult to observe, even with modern laser sources, the achievement of Kerr was spectacular. In announcing his discovery Kerr acknowledged the dependence of his success on the earlier work of Faraday and later Verdet, who in 1854 had demonstrated the Faraday effect in semi-transparent paramagnetic media (Verdet 1854).

The Kerr and the Faraday effects are now collectively known as magnetooptical effects and their microscopic origins are well understood (Freiser 1968). This article is a phenomenological description of the various categories of magnetooptic effects as they may be observed in the laboratory for magnetized media. For obvious historical reasons magneto-optical effects that are observed in transmission are known as Faraday effects. Conversely, effects observed in reflection are referred to as Kerr effects. Often, there is some confusion in referring to the Kerr effect in reflection from materials that are not optically opaque and where radiation may have traveled through the material and back again several times, eventually appearing on the side of reflection as a multiply reflected beam. However, it is convention to refer to effects observed in the reflected field as Kerr effects and in transmission as Faraday effects.

In describing magnetooptical effects it is convenient to categorize them into three principal configurations defined by the orientation of the magnetization vector (**M**) relative to the plane of the reflecting surface and to the plane of incidence of the incident radiation. The three configurations are referred to as the *polar*, *longitudinal*, and *transverse* orientations (Fig. 1).

### 1. Polar and Longitudinal Effects

In the polar and longitudinal cases, effects occur for incident radiation polarized either in the P-plane (electric vector parallel to the plane of incidence) or the S-plane (electric vector perpendicular to the plane of incidence). Radiation incident in either of these linearly polarized states is, on reflection, converted to elliptically polarized light. The major axis of the ellipse is often rotated slightly with respect to the principal plane and this is commonly referred to as the Kerr rotation. There is also an associated ellipticity and this is called the Kerr ellipticity. At the same time, similar effects occur in transmission, in this case producing Faraday rotation and ellipticity. To first order, the size of these effects is directly proportional to the magnitude of the magnetization vector, **M**. Furthermore the sense of rotation and ellipticity is reversed if the magnetization direction is changed by

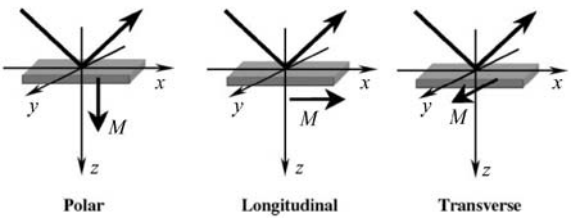

*Figure 1*
The three principal magnetooptical configurations.

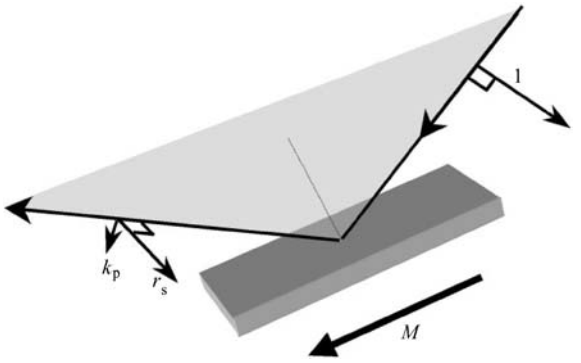

***Figure 2***
Electric field amplitudes associated with the longitudinal Kerr effect.

180°. In each case the magnitudes of the effects vary with angle of incidence. For the longitudinal case the effect is zero at normal incidence, which is not true for the polar configuration.

It is useful to look at these effects in a little more detail by considering the electric field (**E**) vectors associated with incident and reflected fields. It should be noted that it is the interaction between **E** and **M** (indirectly through spin–orbit coupling) that gives rise to the observed magnetooptical effects. The magnetic component of the wave plays no part at optical frequencies. As an example, Fig. 2 shows the longitudinal configuration although the discussion also applies to the polar case. One can see the specific case of the **E** vector incident in the S-plane. If the incident field amplitude is taken as unity, the reflected beam will consist of two orthogonal complex vectors. One is the usual Fresnel amplitude reflection coefficient, $r_s$, while the other is a small component, $k_p$, called the Kerr coefficient. The subscripts p and s refer to the directions parallel and perpendicular to the plane of incidence, respectively. In general, these two vectors represent the amplitudes of oscillating electromagnetic fields and may be out of phase with each other. Together they give rise to elliptically polarized light as illustrated in Fig. 3, where the observer is looking along the reflected beam towards the sample surface. In this case the Kerr rotation, $\theta_k$, is in a clockwise direction and is counted as positive. Likewise, if the locus of the resultant **E** vector rotates in a clockwise direction in time, as indicated in Fig. 3 the ellipticity, $\varepsilon_k$, is positive. In a similar way, the transmitted beam may also become elliptically polarized with amplitude transmission coefficient $t_s$ and Faraday coefficient $f_p$ leading to a rotation $\theta_f$ and ellipticity $\varepsilon_f$.

In general, and with reference to Fig. 3, the Kerr rotation and ellipticity are given by the following ellipsometric expressions:

$$\tan 2\theta_k = \tan 2\chi \cos\Delta_k \tag{1}$$

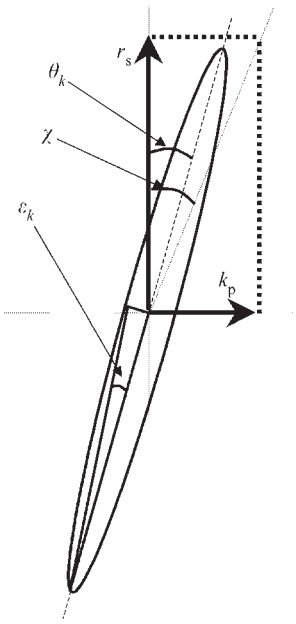

***Figure 3***
Elliptically polarized light showing Kerr rotation, $\theta_k$, and ellipticity, $\varepsilon_k$.

and

$$\sin 2\varepsilon_k = \sin 2\chi \sin\Delta_k \tag{2}$$

where

$$\tan\chi = \left|\frac{k_p}{r_s}\right| \tag{3}$$

$$\frac{k_p}{r_s} = \left|\frac{k_p}{r_s}\right| e^{i\Delta_k} \tag{4}$$

and $\Delta_k$ is the angular phase difference between the two orthogonal vectors. In many instances the magnetooptical coefficients are very small; consequently, when $|k_p| \ll |r_s|$ a simple complex Kerr rotation, $\hat{\theta}_k$, may be defined as

$$\hat{\theta}_k = \theta_k + i\varepsilon_k \approx \frac{k_p}{r_s} = \left|\frac{k_p}{r_s}\right| \cos\Delta_k + i\left|\frac{k_p}{r_s}\right| \sin\Delta_k \tag{5}$$

Similarly, if $|f_p| \ll |t_s|$ a complex Faraday rotation, $\hat{\theta}_f$, may be defined as

$$\hat{\theta}_f = \theta_f + i\varepsilon_f \approx \frac{f_p}{t_s} = \left|\frac{f_p}{t_s}\right| \cos\Delta_f + i\left|\frac{f_p}{t_s}\right| \sin\Delta_f \tag{6}$$

It should be noted that similar expressions apply for light incident in the P-plane, in which case the associated coefficients are $k_s$, $f_s$, $r_p$, and $t_p$. In addition, by reversing the magnetization, the signs of the

magnetooptical coefficients are changed and so too is the sense of the complex Kerr rotation.

### 2. Transverse Effect

The transverse situation is quite different from that described above. First, an effect is only observed for radiation polarized in the P-plane. Second, the radiation remains linearly polarized after reflection, although the reflected intensity changes by a small amount on reversal of the magnetization. This effect varies with angle of incidence and is zero at normal incidence. The situation in reflection is illustrated in Fig. 4 where the incident unit amplitude in the P-plane gives rise to the usual Fresnel amplitude reflection coefficient, $r_p$, together with a small Kerr component, $k_p$. The combination of these two vectors, which are not necessarily in phase, results in an intensity reflectivity that changes as the magnetization is switched between the two antiparallel states, $\pm M$. This is illustrated schematically in the amplitude diagram of Fig. 5 where the resultant amplitudes are shown for the two cases. Since the measurable intensity reflectance is equal to the square of the modulus of the resultant amplitude reflectance, the two reflectances, $R_\pm$, are given by

$$R_+ = |r_p + k_p|^2 \text{ and } R_- = |r_p - k_p|^2 \qquad (7)$$

Hence, on magnetization reversal a change, $\Delta R$, occurs with a mean intensity reflectance, $R$, where

$$\Delta R = R_+ - R_- \text{ and } R = (R_+ + R_-)/2 \qquad (8)$$

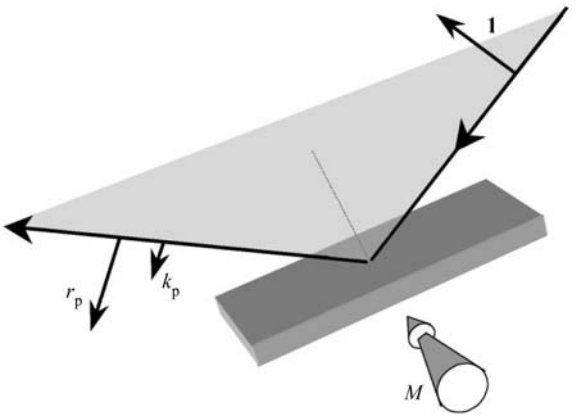

***Figure 4***
Electric field amplitudes associated with the transverse Kerr effect.

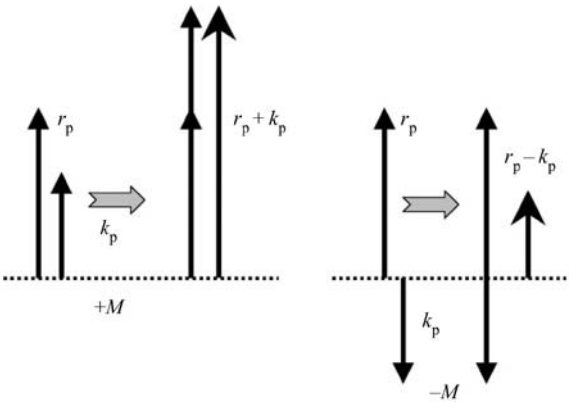

***Figure 5***
Electric field amplitudes associated with the transverse Kerr effect.

### 3. Permittivity Tensor

As already mentioned, it is the interaction of the electric field vector with the medium that gives rise to magnetooptical effects and for this reason the intrinsic material properties are contained within a skew-symmetric permittivity tensor, $[\varepsilon]$. The form of this tensor may be determined on symmetry grounds since a rotation of the Cartesian coordinate system around the magnetization direction should leave the material properties unchanged. The tensor, for an otherwise isotropic medium, is given below for the magnetization vector pointing along the positive $z$-direction:

$$[\varepsilon] = \varepsilon_0 n^2 \begin{bmatrix} 1 & -iQ & 0 \\ +iQ & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \qquad (9)$$

where $\varepsilon_0$ is the permittivity of free space and $n$ $(= n' + in'')$ is the complex refractive index of the material. $Q$ $(= Q' + iQ'')$ is the magnetooptic parameter that gives rise to the previously described effects. It should be noted that the positions of the plus and minus signs in this tensor depend upon the particular sign convention chosen to carry out magnetooptical calculations. Moreover the choice of convention has implications for the sense of the complex magnetooptical rotations. For this reason it is important to adopt a clearly defined system. The various options are described in the literature (Atkinson and Lissberger 1992) and it should be noted that the self-consistent preferred scheme described in this reference is used here.

### 4. Normal Incidence Polar Case

In magnetooptical recording applications the normal incidence polar configuration is most commonly used because the Kerr and Faraday effects are relatively large and normal incidence is convenient from a practical point of view. In such situations the magnetooptical effects can also be understood from the

differential propagation properties of circularly polarized beams or optical modes (Gerber *et al.* 1992). It transpires that a linearly polarized beam may be decomposed into two counter-rotating circularly polarized beams whose **E** vectors are equal and rotate in opposite directions (i.e., clockwise (+) and anticlockwise (−)). At normal incidence, these two beams may be considered to propagate separately through the medium with associated refractive indices $n_+$ and $n_-$ given by

$$n_\pm = n(1 \pm Q/2) \tag{10}$$

At a plane boundary between an incident medium of refractive index $n_0$ and a semi-infinite medium of refractive index $n_\pm$, the amplitude reflection coefficient is simply given by

$$r_\pm = \frac{n_0 - n_\pm}{n_0 + n_\pm} \tag{11}$$

Consequently, after reflection (or transmission), the amplitudes of these two circular polarized modes are different and when recombined result in the amplitude coefficients $r$ and $k$ (or $t$ and $f$), as discussed above. Figure 6 is a vector phase diagram that illustrates this. It is clear that after reflection and since $|Q| \ll 1$ these two modes result in amplitude reflection and Kerr coefficients given by

$$r = \frac{r_+ + r_-}{2} \approx \frac{n_0 - n}{n_0 + n} \tag{12}$$

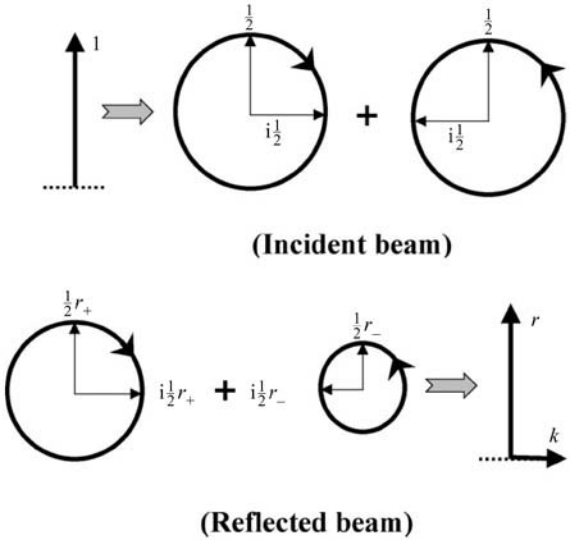

***Figure 6***
Circular polarized modes leading to the normal incidence polar Kerr effect.

and

$$k = \frac{(r_+ - r)}{2} \approx \frac{-in_0 nQ}{(n_0 + n)^2} \tag{13}$$

In most cases $k \ll r$, in which case it follows that the complex Kerr rotation, as previously defined in Eqn. (5), is given by the following expression:

$$\hat{\theta}_k = \frac{k}{r} \approx -\frac{inn_0 Q}{n_0^2 - n^2} \tag{14}$$

By ignoring boundary effects, a simplified calculation can also be carried out for the Faraday effect in a slab of material of thickness $d$. In this case the two circular modes suffer differential absorption owing to the differing complex indices $n_+$ and $n_-$. A straightforward calculation shows that a simple expression for the complex Faraday rotation is

$$\hat{\theta}_f = \frac{f}{t} \approx -\frac{\pi nQd}{\lambda_0} \tag{15}$$

where $\lambda_0$ is the free-space wavelength of the radiation.

## 5. *Summary*

Magnetooptical effects, first discovered by Michael Faraday and John Kerr, can clearly be understood phenomenologically, both in reflection and transmission, in terms of the existence of small electric field amplitudes that appear in the reflected and transmitted fields in addition to the usual Fresnel amplitudes. In longitudinal and polar orientations of the magnetization, with respect to the plane of incidence, these extra magnetooptical components give rise to elliptically polarized light. In the transverse orientation the magnetooptic component results in an intensity change in the reflectivity of P-polarized light. The intrinsic properties of the material, said to be gyroelectric, are fully described by a skew-symmetric permittivity tensor. Formal calculations can be carried out for single surfaces and thin films as well as for multilayered systems. A full discussion of the theoretical techniques used to deal with multilayer systems and their properties is given in *Magneto-optical Effects, Enhancement of* and *Multilayer Optical Film Modelling*.

# Ferrite Ceramics at Microwave Frequencies

The term *ferrite* is used to designate ferrimagnetic materials. Ferrites are similar to magnetic alloys in that both possess magnetic domains and exhibit characteristic phenomena of saturation and hysteresis. However, ferrites are generally ceramics that are hard, brittle, and are poor electrical conductors. Typical values for the physical constants of ferrite ceramics are:

Coefficient of linear expansion $= 10^{-5}\,^{\circ}\mathrm{C}^{-1}$
Specific heat $= 0.2\,\mathrm{cal\,g^{-1}\,^{\circ}C^{-1}}$
Thermal conductivity $= 0.015\,\mathrm{cal\,s^{-1}\,cm^{-1}\,^{\circ}C^{-1}}$
Density $= 5\,\mathrm{g\,cm^{-3}}$

The chemical formula for ferrites can vary significantly, and they can have cubic or hexagonal crystal structure. Ferrites with spinel structure have the formula $MFe_2O_4$, where the iron is trivalent and the symbol M denotes a divalent metal from the series $Mg^{+2}$, $Mn^{+2}$, $Fe^{+2}$, $Co^{+2}$, $Ni^{+2}$, $Cu^{+2}$, $Zn^{+2}$, or $Cd^{+2}$. Another important family of ferrite compounds are those with the garnet structure with chemical formula $M_3Fe_5O_{12}$, where M is a trivalent metal from the lanthanide period of elements, such as yttrium. Ferrites having hexagonal structure correspond to the formula $MFe_{12}O_{19}$, where M is Ba or Sr, M being divalent and Fe trivalent.

Ferrite ceramics are widely used in microwave devices to control transmission path, frequency, amplitude, and phase of microwave signals. Accurate dielectric and magnetic property measurements at the operational frequency and temperature ranges are needed for optimized development of these devices, as well as to assist in the manufacture of the ferrite itself. Both dielectric and magnetic losses must be determined.

## 1. Microwave Measurements

A ferrite is characterized electrically and magnetically by its complex permittivity:

$\varepsilon^* = \varepsilon_0(\varepsilon_r - j\varepsilon_r'') = \varepsilon_0\varepsilon_r'(1 - j\tan\delta_e)$ and its complex permeability:

$\mu^* = \mu_0(\mu_r' - j\mu_r'') = \mu_0\mu_r'(1 - \tan\delta_m)$, where $\tan\delta_e$, $\tan\delta_m$ denote dielectric and magnetic loss tangents, and the free space permittivity $\varepsilon_0$ and permeability $\mu_0$ are given by $8.854 \times 10^{-12}\,\mathrm{F\,m^{-1}}$ and $4\pi \times 10^{-7}\,\mathrm{H\,m^{-1}}$. The superscript * denotes that the quantity is complex. The complex permittivity and permeability are both temperature- and frequency-dependent.

Dielectric losses for most ceramic ferrites are very small ($\leqslant 5 \times 10^{-4}$) and usually vary linearly with frequency. Magnetic losses depend on saturation magnetization, chemical composition, porosity and grain size, and any applied static magnetic field strength. Magnetic losses vary nonlinearly with frequency, often by seven orders of magnitude over the frequency range from 1 MHz to 25 GHz.

When an applied magnetic field bias is applied in the $z$-direction, the complex permeability becomes anisotropic and is then generally written in diagonalized tensor form:

$$\bar{\bar{\mu}}; = \mu_0 \begin{bmatrix} \mu_x^* & 0 & 0 \\ 0 & \mu_y^* & 0 \\ 0 & 0 & \mu_z^* \end{bmatrix} \qquad (1)$$

For the dielectric case, $\mu_x' = \mu_y' = \mu_z' = 1$ and all magnetic losses are 0. For a demagnetized ferrite, $\mu_x^* = \mu_y^* = \mu_z^* = \mu_d^*$, and magnetic permeability becomes a scalar quantity. For a partially magnetized ferrite, $\mu_x^* = \mu_y^* = \mu_t^*$ and $\mu_z' \neq 1$, $\tan\delta_{z,m} \neq 0$, where $\tan\delta_{z,m}$ denotes the magnetic loss tangent parallel to the applied tuning magnetic bias field and $\mu_t^*$ is the magnetic permeability transverse to the bias field. In a saturated ferrite, $\mu_x^* = \mu_y^* = \mu_t^*$, and $\mu_z' = 1$, $\tan\delta_{z,m} = 0$.

The magnetization frequency of a ferrite is defined by $f_M = \gamma_g M_s$, where $\gamma_g$ is the gyromagnetic ratio ($35.19\,\mathrm{MHz \cdot m/kA}$) and $M_s$ is the saturation magnetization (kA/m). At frequencies $f$ less than $f_M$, ferrites have high magnetic loss and are commonly used as ferrite tiles in anechoic chambers or in other shielding applications. Waveguide transmission line techniques can be used for accurate magnetic characterization for $f < f_M$ (Baker-Jarvis *et al.* 1993).

Wireless communication system applications employing ferrites (circulators and phase shifters) usually operate at frequencies greater than the magnetization frequency. Magnetic losses rapidly decrease above $f_M$, and transmission line techniques cannot be used for accurate loss characterization. The most accurate methods for measuring ferrite

magnetic properties at microwave frequencies are techniques that use resonant cavities or that incorporate the ferrite specimen as part of a dielectric resonator system (LeGraw and Spencer 1956, Bussey and Steinert 1958, Green and Kohane 1964, Green and Sandy 1974, Ogasawara *et al.* 1976, Muller-Gronau and Wolf 1983, Le Roux *et al.* 1988, Krupka 1991, Krupka and Geyer 1996). Dielectric resonator system techniques have greater sensitivity than cavity methods to magnetic loss for comparably-sized samples. One measurement procedure, illustrated in Fig. 1 for accurate evaluation of $\varepsilon_r^*$ and $\mu_d^*$ and at frequencies greater than $f_M$, is to place a cylindrical sample in a parallel plate waveguide (Courtney 1970) and:

Apply a large static magnetic field (beyond ferromagnetic resonance) along the cylindrical $z$-axis to saturate the ferrite specimen, causing $\mu_z' = 1$ and $\tan\delta_{z,m} = 0$. The ferrite specimen is equivalent to a dielectric resonator, and $\varepsilon_r'$ and $\tan\delta_e$ may be measured with the $TE_{011}$ mode resonant frequency $f$ and system unloaded $Q$-factor $Q_0$.

Demagnetize the specimen and measure the $TE_{011}$ mode resonant frequency $f_m$ and unloaded $Q$-factor $Q_m$. The real permittivity and dielectric loss tangent are known from the first step, and the real magnetic permeability $\mu_d'$ and magnetic loss tangent $\tan\delta_m$ are evaluated from the second.

Another measurement technique is to employ low-loss dielectric sleeves operated with $TE_{011}$ mode structure (Fig. 2). This system (Krupka and Geyer 1996, Geyer 1999) permits broadband permeability characterization of a *single* ferrite sample at frequencies near and far from the magnetization frequency. The measurement bandwidth is realized by the use of commercially available high-$Q$ ceramic or oriented single-crystal quartz resonators. The aspect ratios and permittivities of the sleeve resonators may be chosen so as to enable spectral characterization of a single ferrite sample from 800 MHz to 25 GHz.

In the absence of an applied static field, the ferrite in the demagnetized state is isotropic and is described

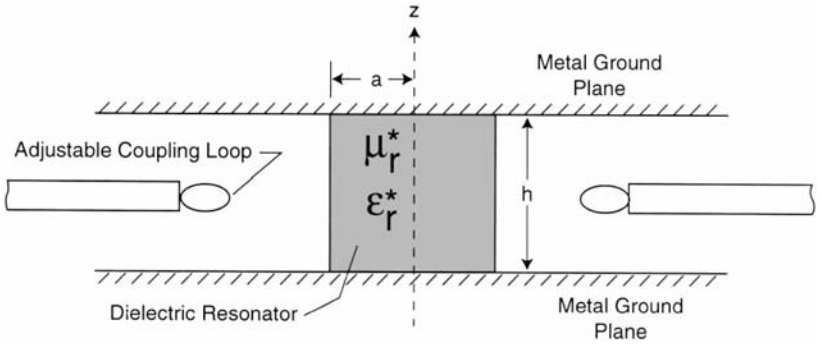

***Figure 1***
Ferrite employed as dielectric resonator in a parallel plate waveguide.

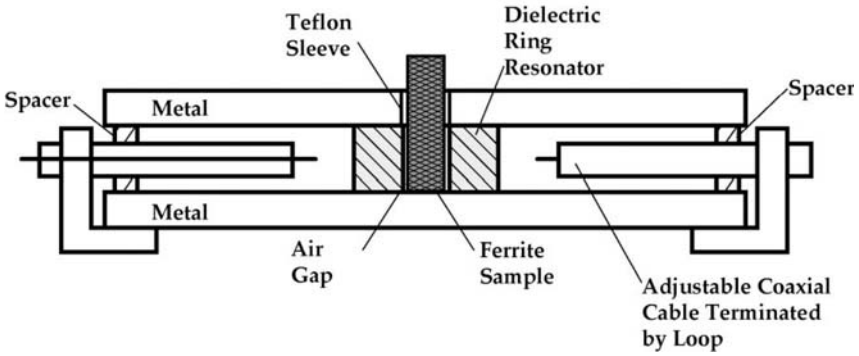

***Figure 2***
Dielectric resonator system for broadband microwave permeability measurements.

by a scalar frequency- and temperature-dependent relative permeability and complex relative permittivity. The resonators are coupled to the external microwave source through two loop-terminated coaxial cables that are adjustable so that the measured loaded $Q$ factor is equal to the unloaded $Q$ factor within any prescribed accuracy.

The measurement procedure follows several steps. First, the complex permittivity of the ferrite is determined with a $TM_{0n0}$ cavity. Second, the complex

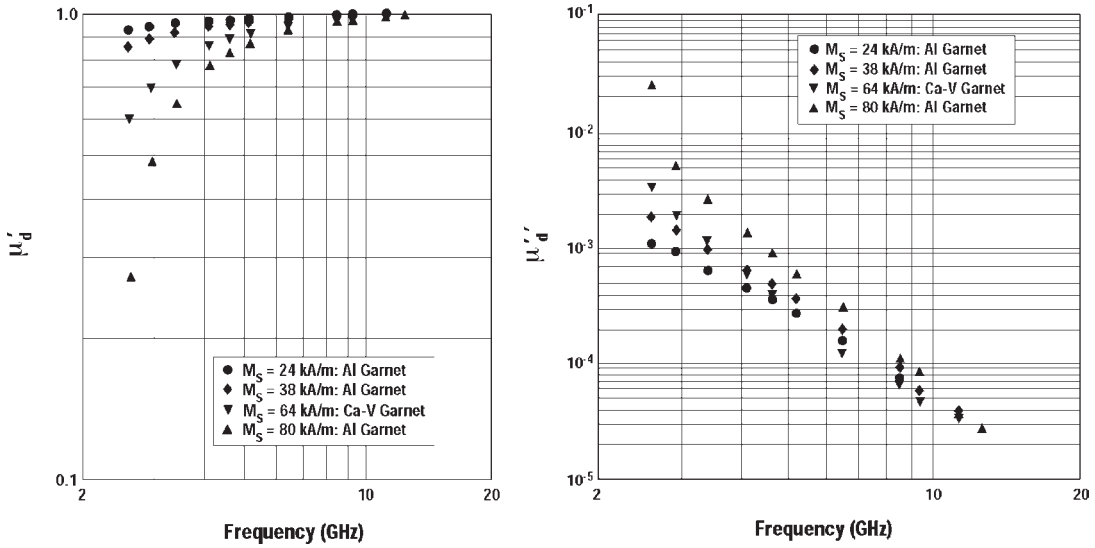

*Figure 3*
Measured complex permeability, $\mu_d^*$, as a function of frequency for various doped garnets having differing saturation magnetizations. $T = 297\,\mathrm{K}$.

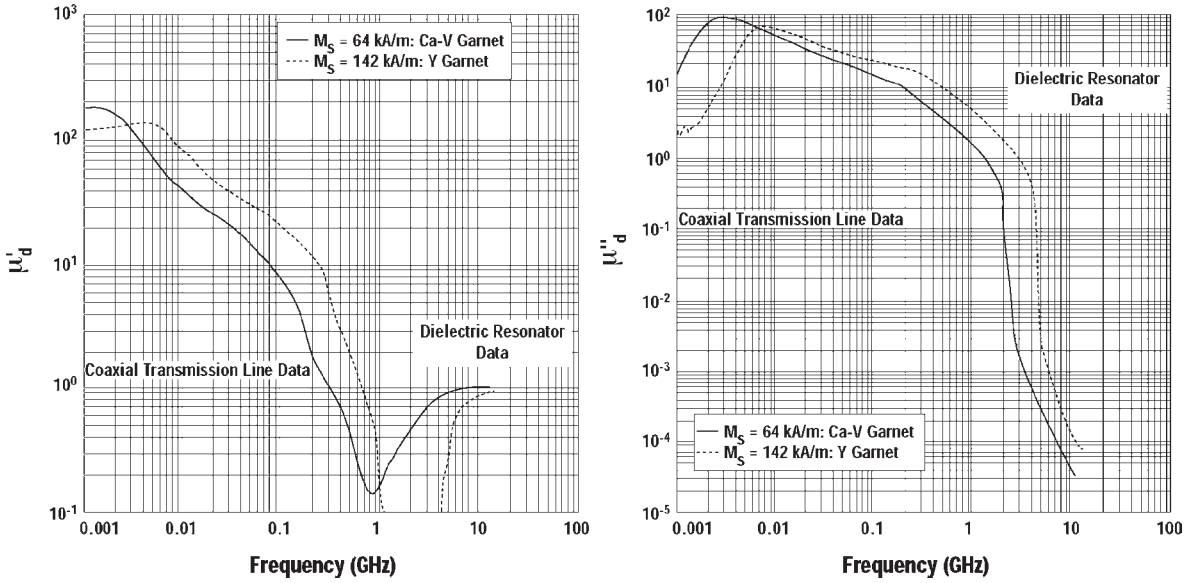

*Figure 4*
Broadband magnetic permeability spectra of demagnetized ferrite above and below magnetization frequency.

relative permittivity of each dielectric ring resonator is found from measurements of the resonant frequency and unloaded $Q$-factor of the empty ring resonators operated in the $TE_{011}$ mode, taking into account conductive microwave losses of the upper and lower metal ground planes. The scalar permeability $\mu_d'(f, T)$ at frequency $f$ and temperature $T$ is determined from measurements of the resonant frequency of the ring resonator with ferrite specimen inserted and solving the $TE_{011}$ eigenvalue equation (Geyer in preparation).

After determining $\mu_d'$, the magnetic loss index $\mu_d''$ is found as a solution to the equation:

$$\frac{1}{Q} = \frac{1}{Q_c} + p_{\varepsilon_s'} \tan\delta_{e,s} + p_{\varepsilon_r'} \tan\delta_e + p_{\varepsilon_d'} \tan\delta_m \qquad (2)$$

where $Q$ is the unloaded $Q$-factor for the $TE_{011}$ mode, $Q_c$ is the $Q$-factor reflecting conductor losses in the metal plates, $p_{\varepsilon_s'}$ is the electric energy filling factor of the dielectric sleeve resonator, $p_{\varepsilon_r'}$, $p_{\varepsilon_d'}$ are the ferrite sample electric and magnetic energy filling factors, $\tan\delta_{e,s}$ and $\tan\delta_e$ are the dielectric loss tangents of the sleeve resonator and ferrite sample, and $\tan\delta_m$ is the magnetic loss tangent of the ferrite. Example complex permeability data for garnets doped with aluminum and calcium-vanadium are given in Fig. 3. Estimated total uncertainty in $\mu_d'$ is 1% and in $\mu_d''$ is $2 \times 10^{-5}$. These data clearly show the shift in magnetization frequency to higher frequencies as saturation magnetization increases, as well as rapidly increasing nonlinear magnetic losses as the magnetization frequency is approached. Dielectric resonator and transmission line data may be combined to yield accurate complex permeability spectra of ferrite ceramics over five decades in frequency (Fig. 4).

When a tuning bias is applied so that the ferrite specimen is partially saturated, two dielectric low-loss sleeve resonators having the same height but differing diameters may be used to evaluate the complex tensor permeability components (Krupka 1991, Geyer *et al.* 1998). In this case, two circularly polarized, oppositely rotating $HE_{111}^{+}$ and $HE_{111}^{-}$ resonant modes are used with one sleeve for evaluating $\mu_x^*$ and $\mu_y^*$, and the $TE_{011}$ resonant mode with the second sleeve is used for $\mu_z^*$. The aspect ratios of the sleeves are chosen so that, for the nominal measurement frequency of interest, all three resonant modes for both sleeves with ferrite sample insertion occur at the same frequency with zero bias field. For this case, the tensor magnetic properties are evaluated as a function of tuning bias (Geyer *et al.* 1998)

## 2. Summary

Comparisons between experimentally evaluated demagnetized real permeability spectra of ferrites and quasi-static theoretical formulations given by Schlömann (1970) have been reported (Green and Sandy 1974, Le Roux *et al.* 1988, Geyer 1999). These comparisons show good agreement when $f_M/f < 0.75$. The effect of cooling magnesium spinel ferrite ceramics on both dielectric and magnetic losses at microwave frequencies has also been studied (Geyer 1999) using dielectric resonator techniques. Generally, dielectric losses of a ferrite ceramic decrease as the specimen is cooled, albeit with increasing magnetic loss and decreasing magnetic permeability. Hence, with cooling, the same ferrite ceramic may be used in microwave tuning devices at higher frequencies.

Accurate magnetic characterization from 2 GHz to 25 GHz of a *single* ferrite specimen can be accomplished with low-loss dielectric sleeve resonators, and combined with transmission line measurements to reveal both low-frequency, high-loss and high-frequency, low-loss properties.

# Ferrite Magnets: Improved Performance

Ferrite magnets, based on the compound $AFe_{12}O_{19}$ (A = Sr, Ba) and the magnetoplumbite or *M* crystal structure, have a dominant position on the magnet market (57% by value and 95% by weight), thanks to the favorable performance/price ratio. The main application for high-grade ferrite magnets is as segments in various d.c. motors for the automotive industry. Their market share would be even larger if their magnetic performance, notably remanence $B_r$ and coercivity $H_{cJ}$, could be further improved. This can no longer be expected from the conventional technology, which has almost attained its saturation. In recent years, however, it has been recognized that LaCo or related substituents may lead to significantly improved performance. This has initiated a renaissance of its basic research as well as a new generation of high-performance ferrite magnets. After a short survey of the conventional ferrite magnets, the new LaCo–M ferrites are discussed, referring to a recent more extended review article (Kools *et al.* 2002).

## 1. Conventional Ceramic Ferrite Magnets

The manufacturing process of ceramic ferrite magnets is a classical ceramic process (see *Alnicos and Hexaferrites*), having several specific features (Kojima 1982, Kools 1992). Most characteristic are the wet pressing in a magnetic field to align the powder particles in order to obtain high remanence, the fine milling into alignable particles of $\sim 1\,\mu m$, the natural tendency to lateral grain growth (platelet-shaped crystals), and, finally, the necessity to keep the fired grains small to obtain high coercivity.

In the 1970s and 1980s it became gradually clear that increased magnetic performance can only be attained by further decreasing the particle size of the milled powders. This implies increased milling effort and more difficult wet pressing, two factors which largely contribute to the production costs. This has led to the following definition of the magnetic performance IP in terms of remanence ($B_r$) and coercivity ($H_{cJ}$): $IP(mT) = B_r + 0.4\mu_0 H_{cJ}$. It is governed uniquely by the particle size obtained after milling. For technical and economical reasons, however, there is a lower limit for the latter particle size. The corresponding upper performance level of IP $\approx 550\,mT$ characterizes the saturation state of the conventional technology in the early 1990s.

### 1.1 Intrinsic Properties

The intrinsic properties stem from the M-crystal structure and, notably, from the five distinct Fe-sublattices, coupled by superexchange. Two intrinsic properties are crucial: the saturation magnetization ($J_s^0$) determines $B_r$ and the magneto-crystalline anisotropy field strength ($H_a$) determines $H_{cJ}$.

The magnitude of $J_s^0$ derives from the mutual orientations of the five Fe-sublattice moments, as given by the Gorter model: the moments at 2a, 12k, and 2b are mutually parallel and antiparallel to the moments at 4f1 and 4f2. This model is supported by magnetization measurements, Mössbauer spectrometry, and, recently, also by *ab initio* calculation (Fang *et al.* 2003). The $J_s^0 - T$ curve (Fig. 1) is almost linear in the room temperature region with $dJ_s^0/dT = -0.9\,mT\,K^{-1}$.

The anisotropy field $H_a$ represents the hypothetical field that would be able to align the magnetization perpendicular to the easy direction, the *c*-axis. It is defined by $H_a = 2K_1/J_s^0$, where the anisotropy constant $K_1$ characterizes the associated anisotropy energy. The origin of $K_1$ is related to spin–orbit

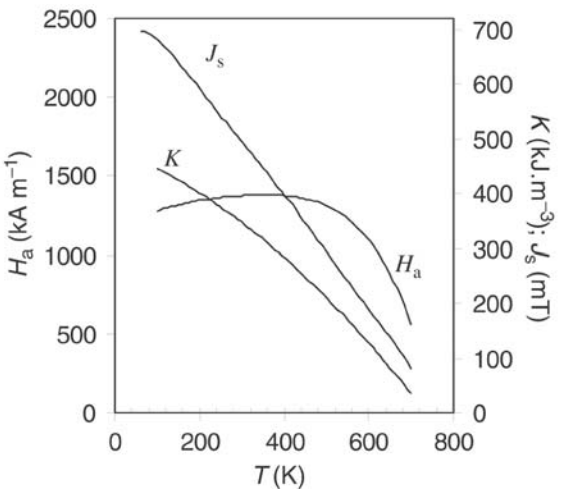

***Figure 1***
Temperature dependence of $J_s$, $K$, and $H_a$ for BaM.

coupling at the 2b and 12k sites, but a detailed model is still lacking. The $K_1-T$ curve is analogous to the $J_s^0-T$ curve, but less curved at low temperature, resulting in a flat $H_a-T$ curve with $dH_a/dT \approx 0$ at room temperature (Fig. 1).

### 1.2 Modeling $B_r$ and $H_{cJ}$

The formulas given below refer to medium- and high-grade ferrite magnets in which the grains are supposed to be single domain in the remanent state and magnetization reversal inside the grains is supposed to be governed by domain nucleation.

The remanence is described by the formula

$$B_r = k\,J_s^0 = f\left(d/d^0\right)s\,J_s^0 \qquad (1)$$

The factor $k$ takes account of the influence of the microstructure. It consists of three contributions: the degree of alignment $f$ ($0.5<f<1$), the amount of M-phase $s$, and the relative density $d/d^0$. Typical values for (unsubstituted) high-performance magnets ($B_r = 420\,\mathrm{mT}$) are: $f=0.92$, $d/d^0=0.98$, $s=0.98$ ($k=0.88$). The (relative) temperature coefficient of the remanence, $TC(B_r)$, derives from the temperature coefficient of the saturation magnetization, $TC(J_s^0)$, and amounts to $-0.19\%$ for nonsubstituted grades.

The coercivity is described by the expression

$$\begin{aligned} H_{cJ} &= aH_a - (N/\mu_0)(B_r + J_s^0) \\ &= aH_a - (N/\mu_0)(k+1)J_s^0 \end{aligned} \qquad (2)$$

Its dependence on the microstructure is described by $k$ and, in particular, by the factors $a$ and $N$. The factor $a$ increases with decreasing grain size, thus reflecting the well-known $H_c$-grain size dependency. The factor $N$ is governed by the grain shape and increases when the grains become more platelet shaped. For an unsubstituted high-grade magnet ($H_{cJ}=270\,kA\,m^{-1}$), typical microstructural factors are: $a=0.52$ and $N=0.7$. The value of $TC(H_{cJ})$ is easily derived from Eqn. (2) by differentiation. Substituting the typical values given above, one obtains $TC(H_{cJ}) \approx +1\,\mathrm{kA\,m^{-1}\,K^{-1}}$ or $\approx 0.4\%\,\mathrm{K^{-1}}$.

### 1.3 Substitutions

Until recently, it seemed impossible to improve the magnet performance by means of substitutions. The $J_s^0$ can be increased, indeed, but only at the costs of $H_a$ and vice versa. Only the substitution of Al and/or Cr for Fe has been of practical importance, including a decreased $J_s^0$ at constant $K_1$, thus leading to increased $H_a$ and $H_{cJ}$.

### 1.4 Microstructure

Grain growth and platelet grain shape should be suppressed during high-density sintering, otherwise the $H_{cJ}$ deteriorates. Si-based additions are commonly applied. As the underlying mechanism, the reaction induced grain growth inhibition (RIGGI) has been put forward, being related to the slow incorporation of silica.

## 2. LaCo-type Substituted M-ferrite Magnets

Scattered over the period 1959–1996, several studies have been published, that included occasionally LaCo-M-type compositions, corresponding to the general formula $A_{1-x}R_xFe_{12-x}B_xO_{19}$ (ARB-M), where A = Ba, *Sr*, …, R = $La^{3+}$, $Pr^{3+}$, $Bi^{3+}$, …, and B = $Co^{2+}$, $Ni^{2+}$, $Fe^{2+}$,…. The recent recognition that LaCo-type ferrite magnets can represent a new generation of high-performance ferrite magnets has provoked a wave of investigations, being initially practically oriented in order to secure patent rights (Taguchi *et al*. 1998, Takami *et al*. 1999). The results obtained share the following general features:

- increased performance ($IP \approx 600\,\mathrm{mT}$), notably from increased $H_{cJ}$, but $B_r/H_{cJ}$ may vary;
- reduced $TC(H_{cJ})$, down to $\sim 50\%$ of the unsbstituted value;
- wide composition range ARB-M, including also $(Fe+B)/(A+R) \neq 12$ with optimum properties for SrLaCoM ($x \approx 0.25$), where Co may be partly replaced by $Fe^{2+}$; and
- classical processing: only the calcination time is longer than usual.

These promising results have provoked an intensive study as to the precise effects and their backgrounds. This is briefly reviewed below, based on our own studies.

### 2.1 Effects on the Magnet Properties

The main effects illustrated in Figs. 2–5 show the following:

- a significant increase of $H_{cJ}$ up to $x=0.25$ (25%), followed by a similar decrease for $0.25<x\leqslant 0.4$;
- reduced $TC(H_{cJ})$ (50% for $x=0.3$);
- slight increase of $B_r$ (3.5% for $x=0.4$); and
- moderate squareness of the demagnetization curve, which strongly deteriorates for high $x$ ($x>0.2$).

These effects refer to SrLaCo-M, but analogous effects are found for BaLaCo-M.

### 2.2 Background of the Effects

The coercivity is explained on the basis of the coercivity model (Eqn. (2)), where an increased $H_a$ value is substituted (Fig. 3), as measured by single

Low-temperature behavior of $H_a$ for $Sr_{1-x}La_xFe_{12-x}Co_xO_{19}$ ($x = 0.2$) (reproduced by permission of Grössinger *et al.* (2000) from *Ferrites, Proc. Int. Conf. on Ferrites*, ICF8, pp. 428–30).

point detection (SPD) $H_a$ measurements (see *Magnetic Measurements: Pulsed Field*). Since the values for $B_r$, $a$, and $N$ (Fig. 4) appear to be quite normal, the increased $H_{cJ}$ is dominated by the increased $H_a$.

The decrease of $H_{cJ}$ for $x > 0.25$ stems from the more pronounced platelet shape. The microstructure parameters $a$ and $N$ were measured both magnetically and by SEM observation. For $x > 0.25$ the $N$ value increases sharply (Fig. 4), while the $a$ value remains essentially constant, thus explaining the drop in $H_{cJ}$.

The $TC(H_{cJ})$ is explained by the same coercivity model in the differential form, substituting apart from the experimental $a$ and $N$ values, the measured values for $dJ_s^0/dT$ and $dH_a/dT$ (Fig. 5). This formula explains that $TC(H_{cJ})$ deviates significantly from the usual one: $dH_a/dT$ is no longer close to zero as usual, but has become negative, resulting in a decreased $TC(H_{cJ})$.

The explanation of $B_r$ is based on Eqn. (1) and separate measurements of $f$, $(d/d^0)$, and $s$. The factor $J^0_{s(300\ K)}$ is decomposed into two factors: $J^0_{s(0\ K)}$ and a new parameter $R_{jt} = J^0_{s(300\ K)}/J^0_{s(0\ K)}$ characterizing the curvature of the $J^0_s - T$ curve. Density and $J^0_{s(0\ K)}$ appear to be constant; so the slight increase of $B_r$ is dominated by the alignment factor ($f$) and the curvature factor ($R_{jt}$), both showing a slight increase (Fig. 6).

The poor squareness was attributed to chemical and microstructural inhomogeneities. Mössbauer analysis and resistivity measurements showed that the Co substitution is not complete, Co being partly

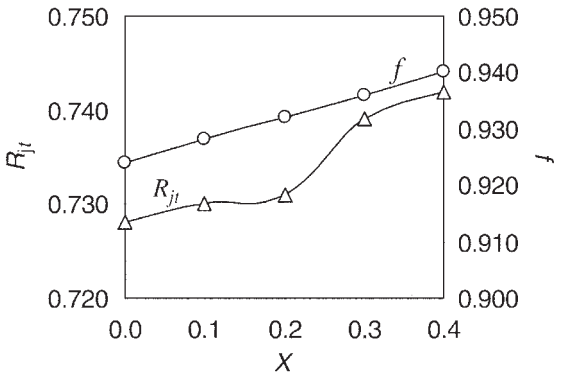

***Figure 6***
Remanence factors vs. $x$ for $Sr_{1-x}La_xFe_{12-x}Co_xO_{19}$ magnets (reproduced by permission of Kools *et al.* (2002) from *J. Magn. Magn. Mater.*, **242–245** (Part 2), 1270–6).

replaced by $Fe^{2+}$. The strong deterioration of the squareness for $x > 0.2$ was related to a bimodal grain size distribution.

### *2.3 Intrinsic Aspects*

Substituted M-ferrite magnets are single phase for $0 < x < 0.35$. The cell constant $a$ remains constant, whereas $c$ decreases slightly and linearly up to $x = 0.4$. The latter holds also for $T_c$.

The analogy between Sr and Ba compounds points to Co as the active ion. The Co sublattice occupation was studied by various techniques, but all being at the limit of detection. The provisional conclusion is that $Fe^{2+}$/Co is at $2a$ and Co at $4f_2$. For CoTi substituted M-ferrites and related compounds, Co prefers other sites and acts negatively on the anisotropy (Kojima 1982). Apparently, the excess charge of La and its fixed position on the Ba sites forces Co to a special site, where it can contribute to the anisotropy.

The increase of $H_a$ (obtained from SPD data) with increasing $x$ is due to an increase of the magneto-crystalline anisotropy $K_1$. In addition, $H_a$ increases further when $T$ decreases, similar to $LaFe^{2+}M$ (Lotgering 1974). In view of that, a similar mechanism is assumed: the increased $K_1$ stems from the single-ion contribution of $Fe^{2+}$/Co at $2a$ and Co at $4f_2$.

### *2.4 Microstructural Aspects*

There are three major effects: (1) The grain size after calcination decreases with $x$, (2) the grain size after firing and the platelet grain shape increase with $x$, and (3) the microstructure becomes more nonuniform when $x$ increases. The first effect is related to incomplete substitution of LaCo during calcining, thus provoking RIGGI from LaCo. The second effect is also related to the incomplete calcination by means of which Co remains in the secondary phase and counteracts during sintering the RIGGI from silica (Kools *et al.* 2001). The third effect is related to the first one. By optimizing the chemical homogeneity (decreased particle size of the LaCo raw materials) and decreasing the Co/La, ratio, the squareness could be restored to the unsubstituted level (Morel and Tenaud 2002).

## *3. Concluding Remarks*

LaCo-type substituted ferrite magnets can be described by the classical models for M-ferrite magnets, having as a characteristic feature the increased magneto-crystalline anisotropy at 300 K and its increased temperature dependence.

The increased $H_{cJ}$ and reduced TC($H_{cJ}$) of LaCo-type ferrite magnets allow new applications. Due to the more expensive raw materials (La, Co), the costs are somewhat higher, but optimization will certainly lead to cost reduction. It is expected that the new LaCo-type ferrite magnets will acquire a significant market share in the near future, notably for starter motors and small motors.

## Ferrites

Since their commercial introduction in 1948 by Philips, soft ferrites have found widespread use in electronic applications as inductor or transformer cores, because of their high resistivity in comparison to metallic soft-magnetic materials. This makes soft-magnetic ferrites considerably better suited for applications at frequencies $\geqslant 10$ kHz. Soft-magnetic ferrites belong to the class of ferrites which have a cubic, spinel lattice structure. These ferrites have the structural formula $MeFe_2O_4$ with Me being a divalent metal ion from the 3*d* transition elements: manganese, iron, cobalt, nickel, copper, zinc, or combinations of these. In addition, also other ions such as $Li^+$, $Mg^{2+}$, $Cr^{3+}$, $Ti^{4+}$, or $Sb^{5+}$ can be incorporated in the spinel lattice. There is also a class of soft-magnetic ferrites with a hexagonal crystal structure, which has soft-magnetic properties. However, this class of soft ferrites has found limited application thus far, and is not treated here. The reader is referred to the treatise by Smit and Wijn (1959).

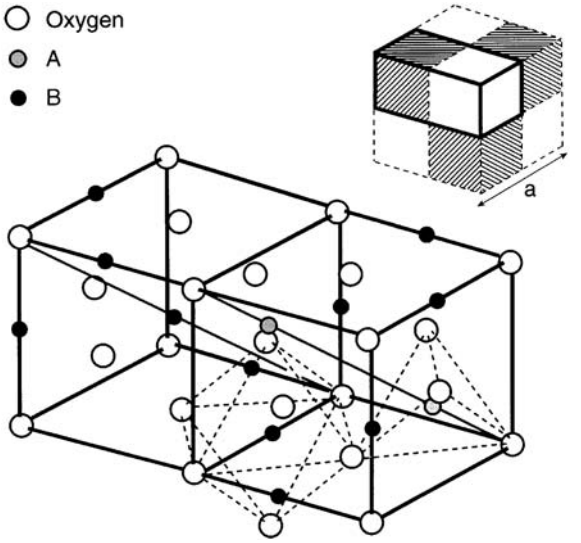

***Figure 1***
The spinel lattice structure.

The spinel-type lattice structure characterizing the conventionally applied ferrites is depicted in Fig. 1. This lattice structure has a lattice parameter *a* in the range 8.30–8.50 Å depending on the composition of the ferrite (Smit and Wijn 1959). In the unit cell, of which $\frac{1}{4}$ is drawn in detail in Fig. 1, the oxygen ions (O in Fig. 1) form a close-packed face-centered cubic lattice. There are 64 possible tetrahedral (or A) and 32 possible octahedral (or B) interstices or sites in which metal ions can be incorporated. Only eight of the octahedral and 16 of the tetrahedral sites are filled with metal cations. The magnetic interactions are such that the two neighboring magnetic ions on the B-site are ferromagnetically (that is parallel) coupled, whereas the much larger coupling between the magnetic ion on the A-site and the ions on the B-sites is antiferromagnetic (antiparallel). Since, there are two ions antiparallel coupled to each magnetic ion on the A-site, a net magnetic moment still results.

This gives rise to the so-called ferrimagnetism, a net magnetic moment in a magnetic material in which the dominant magnetic interaction is antiferromagnetic. This behaviour can be understood on the basis of super exchange interaction between the magnetic ions as explained by Anderson (1963) and Goodenough (1963).

As shown in Fig. 1 the magnetic ions in ferrites are separated by oxygen ions, which precludes a direct exchange interaction between the magnetic ions. Since, in addition, ferrites are insulators (or very poor semiconductors) exchange interaction by itinerant electrons is also not possible. The explanation for

magnetism in these oxides is that the exchange interaction between the magnetic ions is mediated by the intermediate oxygen ion through super exchange (Anderson 1963, Goodenough 1963). Assuming that the magnetic ions $M_1$ and $M_2$ lie on a straight line through the intermediate oxygen ion O, the magnetic super exchange interaction can be explained in the following covalent bonding picture for magnetic ions with at least a half-filled shell: one of the electrons of the oxygen p-orbital directed to the magnetic ions will be excited or transferred to the ion $M_1$.

On $M_1$ the electron can only enter an empty orbital with its spin direction antiparallel to the magnetic moment of $M_1$. The other electron of the p-orbital pointing along the $M_1$–O–$M_2$ bond can only be excited to the $M_2$ ion and lower the total energy of the system, if the magnetic moment of $M_2$ is oriented antiparallel to $M_1$. This is so because both electrons involved originate from the same oxygen p-orbital, and thus their spins must be antiparallel according to the Pauli exclusion principle. Hence, the magnetic (spin) moments of both ions should be aligned antiparallel to obtain the lowest energy state and to fulfill the Pauli principle at the same time. More about the super exchange interaction can be found in the reviews by Anderson (1963) and Goodenough (1963). For the super exchange interaction it can be derived that it is strong and antiferromagnetic along a 180° bond, i.e. when $M_1$–O–$M_2$ form a straight line, while it is weak and ferromagnetic along a 90° bond. This explains that the interaction between the magnetic ions on the A- and B-sites in spinel ferrites, which make an angle of around 125° (see Fig. 1), is much stronger than between those on the B-sites which make an angle of around 90° (Smit and Wijn 1959). Thus in ferrites the dominant magnetic interaction is the AB interaction, which is typically 15–20 times stronger than the BB interaction. This causes the magnetic moments on the A and B sites to be antiparallel oriented whereas those on the B-sites are parallel to each other.

The net magnetic moment of spinel ferrites is thus determined by the sum of the magnetic moments of the two spins on the B-site minus the moment of the A-site. This results in typical saturation magnetizations, $M_S$, of spinel ferrites between 143–560 $kAm^{-1}$ at 0 K and 120–477 $kAm^{-1}$ at room temperature (Smit and Wijn 1959), which are lower than what can be attained in metallic magnetic materials (where the dominant magnetic interaction is ferromagnetic). Most of the spinel ferrites, with the exception of $ZnFe_2O_4$, have a Curie temperature $T_C$ in excess of room temperature, with typical values ranging from 300 °C for $MnFe_2O_4$ to 670 °C for $Li_{0.5}Fe_{2.5}O_4$ (Smit and Wijn 1959). This $T_C$ of ferrites is acceptable for most applications that require typically an operating temperature of the ferrite of 80 °C. In most commercial applications either MnZn-ferrites or NiZn-ferrites are used. The MnZn-ferrites have the advantage that high values of the permeability $\mu$ can be reached, whereas NiZn-ferrites offer advantageously higher values of the resistivity $\rho \approx 10^5\,\Omega$m versus 1 Ωm for MnZn-ferrites. This makes NiZn-ferrites more suited for high frequency application, in particular for frequencies $\geqslant 1$ MHz. For applications which require a high resistivity and low material costs, MgZn-ferrites ($\rho \approx 10^6\,\Omega$m) are used. For instance, the yoke-rings in the deflection unit of cathode-ray tubes are made of MgZn-ferrites as this makes it possible to directly wind the deflection coil on the ferrite yoke.

For applications the magnetic softness characterized by the permeability $\mu = dB/dH$ is relevant as it gives the response of a ferrite to an applied field $H$. Depending on intrinsic properties (composition, additions) and extrinsic properties (microstructure, preparation) permeabilities of $\geqslant 15\,000$ can be obtained. The highest permeabilities are typically reached in MnZn-ferrites with large grains, which are free from pores. NiZn-ferrites generally have lower permeabilities, in commercial applications between 100 and 1000. This is because compensation of the magnetocrystalline anisotropy, as can be done in MnZn-ferrites, is not possible in NiZn-ferrites (Smit and Wijn 1959).

The only commercial application in which monocrystalline spinel ferrites are used on a large scale is the magnetic recording head production for VCRs. For most applications ferrites are made by ceramic processing which results in polycrystalline materials. Ceramic processing is done by mixing and calcining of oxide and carbonate powders of the constituent metals. Subsequently, the powder is pressed in the desired shape and the final processing step is a sintering process following a selected temperature profile under a carefully controlled atmosphere. Typically sinter temperatures needed to have the required solid state reactions proceed are 1100 °C or more. Details can be found elsewhere (Smit and Wijn 1959, Snelling 1988).

For further information about soft ferrites the reader is referred to the book by Smit and Wijn (1959) and the review by Brabers (1995) and also to *Transition Metal Oxides: Magnetism.*

## 1. Applications

Traditionally the main application areas of soft-ferrites are transformer cores, inductors, and yoke-rings in cathode-ray tubes (Snelling 1988). Since the 1990s new applications have arisen, such as cores for induction lighting and magnetic antennas for pagers. The trend in *all* these applications and the driving force for ferrite development is that the operating frequency increases to achieve miniaturization. This trend is illustrated in Fig. 2 which gives the weight and operating frequency of a 100 W power supply since the 1960s. A reduction in weight from approximately 8 Kg to around 100 g has been achieved.

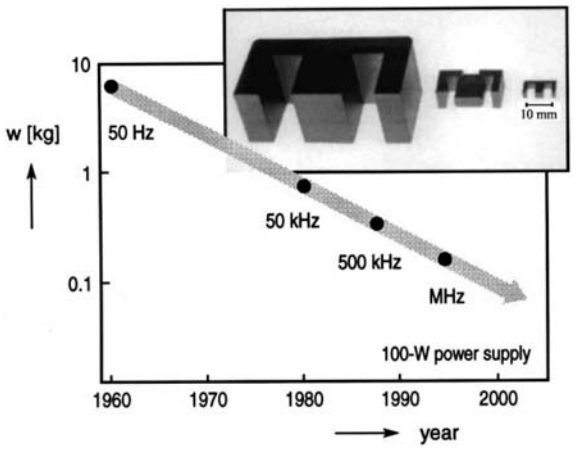

***Figure 2***
The miniaturization trend in the weight of transformer cores since the 1960s. The resulting operating frequencies are indicated. The inset shows various sizes of E-cores used for transformers.

The reason that miniaturization necessitates higher operating frequencies can be understood by considering the throughput power $P_{\mathrm{thr}}$ of a transformer core, which can be given as:

$$P_{\mathrm{thr}} = I_{\mathrm{in}} \times V_{\mathrm{in}} \tag{1}$$

with $I_{\mathrm{in}}$ the input current and $V_{\mathrm{in}}$ the input voltage. Expressing $V_{\mathrm{in}}$ in terms of the change of flux in time $\mathrm{d}\Phi/\mathrm{d}t$ gives:

$$P_{\mathrm{thr}} = I_{\mathrm{in}} \times N\frac{\mathrm{d}\Phi}{\mathrm{d}t} = I_{\mathrm{in}} \times N2\pi fBA \tag{2}$$

with $N$ the number of turns of the primary winding of the transformer, $f$ the operating frequency, $B$ the induction level in the core, and $A$ the cross-sectional area of the core. Since the maximum induction level within the core is limited by the saturation magnetization of the ferrite, $M_{\mathrm{S}}$, it is obvious from Eqn. (2) that in order to decrease the size and hence cross-sectional area of the transformer, without sacrificing throughput power, the operating frequency $f$ should be increased. Hence, a key aspect of modern research and development in soft ferrites is to reduce the dissipation, i.e., losses in ferrites at increasing frequencies, in the range of 100 kHz to 3 MHz.

Traditionally, three contributions to the dissipation or loss, $P_{\mathrm{tot}}$, in soft ferrites are distinguished: d.c. hysteresis loss, $P_{\mathrm{h}}$; eddy current loss, $P_{\mathrm{e}}$; and residual loss, $P_{\mathrm{r}}$. The justification for this subdivision resides in part in the differences in frequency response of each contribution, although it is to a large part phenomenological. The d.c. hysteresis loss corresponds to the dissipation incurred by cycling the d.c. *B-H* loop of a soft-magnetic ferrite. Through the number of times the loop is cycled per unit time, $P_{\mathrm{h}}$ depends on frequency $f$ as $P_{\mathrm{h}} = f\oint B\mathrm{d}H$. The standard approach to limit the hysteresis loss in ferrites (Smit and Wijn 1959, Snelling 1988) is to facilitate domain wall movement by using ferrites with a low coercivity, $H_{\mathrm{C}}$. This is done by selecting ferrite compositions which have a low magneto-crystalline anistropy constant $K$. Ideally the ferrite should have its anisotropy compensation point, at which $K$ passes through zero, at the required operating temperature. Typically this is 80 °C. In addition, the ferrite composition used should have a low magnetostriction constant and internal and external stress should be avoided to limit adverse magnetostriction effects. Finally, ferrites with a large grain size are used as $H_{\mathrm{C}} \propto D^{-1}$, with $D$ the grain size (see van der Zaag 1999).

The eddy current contribution is the dissipation caused by eddy currents in the ferrite. Although, due to their oxidic character, ferrites have a much higher resistivity than metallic soft magnetic materials, their conductivity is not zero and eddy currents can occur. One can derive that the dissipation $P_{\mathrm{e}}$ is (Snelling 1988):

$$P_{\mathrm{e}} = C_{\mathrm{e}} f^2 B^2/\rho \tag{3}$$

with $C_{\mathrm{e}}$ a dimensional constant and $\rho$ the resistivity at the measurement frequency. Hence, the $P_{\mathrm{e}}$ contribution can be separated by plotting $P_{\mathrm{tot}}/f$ vs $f$, as has been done in Fig. 3. Traditionally, the remainder of the dissipation, such as the dissipation due to ferromagnetic resonance (Snoek 1948) has been treated as the residual loss contribution, $P_{\mathrm{r}}$. The residual loss is thus the extra loss under a.c. measurement conditions not attributable to eddy current loss (i.e., not matching Eqn. (3)). Thus $P_{\mathrm{r}}$ has a higher than quadratic dependence on the frequency $f$. As Fig. 3 illustrates at higher frequencies both the eddy current and residual loss dominate the ferrite dissipation. Consequently, considerable work was done in the 1990s to determine and minimize the mechanisms responsible for these losses (van der Zaag 1999).

To reduce the eddy current loss, the resistivity of ferrites should be increased. The resistivity of the ferrites used in commercial applications is determined by the resistivity of the grain boundary in these polycrystalline materials. Hence, considerable effort has been devoted to increase the grain boundary resistance by careful control of the processing conditions and by adding dopants such as $Nb_2O_5$, $ZrO_2$, and $Ta_2O_5$ besides the well-known glass-forming additions CaO and $SiO_2$ (Snelling 1988). The glass formers segregate to the grain boundary to form a secondary phase, which forms an insulating layer around each grain preventing current flow from one grain to the next. At higher frequencies also the capacitive shunting of the grain boundary impedance becomes an issue. It is thought that the addition of

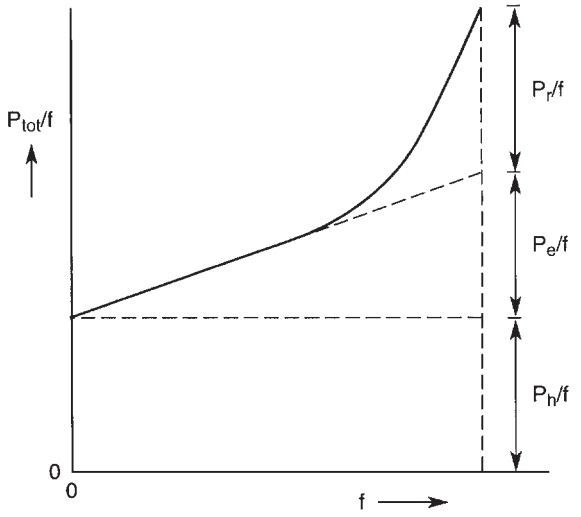

***Figure 3***
Schematic diagram of the total dissipation, $P_{tot}$, versus the frequency, $f$, for soft-magnetic ferrites. The various contributing terms to the ferrite dissipation: hysteresis loss $P_h$, eddy current loss $P_e$ and residual loss $P_r$ are indicated. All terms have been scaled by the frequency.

dopants like $Nb_2O_5$, $ZrO_2$, and $Ta_2O_5$ play a role in reducing this effect.

The residual loss has been shown to be a dominant contribution to the dissipation of ferrites in the 500 kHz to 3 MHz frequency range. Microscopic mechanisms contributing to the residual loss are: the ferromagnetic resonance loss (Snoek 1948) and the intragranular domain wall loss (van der Zaag 1999). The former is caused by excitation of the uniform spin precession in the ferrite. The latter is due to domain wall movement of intragranular domain walls within the grains of a polycrystalline ferrite. Both contributions can be eliminated by using a fine-grained ferrite material. In the case of the ferromagnetic resonance loss this causes a reduction in the permeability of the ferrite and hence an upward shift of the ferromagnetic resonance (Snoek 1948). In well-developed ferrites the ferromagnetic resonance should be above the frequency at which the ferrite is operated. The intragranular domain wall loss is eliminated by using fine-grained ferrites in which all the grains are monodomain, i.e., intragranular domain walls are absent. Such a situation occurs in fine-grained ferrites, since below a certain grain size the monodomain state has a lower magnetostatic energy than a domain state in which a domain wall is present (van der Zaag 1999). For further reading on the subject of dissipation in ferrites the reader is referred to (Snoek 1948, van der Zaag 1999).

## 2. *New Developments: Ferrite Films*

A new development in the field of soft-ferrite research and their application is their deposition and use in thin films (see Brabers 1995). Spurred by the work on high-$T_C$ superconductors, there has been considerable improvement in the deposition of thin film oxides, making it possible to deposit thin film ferrites in the nanometer to micrometer thickness range. The interest in these thin film ferrites is driven in part by the possibility to improve integrated inductors (Suzuki *et al*. 1996).

In the IC industry a problem is that present inductors, amongst others for RF-applications, with typical diameters of 0.2–0.8 mm are huge in comparison to the active elements on ICs. Thus they require a too large surface area to make integration on chip economically attractive. A possible solution would be to apply a magnetic substrate or a thin magnetic film on the coil as this may result in a reduction to a $\frac{1}{4}$ of the area needed for the same inductance while maintaining the quality factor $Q$ (as is illustrated in Fig. 4 by using a ferrite substrate). In view of their resistivity, which makes application at higher frequencies possible, ferrite films deposited on the integrated inductors can provide a possible solution. A problem is the high substrate temperature ($\geqslant 600\,^{\circ}C$) needed to assure the formation of a ferrite film with a proper cation distribution and an adequate grain size to assure that the ferrite films have a sufficiently high permeability. Wet-chemically prepared films grown by ferrite plating at 80 °C provide a useful method as permeabilities $\geqslant 25$ have been obtained in $\mu$m thick films (van der Zaag *et al*. 1999).

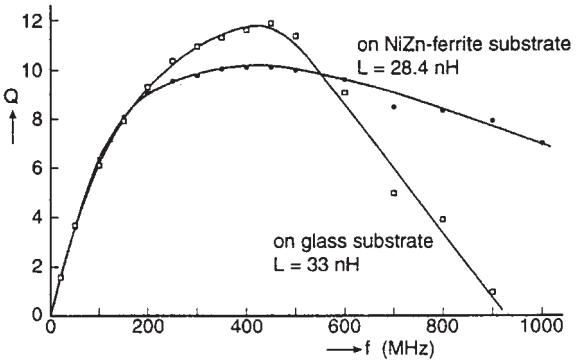

***Figure 4***
The quality factor, $Q = \omega L/R$ with $\omega$ the angular frequency, $L$ the inductance and R the resistance of the inductor, of two planar inductors, one on a glass substrate and the other on a NiZn-ferrite substrate. Although both inductors have comparable inductances ($L = 33$ and 28.4 nH) and $Q$, the inductor using a ferrite substrate has half the diameter, i.e., needs 1/4 of the area.

Another interesting trend is the work on magnetite, $Fe_3O_4$, films in view of their intrinsic fully spin-polarized electron transport for magnetoresistive sensors (Coey *et al*. 1998, Seneor *et al*. 1999). $Fe_3O_4$ is a half-metallic ferromagnet (see *Half-metallic Magnetism*) as it has a gap in the minority spin band, whereas there is no gap in the majority spin band (Brabers 1995). Thus for the majority spins $Fe_3O_4$ behaves as a metal with spin-polarized electron transport along the B-sites by hopping conduction. This property is of interest as it could be employed in magnetic tunnel junctions leading to a magnetic field sensor element with, theoretically, an infinite magnetoresistance effect, as electrons with minority spin cannot pass the $Fe_3O_4$ layer. The degree to which a proper $Fe_3O_4$ layer can be grown in these magnetic tunnel junctions, or needs to be grown to have a positive effect on the magnetoresistance is not known precisely. The same holds for the role played by the interfaces of the $Fe_3O_4$ layer or anti-phase boundaries, causing so-called ''dead'' magnetic interface layers. A first indication of an increased magneto-resistance effect due to the incorporation of a $Fe_3O_4$-like layer in a magnetic tunnel junction has been reported by Seneor *et al*. (1999).

## Ferrofluids: Applications

The first synthesis and application of a magnetic fluid as a magnetocaloric device was reported by Neuringer and Rosensweig (1964), although attempts to create stable ferromagnetic colloids can be traced back to (Elmore 1938). Papell (1965) at NASA was awarded the first patent for the process of making ferrofluid. The fluid was developed for the purpose of retention and orientation of rocket fuel with an external magnetic field under reduced gravity. Although the earlier applications never materialized, the new discovery nonetheless laid the foundation of a whole new industrial sector (Berkovski 1996).

For his lifelong contributions to the field, Ronald Rosensweig is considered the father of the technology. His NASA-funded research, which began in 1965 at AVCO Corporation, demonstrated that ferrofluids can be prepared in a wide variety of carriers and in high magnetization values. His patents in magnetic fluids, staged rotary seals, magneto-gravimetric separators, and display devices created a base for industrial enterprise. Serious marketing efforts began when Ronald Rosensweig and Ronald Moskowitz founded Ferrofluidics Corporation in 1968. The first product based on ferrofluid, introduced in 1969, was the dynamic seal capable of operating under pressure or vacuum. Since then a number of new applications of the technology have been discovered and are listed in chronological order in Table 1. Although the technology may be present in many consumer products, the ferrofluid in the devices is hidden from view. It is estimated that over 200000 rotary vacuum seals, 350 million loudspeakers, 500 million computer disk drives, and 15 million DVD–ROM drives have been built with ferrofluids.

## 1. Ferrofluids

In ferrofluids, magnetic and liquid states coexist. On the surface, they are deceptively simple systems: a homogeneous phase comprised of three constituents, namely the magnetic particles, surfactant, and the liquid carrier. However, a complex chemistry and a balance of inter-particle forces determine the colloidal stability (Rosensweig 1979). The magnetite particles must be in the range of 10 nm. The surfactant tails should be long enough to prevent particle agglomeration. Ferrofluids synthesized about 30 years previously are still stable.

Both magnetic and liquid properties influence the device performance. The saturation magnetization values of commercial ferrofluids range from 0.0001–0.1 T. Liquid properties such as viscosity, volatility, working temperature range, environmental compatibility, thermal degradation, and dielectric behavior dictate the choice of the carrier in which the particles are suspended. The most commonly used ferrofluids fall in the viscosity range of 1–2000 cp at 27 °C. There exist several different chemical families of ferrofluids such as the petroleum oils, synthetic esters and hydrocarbons, perfluoropolyethers, silicones, water, organic solvents, etc. Within each family a range of physical properties may be achieved by altering the concentration of magnetic solids and the molecular weight of the carrier. Thus, literally hundreds of different commercial magnetic colloid formulations are available.

## 2. Applications

Ferrofluids offer design solutions to a myriad of complex engineering problems. Patents in the field exceed 2800.

Magnetic and liquid properties in a ferrofluid, although mostly independent of each other, work together to create successful products (Raj and Chorney 1998). The rotary shaft seal relies on the magnetic properties of ferrofluid for pressure capacity, but the liquid carrier determines the service life, operating range, power requirement, and high vacuum performance of the product. In a loudspeaker, the magnetism associated with the colloid simply retains the fluid in the air gap, but the carrier provides the benefits of damping and heat transfer. Similarly the viscosity and lubricity of the base oil are relevant parameters for the performance of a ferrofluid film bearing. When ferrofluid is used in a domain detection application, the particles migrate through the carrier and accumulate at the transition zones of the specimen. The carrier subsequently evaporates making the domain boundaries visible in colorful patterns.

Magnetic fluids exhibit levitation phenomena, a unique feature not found in ordinary liquids. A permanent magnet with density much greater than the fluid floats in the ferrofluid (Rosensweig 1966a). A pool of magnetic colloid exposed to a gradient magnetic field can suspend heavy nonferrous objects (Rosensweig 1966b). These two principles form the basis of several industrial devices such as dampers, sensors, and material separators.

A list of ferrofluid applications, the types of fluids used, and their key properties are presented in Table 2. Devices such as seals and loudspeakers generally require ferrofluid amounts in microliters, material separators in liters and power transformers in gallons. The multistage rotary shaft seal is the oldest and most recognized ferrofluid-based product. This device is used in many industries such as the semiconductor, nuclear, aerospace, laser, and lamp manufacturing industries. The basic construction of the seal is shown in Fig. 1. A magnetic circuit is formed to create alternate regions of high and low magnetic fields in an air gap. The shaft is supported by two high precision ball bearings to allow for rotation. A tooth or ridge structure either on the pole pieces or shaft configures the magnetic field into the desired pattern. A ferrofluid fills the regions of high magnetic field forming a series of liquid O-rings with intervening annular open spaces. Each fluid O-ring sustains a pressure differential dictated by the field strength and the magnetization of the ferrofluid. The total pressure capacity of the seal is the sum of the capacity of individual O-rings and generally exceeds two atmospheres. The use of a low vapor pressure ferrofluid maintains a high vacuum integrity, up to $10^{-9}$ torr, in the process chamber. The seal is leak tight, essentially nonwearing and consumes low power. It is typically used in gaseous environments but can also withstand occasional liquid splashing.

An example of an application of a ferrofluid vacuum seal is shown in Fig. 2. The seal is mounted on a sterilizer and rotates an impeller at speeds of 1750–3500 rpm inside a chamber charged with a gaseous mixture of ethylene oxide and nitrogen at temperatures close to ambient. The system may be used to sterilize heart pacemakers and sutures. Due to the toxic nature of the gas, the process must be carried out under leak-tight conditions. To ensure personnel safety, dual magnetic fluid seals are employed and the space between the two seals is monitored. If the process end seal fails, escaping gas can be detected while the secondary seal prevents gas emission into the work area.

Manufacturing of integrated circuits requires that the environments be free of any particulate contaminants. In Fig. 3, a coaxial seal is employed in a robotic arm to transport 200 mm silicon wafers in a cluster tool. The arm picks up wafers from a carousel and places them sequentially at different locations. This seal is composed of two coaxial shafts, which provide two independent angular drive mechanisms to the arm.

Thin profile ferrofluid seals with a typical thickness of about 1mm are employed in computer disk drive

***Table 2***
Types of ferrofluids employed in applications and key properties.

| Typical applications | Types of ferrofluids | Main ferrofluid property | Physical parameters (room temperature) |
|---|---|---|---|
| Biomedical/catalysis/ magnetic adhesive/ magnetic shielding | Surfacted magnetite microspheres | Micromagnetics | 10 nm supermagnetic particles |
| Sealing | Perfluropolyethers Polyphenyl ethers Hydrocarbons Silahydrocarbons Esters | Chemically inert Radiation resistant Wide temperature range Hydrolytic stability Good lubricant | 0.02–0.06 T 200–2500 cp |
| Damping/heat transfer/ noise control | Hydrocarbons Esters Perfluoropolyethers Silicones | Low volatility Wide viscosity Fire resistant High viscosity index | 0.01–0.04 T 200–10000 cp |
| Sensing | Mineral oils Hydrocarbons Esters | Large liquid range Thermal stability Boundary lubricant | 0.005–0.004 T 2–100 cp |
| Domain detection/ material separation/ polishing/ magnetic ink/display/inspection | Water | Environmentally safe | 0.0001–0.004 T 1–5 cp |
| Power transmission | Mineral oils Vegetable oils | Improved dielectrics Biodegradable, cooling | 0.0001–0.001 T 10–25 cp |
| Magnetic ink/magnetic polymer/research activities | Organic solvents (heptane, xylene, toluene, MEK) | High volatility | 0.005–0.1 T 1–25 cp |

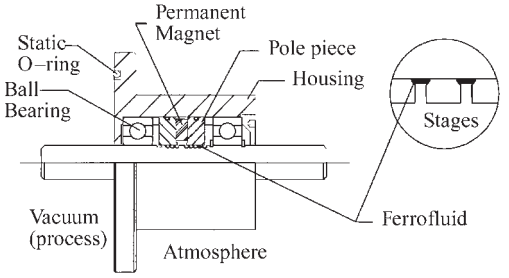

***Figure 1***

spindles, Fig. 4. The seal pressure capacity is in the region of 100 mm $H_2O$ and operating speed 3600–7500 rpm. Several million of these seals are produced each year. The seals prevent the bearing lubricant and other airborne contaminants from reaching the disk cavity. The flying height of the read–write head above the disk surface is only 0.2 μm. The presence of even a small dust particle (24 μm) can easily cause a head crash or soft error.

As an electromechanical device, a dynamic loudspeaker, Fig. 5, has a natural resonance point in its operating frequency range of 20 Hz to 20 KHz. At resonance the system is underdamped. Also the coil easily burns out when the speaker is over powered. The air surrounding the coil cannot remove heat efficiently. Ferrofluid is incorporated into the speaker gap. Thermal conductivity of ferrofluid is about four times higher than air and consequently the transient power handling of the speaker is increased. The damping requirements of the driver can be achieved with a precise selection of ferrofluid viscosity. The fluid is naturally retained in the gap by the prevailing magnetic field. Ferrofluid also aids with voice-coil centering, reduction in distortion and simplification of cross-over network.

The magnetic permeability of a ferrofluid can produce measurable inductive changes in an electrical circuit. In a tilt sensor, Fig. 6, ferrofluid is used as a movable magnetic core. An angular displacement of the tube moves the fluid partly from one side to the

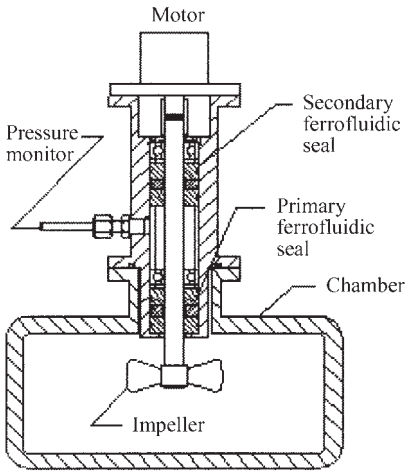

***Figure 2***
Seal application in a sterilizer.

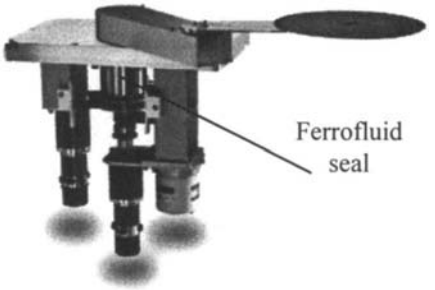

***Figure 3***
Coaxial seal used in a robot arm.

other creating an inductive unbalance and an electronic signal proportional to the tilt angle. These sensors operate in the region of $\pm 45^{\circ}$ and are utilized in the construction industry to measure the tilt of underground pipes.

The levitation of a permanent magnet in a pool of ferrofluid is the basis of another type of sensing device used in the oil well industry. The position of the freely suspended magnet, influenced by the inclination or acceleration of the encasement, can be detected by means of inductance coils. This rugged sensor accurately measures the orientation of an underground drill bit during oil prospecting.

The apparent density of a ferrofluid increases steadily with increasing magnetic field gradient producing a levitation force upon immersed nonmagnetic objects. Thus, nonferrous materials of various density values float to different levels in the fluid. Two

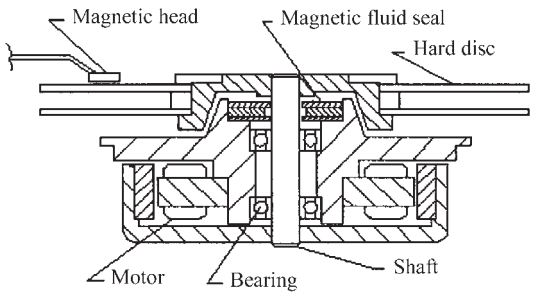

***Figure 4***

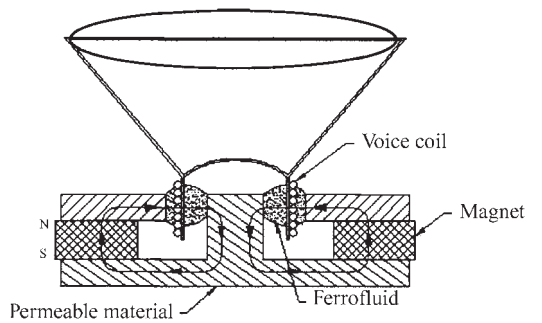

***Figure 5***
Moving coil loudspeaker using ferrofluid.

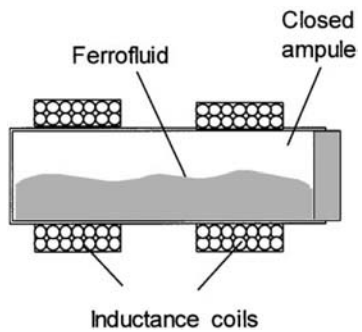

***Figure 6***
Ferrofluid tilt sensor.

different commercial separators utilize this principle: one is the static (sink/float) apparatus in which ferrofluid is stationary and the other is a dynamic system in which ferrofluid is rotating in a vertical duct. These machines are employed for separation of scrap metals and minerals from ore deposits. Figure 7 is a

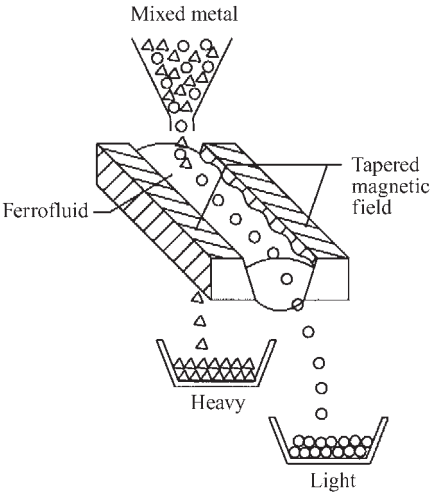

***Figure 7***
Recycling of scrap metals with sink/float apparatus.

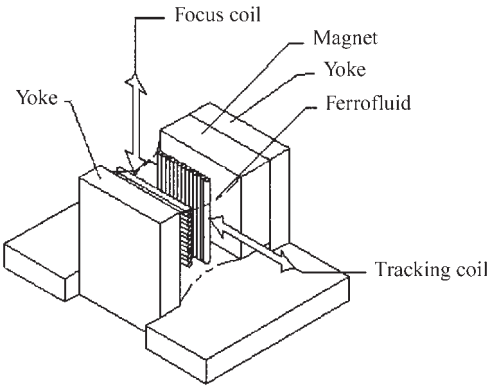

***Figure 8***
CD/DVD-ROM actuator damping with ferrofluid.

schematic of a sink/float device. A mixture of fine particles is passed through a pool of ferrofluid. The magnetic field gradient is adjusted so that the heaviest metal sinks to the bottom and the remainder floats to the top. The mixed light fraction can be further processed until all grains are sorted out. These scrap metals, which are generally dumped in a landfill as waste, now become a valuable commodity through recycling.

The CD-ROM and DVD-ROM technology, which has revolutionized the entertainment industry with crisp sound and sharp images, relies on ferrofluid for high performance. A laser beam retrieves recorded digital signals from a rotating disk, Fig. 8. A flexible lens assembly, integral to an optical actuator, directs the beam at the disk. The lens is supported by two cross coils: the focusing coil aims the beam precisely on the disk surface and the tracking coil ensures that the beam stays on the optical track. If an error occurs, a feedback signal actuates the coils to reposition the lens and thus the beam. The coils must be damped to minimize settling time and improve the access time. Additionally, the fluid noticeably reduces resonance and hence reading errors.

The mono domain $Fe_3O_4$ particles in ferrofluids are nontoxic and can pass easily through capillaries of living systems. The particles may be coated with biocompatible dispersants such as dextran or starch and suspended in water. Such a magnetic liquid holds great potential in diagnostic and therapeutic fields (Häfeli *et al.* 1997). Magnetic microspheres based on ferrofluid particles are commercially available for *in vitro* applications such as separation of cells, enzymes, proteins, antibodies, DNA, and RNA, and attachment of bacterial and virus cells for immunoassays. Immunomagnetic beads can transport drugs to a specific organ or tissue. Thus, radionuclides can be targeted to a lesion for radiation therapy. Also, the magnetic carriers may be heated *in vivo* with an external radio frequency source (hyperthermia) to a temperature of up to 47 °C, thereby destroying AIDS viruses and tumors. The particles have been shown to enhance the magnetic resonance (MR) imaging, thus making it possible to detect metastases. Superparamagnetic iron oxide as a contrast agent has been approved by the FDA for clinical trials.

## 3. *Future Trends*

New applications of ferrofluid with significant growth potential include: NMR contrast agents for both biomedical and oil prospecting fields, quiet solenoid valves for the medical industry, environmental seals for pollution control, cooling and dielectric benefits in power transformers, replacement of toxic mercury in switches, displays for education and entertainment markets, a new generation of sensing devices, low noise and efficient steppers, magnetic ink printing, actuator damping, optical shutters, precision fluid film bearings, critical lubrication, magnetically-responsive adhesives, precision grinding, and fabrication of high strength composites. The next generation of ferrofluids may combine magnetism, electrical conductivity, and liquidity into one state, which will undoubtedly uncover new technological frontiers. Magnetic liquids, due to their inherent composition, may also have a role in the development of nanodevices.

# Ferrofluids: Introduction

It is unlikely that any liquid will be found that is intrinsically ferromagnetic. Nickel, cobalt, and iron, for example, are only ferromagnetic in the solid state. It is fluid media composed of solid magnetic particles of very small size, colloidally dispersed in a liquid carrier, that are the basis for the highly stable, strongly magnetizable liquids known as magnetic fluids or ferrofluids, see Fig. 1. Ferrofluids are extremely interesting due to the interplay between hydrodynamic and magnetic phenomena with detailed information the subject of several books (Bashtovoy *et al.* 1988, Berkovsky 1996, Blums *et al.* 1997, Rosensweig 1985, and others). The typical particle size in a ferrofluid is about 10 nm, which is smaller than a magnetic domain, hence each particle is permanently magnetized. The particles experience appreciable thermal translation that maintains them in suspension against the force of gravity, while in the absence of field thermal reorientation of the particles results in zero remanence or coercivity, i.e., ferrofluids are magnetically soft. The ferrofluids behave remarkably as highly homogeneous, magnetizable media that retain their fluid property in the most intense applied magnetic fields and magnetic field gradients.

Following a brief discussion of their origin, this article outlines methods for the synthesis of ferrofluids and discusses physical requirements for their colloidal stability. In addition, basic magnetic and physical properties are described quantitatively.

## *1. Origin*

By remarkable coincidence, ferrofluids were invented in the USA independently at least three times in the 1960s. Of these inventions, the best known is that of Papell (1965) who employed grinding in the presence of a carrier liquid and a surfactant to reduce large grains of magnetite ($Fe_3O_4$) to colloidal size. The physical chemistry of the process was clarified and the process further developed by Rosensweig *et al.* (1965). O'Connor (1962) synthesized a ferrofluid using chemical precipitation with an ion exchange technique to purify the product. Gable employed chemical synthesis, filing a patent application in 1965 that issued only much later (Gable and Kerr 1977). Dry powders of Gable display remarkable solubility in water. All these ferrofluids use a surface-sorbed layer of a long-chain surfactant, polymer, or protein molecule to provide a short-range repulsion preventing particles from sticking to each other.

Massart (1981) developed ferrofluids in aqueous media that are stabilized by the electric double layer mechanism.

Elmore (1938a, 1938b) produced fine dispersions of magnetite (Bitter colloid) used to detect the boundaries of magnetic domains in bulk ferromagnetic materials. But as the particle size was too large (20 nm) to prevent sedimentation the material does not qualify as a ferrofluid.

## *2. Preparation*

Chemical precipitation is the most often employed process although grinding is useful in some circumstances. Chemical decomposition and vapor-liquid reaction are used to produce certain specialized ferrofluids. In all cases, a repulsive layer is provided that envelopes each particle to prevent them sticking to each other.

The essential chemical reaction in the precipitation of ferrofluid particles is indicated by the reaction:

$$2Fe^{3+} + Fe^{2+} + 8OH^- = FeO \cdot Fe_2O_3 + 8H_2O \quad (1)$$

where $FeO \cdot Fe_2O_3$ is magnetite written to emphasize the ratio of divalent to trivalent iron atoms in it, $Fe^{III}/Fe^{II} = 2$. The iron salts used in the preparation may be any combination of soluble salts such as the chlorides or sulfates and the alkali can be ammonium hydroxide, sodium hydroxide, or another base. Following precipitation in the procedure of Khalafalla and Reimers (1974) the small particles are extracted into a mixture of surfactant in an organic solvent. Massart (1996) discusses procedures for bonding species of small ions of a desired electical sign to the

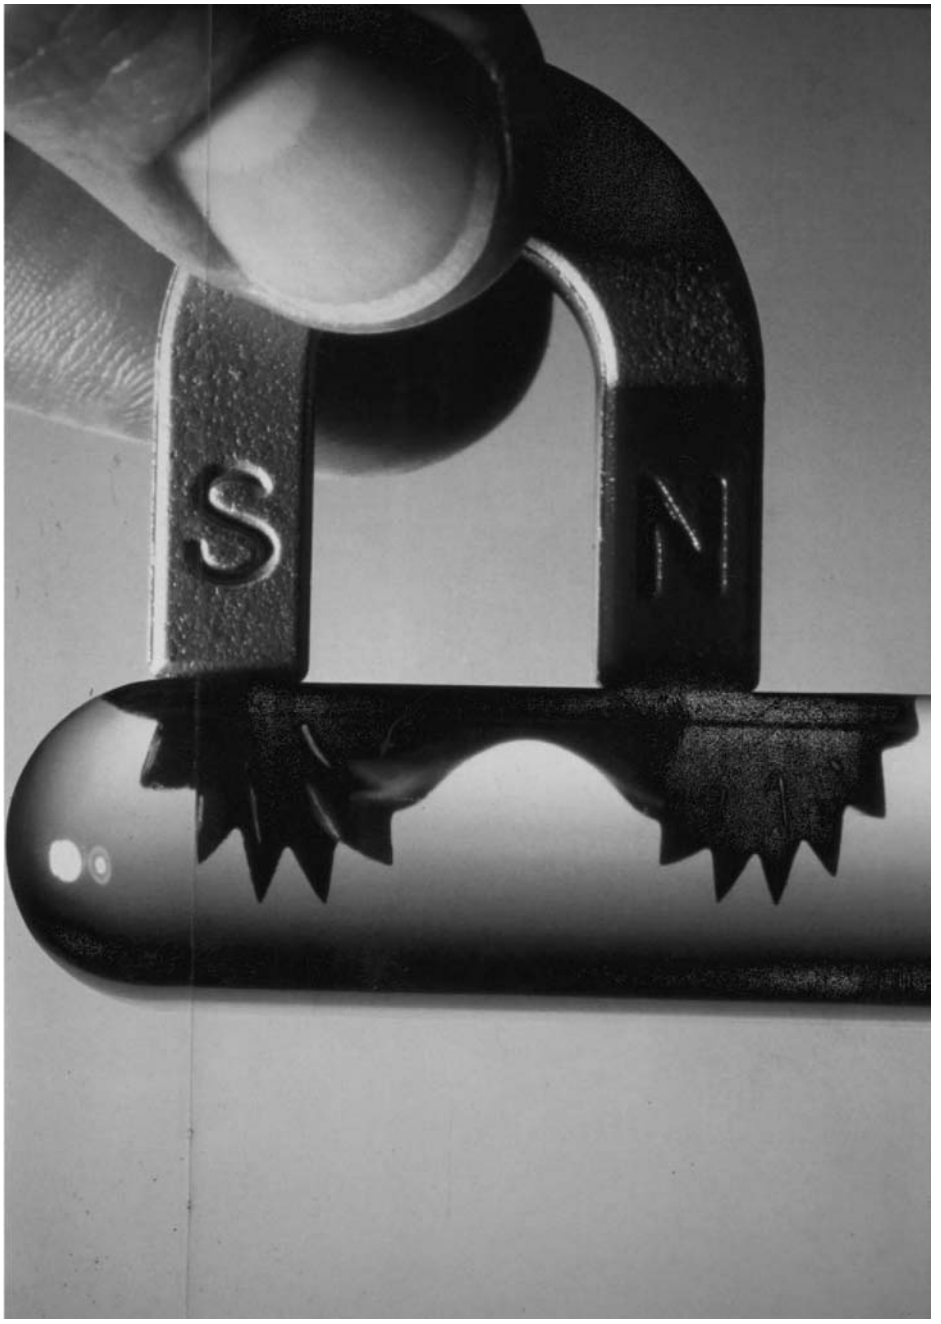

***Figure 1***
Attraction of ferrofluid against gravity to the poles of a magnet; peaks on the surface result from a competition between gravitational, surface, and magnetic energies (courtesy of Ferrofluidics Corporation).

surface of oxide particles. In this manner, ferrofluids can be conferred stability over ranges of pH values.

In the grinding process, magnetic powder, most commonly magnetite of several microns size, is mixed with 10–20 vol.% of dispersing agent based on solvent volume, and 0.2 kg $l^{-1}$ of magnetite may be used. The proportion of dispersant to solid corresponds closely to a monolayer coating on the particles in the

product liquid. After a prolonged period of grinding in a ball mill (500–1000 h) near-quantitative conversion of the feed solids to colloidal particles of the order of 9–10 nm results. A representative composition consists of magnetite particles, oleic acid dispersant, and an aliphatic hydrocarbon carrier such as hexadecane. Oversize material can be removed by centrifuging or with magnets and the concentration of particles adjusted by the evaporation or addition of the carrier solvent.

The domain magnetization of elemental iron or cobalt exceeds that of magnetite at normal temperatures by three- to four-fold giving incentive to the preparation of more highly magnetizable ferrofluids containing these metals. A problem that arises is the reactivity of the elemental particles with atmospheric oxygen. Nakatani *et al.* (1993) prepared dispersions of iron-nitride particles, e.g., $Fe_3N$, in oils. Gaseous ammonia is bubbled through a solution of liquid iron carbonyl, $Fe(CO)_5$, dissolved in kerosene containing a polyamine surfactant and produces a well dispersed colloid with particles of highly uniform size. The iron nitrides possess a domain magnetization approaching that of iron and are resistant to oxidation. Ferrofluids having saturation magnetization up to $\mu_0 M = 0.233$ T are reported.

## 3. Colloidal Stability of the Particles

### 3.1 Stability Against Sedimentation

Ferrofluids employ the same principle that keeps the atmosphere suspended above the earth, preventing it from collapsing under gravitational pull, to keep the tiny magnetic particles suspended. In addition, the finite size of the particles plays an important role.

Consider a container of ferrofluid exposed to a nonuniform magnetic field of sufficient intensity to magnetically saturate the sample at all points. At an arbitrary point $P$ the magnetic force acting on a unit volume of the fluid in a given direction $s$ is given from the Kelvin force expression for dipolar matter as $\mu_0 mn\mathrm{d}H/\mathrm{d}s$ where $\mu_0$ is the permeability of free space ($4\pi \times 10^{-7}$ kgms$^{-2}$A$^{-2}$), $m = M_\mathrm{d} V_\mathrm{d}$ is the magnetic moment of a particle, $M_\mathrm{d}$ is domain magnetization ($4.46 \times 10^5$ Am$^{-1}$ for magnetite), $V_\mathrm{d}$ particle volume (m$^3$), $n$ the number concentration of particles (m$^{-3}$), and $H$ magnetic field magnitude (Am$^{-1}$) where $B = \mu_0(H + M)$. Balance of the forces acting at equilibrium on a differential slice of the medium centered about $P$ and oriented perpendicular to $s$ yields the relationship:

$$\mathrm{d}p = \mu_0 mn\mathrm{d}H = \mu_0 M_\mathrm{d} \varepsilon \phi \mathrm{d}H \qquad (2)$$

where $p$ is osmotic pressure of the particles (regarding the particles as a gas occupying the volume of the fluid space), $M_\mathrm{d}$ is domain magnetization ($4.46 \times 10^5$ for magnetite) $\varepsilon$ the volume fraction within a coated particle that is magnetic, and $\phi$ the local volume fraction of coated particles in the ferrofluid. An equation of state relates $p$ to the concentration of the particles.

A semi-van der Waals relationship that accounts for the volume occupied by the particles is given by:

$$p\left(\frac{1}{\phi} - \frac{1}{\phi_\mathrm{m}}\right) = \frac{kT}{V_\mathrm{d}} \qquad (3)$$

where $\phi_\mathrm{m}$ is the maximum value of $\phi$ to which the colloid can be concentrated as limited by the size of the coated particles, $k$ the Boltzmann constant ($1.38 \times 10^{-23}$ NmK$^{-1}$), and $T$ absolute temperature (K). A representative value of $\phi_\mathrm{m}$ is 0.74 corresponding to hexagonal close packed spheres, and a typical value of $\varepsilon$ is 0.36 corresponding to 10 nm core particles coated with a surfactant of 2 nm thickness. Combining Eqns. (2) and (3) to eliminate $p$ yields a differential equation governing the distribution of the particles. Integration yields the plot of Fig. 2 showing the distribution of the finite size particles as a function of the local field; concentration never exceeds the maximum value which is less than one. A curve showing the distribution for point particles is shown for comparison. In the application of ferrofluids to zero leakage rotary shaft seals and related devices, a concentrated ferrofluid is generally employed. The steric hindrance due to the finite particle size is responsible for the high retention of fluid homogeneity required for the successful operation of these devices.

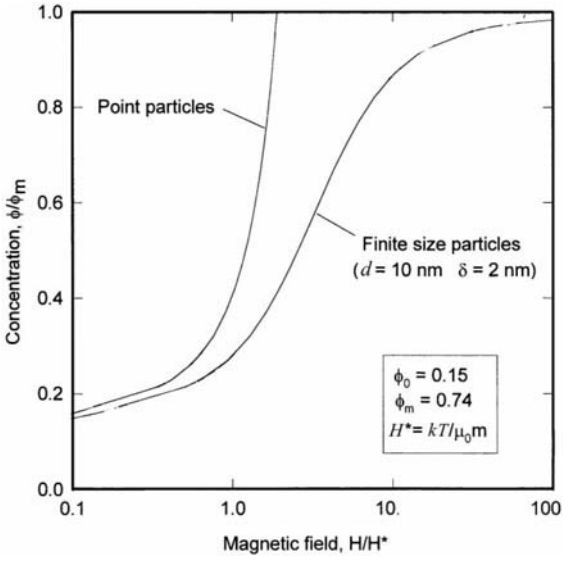

***Figure 2***
Sedimentation equilibrium of ferrofluid particle concentration in nonuniform magnetic field. The steric hindrance of finite-size particles limits their maximum concentration to a physically realistic value.

### 3.2 *Stability Against Agglomeration*

A typical ferrofluid contains on the order of $10^{17}$ particles per cubic centimeter, and collisions between particles are frequent. Hence, if the particles adhere together, agglomeration will be rapid. The particles are permanently magnetized, so the maximum energy to overcome the magnetic attraction between a pair of particles each of radius, $R$, occurs when the particles are aligned. The corresponding dipole–dipole magnetic interaction is given by:

$$E_{\mathrm{M}} = -\frac{8\pi\mu_0 M_{\mathrm{d}}^2 R^3}{9(x+2)^3} \tag{4}$$

where $x = s/R$ with $s$ the surface to surface separation distance.

In addition, van der Waals forces of attraction arise between neutral particles due to the fluctuating electric dipole-induced dipole forces that are always present. It is also necessary to guard against these forces. London's model predicts an inverse sixth power law between point particles which Hamaker extended to apply to equal spheres with the following result.

$$E_{\mathrm{V}} = -\frac{A}{6}\left[\frac{2}{x^2+4x} + \frac{2}{(x+2)^2} + \ln\frac{x^2+4x}{(x+2)^2}\right] \tag{5}$$

$A$ is the Hamaker constant, roughly calculable from the optical dielectric properties of particles and the medium. For Fe, $Fe_2O_3$, or $Fe_3O_4$ in hydrocarbon carrier, $A = 10^{-19}$ Nm is representative within a factor of three.

A technique to prevent particles from approaching too close to one another is the steric repulsion arising from the presence of long chain molecules adsorbed onto the particle surface. A lattice model for the steric repulsion based on the theory of polymer configurations in a good solvent (deGennes 1975) yields an expression for steric repulsion $E_{\mathrm{S}}$.

$$E_{\mathrm{S}} = kT\frac{\delta^3}{a^3}\left[\ln\left(\frac{1}{1-\phi_{\mathrm{s}}}\right) - \phi_{\mathrm{s}}\right] \times \left[\frac{\pi}{12}\left(2 - x\frac{R}{\delta}\right)^2\left(6\frac{R}{\delta} + 5\right)\right] \tag{6}$$

In Eqn. (6) $\delta$ is coating thickness, $a$ is the length associated with the lattice spacing, i.e., the correlation length along a chain, and $\phi_{\mathrm{s}}$ is mean volume fraction of surfactant in the space between the surfaces.

The net sum, $E_{\mathrm{N}}$, of the magnetic, van der Waals, and steric energy terms is decisive for determining monodispersity of the colloidal ferrofluid.

$$E_{\mathrm{N}} = E_{\mathrm{M}} + E_{\mathrm{V}} + E_{\mathrm{S}} \tag{7}$$

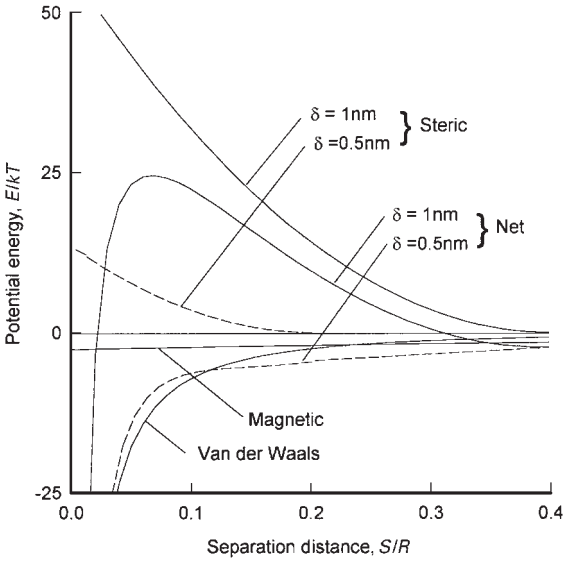

***Figure 3***
Potential energy versus surface separation distance of sterically protected 10 nm magnetite particles of a ferrofluid. A net energy barrier greater than about 10 kT prevents agglomeration of particles.

Figure 3 illustrates calculated behavior for given size particles with two different thicknesses of coatings. The curve of magnetic energy is the same in both cases as is the distribution of van der Waals energy. Magnetic interaction can nearly be neglected in comparison. Steric repulsion with the thicker coating (1 nm) yields a net energy curve presenting a barrier energy of nearly 25 kT. Statistically, few particles cross the barrier and the colloid is stable against agglomeration. The thin coating (0.5 nm) yields a net energy curve that is attractive at all distances thus yielding an unstable preparation.

Various sorbent configurations that confer steric stability to ferrofluids are illustrated schematically in Fig. 4. A particle coated with a sorbed monolayer of a long tail molecule having a polar head group, e.g., oleic acid, is shown in Fig. 4(a). Figure 4(b) illustrates a polymeric species having multiple polar groups distributed along its length. Loops of polymer rather than tails serve as the protective layer. Because more than one polar group attaches to the particle surface, the colloidal stability at elevated temperatures is enhanced; polybutenylsuccinpolyamines are an example. Figure 4(c) illustrates a double layer configuration with inwardly oriented tails of polar molecules in an outer layer associated with the tails of the surface-sorbed layer. This configuration serves to disperse particles in aqueous media. Example combinations are: sodium oleate/sodium oleate and sodium oleate/sodium dodecyl benzene sulfonate.

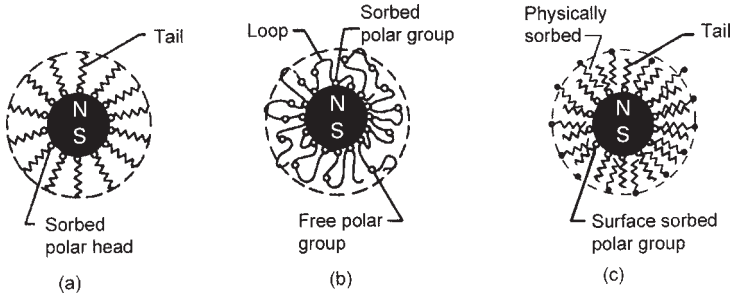

***Figure 4***
Sorbed protective layers of various types yield stably dispersed particles in a ferrofluid.

Charge stabilized colloids prepared with the Massart technique use the sorption of small moities to adjust electrical charge on the particle. Sorption of tetramethylammonium ion $(N(CH_3)_4^+)$ yields stable dispersions in alkaline solution (pH > 9) where hydroxyl ion $(OH^-)$ furnishes the counterion, whereas perchlorate ion $(ClO_4^-)$ and nitrate $(NO_3^-)$ peptize particles in acidic media (pH < 5) where hydrogen ions $(H^+)$ are the counterions. Magnetic particles coated with citrate ligands are peptizable at intermediate levels of pH and are candidates for medical application at neutral pH.

## 4. Phase Transition

Under certain conditions, ferrofluids undergo phase separation in which micronic droplets of a concentrated phase exist in equilibrium with a continuous dilute phase. The appearance of a drop is shown in Fig. 5(a). The phenomenon can be brought on in various ways—by application of magnetic field intensity in excess of a critical value, addition of a foreign solvent, change of pH or counter ion concentration of an electrically stabilized preparation, and by reduction of temperature. It is sometimes possible to take advantage of such a phase separation, e.g., to sort particles by size, or to induce colors in thin layers by diffraction of light. In other cases, where a dilute magnetic fluid is retained by application of a field gradient, the separation can lead to undesired weeping of the dilute phase.

Optical methods are useful for detecting the droplets. Direct microscopic observation via light transmitted through a thin layer is possible for droplets having size of a few micrometers; the layer is transparent red-orange in the homogeneous region. Laser light scattering being very sensitive to the presence of small clusters may be more suitable for direct detection of the very onset of the transition.

Figure 6 shows coexistence curves for a hydrocarbon-based ferrofluid that has particle size $d_{mp} = 7.4\,\text{nm}$ as determined by electron microscopy. Field

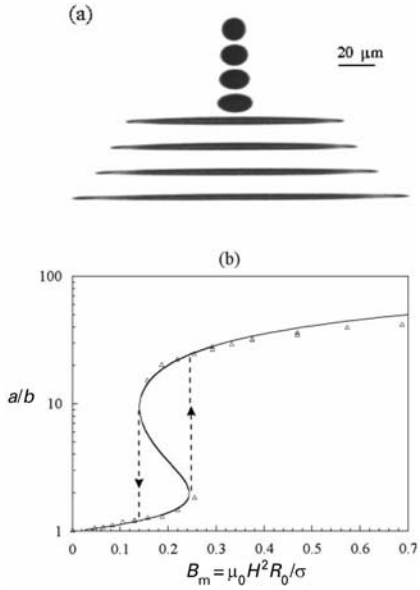

***Figure 5***
As shown in (a) a stretched droplet of phase-separated ionic ferrofluid exhibits a jump in length as applied field exceeds a critical value; (b): hysteresis results when field is decreased. Viscosity of the drop phase exceeds that of the dilute phase by a factor of more than 300 as determined from birefringence (after Bacri and Salin 1983).

intensity producing transition can be increased using a sample containing smaller size particles. A sample with particle sizes $d = 5.0\,\text{nm}$ tested homogeneous at all concentrations in the highest field applied $(12.7\,\text{Am}^{-1})$.

## 5. Ferrofluid Modification

If an excess of a polar solvent such as acetone or a lower molecular weight alcohol is added to an

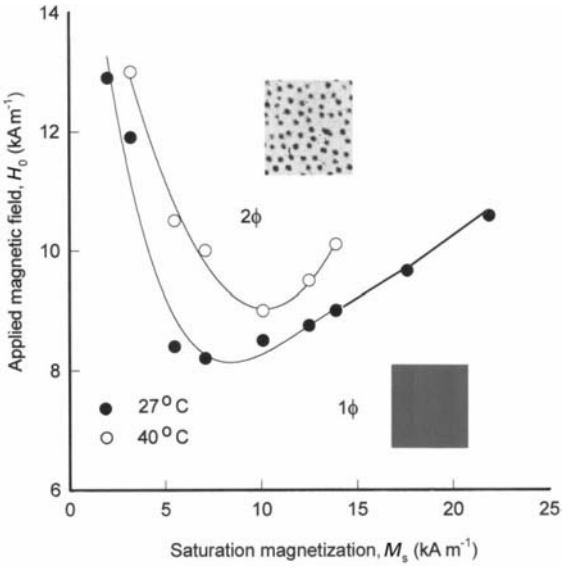

***Figure 6***
Coexistence curves for a hydrocarbon-based ferrofluid of magnetite particles. Insets show appearance of a thin layer seen through a microscope: one-phase region shows homogeneous coloring; cross-sections of stretched droplets in the two-phase region form a patterned array due to mutual repulsion; applied field is normal to the layer (after Popplewell and Rosensweig 1992).

oleic-acid-stabilized ferrofluid in hydrocarbon carrier the magnetite particles flocculate and settle out in an external force field. Evidently, the surface layer retracts and becomes ineffective in providing steric repulsion. The particles redisperse spontaneously when fresh solvent is added, showing that the surfactant remains bound onto the particle surface. The technique permits the concentration of the colloid to be adjusted and excess surfactant removed. Removing the excess generally reduces the viscosity, especially of high concentration, more magnetic preparations. Also, the initial solvent, e.g., high volatility heptane, can be exchanged for one of low volatility, useful in applications where the ferrofluid is exposed to the atmosphere as in magnetic fluid rotary shaft seals and acoustic drivers.

Certain surfactants are only weakly adsorbed and dissolve off into the polar liquid mixture. Contacting the settled out particles with fresh solvent fails to produce a stable dispersion. An example is aqueous ferrofluid having particles coated with Aerosol C61, an amine complex. After washing the precipitated particles with solvent, a different surfactant may be added which is capable of strongly adsorbing onto the particle surface. The new surfactant can be chosen to confer dispersibility of the particles in a totally different solvent. The technique confers great flexibility in the production of ferrofluids in diverse carriers such as mineral oils, esters, silicones, etc.

## 6. Magnetic Properties

### 6.1 Equilibrium Magnetization

The magnetic torque, $\tau$, experienced by a single particle of volume $V$ and domain magnetization $M_d$ whose moment is oriented at angle $\theta$ to applied induction $B$ is given by $\tau = mH\sin\theta$ where $m = M_d V$ is the magnetic moment of the particle. The associated energy to rotate the particle away from alignment with the field is $W = mB(1-\cos\theta)$ with the probability $p(\theta)$ of finding a particle oriented between angle $\theta$ and $\theta + d\theta$ proportional to the Boltzmann factor $\exp(-W/kT)$ times the steradians in orientational space, $\sin\theta d\theta$, with the component of the moment along the field direction given by $m\cos\theta$. The mean value of magnetization for monodisperse particles is given by the integration:

$$\frac{\bar{m}}{m} = \frac{\int_0^\pi \cos(\theta)p(\theta)d\theta}{\int_0^\pi p(\theta)d\theta} = \coth\gamma - \frac{1}{\gamma} \equiv L(\gamma) \qquad (8)$$

where $L(\gamma)$ is the Langevin function and $\gamma = mB/kT$. $L(\gamma) = \gamma/3$ for $\gamma \ll 1$ and $L(\gamma) = 1 - 1/\gamma$ for $\gamma \gg 1$. Noting that $\bar{m}/m = M/M_s$ where $M$ is magnetization of the ferrofluid and $M_s$ is the saturation value of $M$, magnetization curves for monodisperse spherical particles calculated with the domain magnetization of magnetite are shown in Fig. 7.

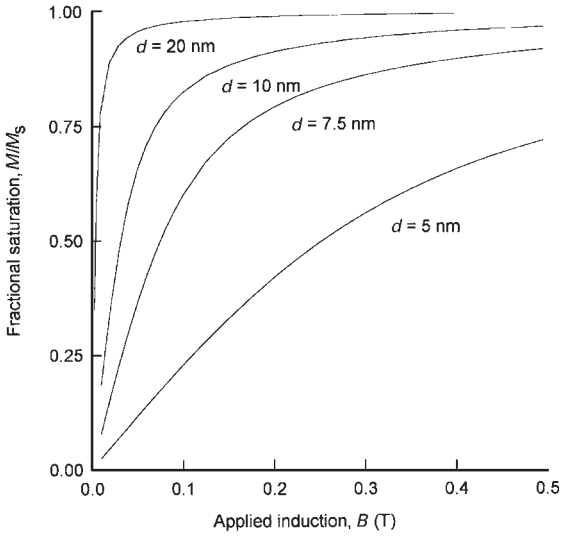

***Figure 7***
Magnetization curves computed from the Langevin relationship (magnetite, $M_d = 4.46 \times 10^5\,\mathrm{Am}^{-1}$).

For a polydisperse system the shape of the magnetization curve depends on the distribution of particle sizes. Commonly a good fit to the distribution is given by the log normal distribution function $P(d)$ where $P(d)\mathrm{d}(d)$ is the fraction of total magnetic volume having diameter between $d$ and $d+\mathrm{d}(d)$.

$$P(d) = \frac{1}{\sigma d\sqrt{2\pi}} \exp\left[-\frac{\ln^2(d/d_0)}{2\sigma^2}\right] \tag{9a}$$

and

$$\int_0^\infty P(d)\mathrm{d}(d) = 1 \tag{9b}$$

where $\ln(d_0)$ is the mean of $\ln(d)$, $d_0$ is the median diameter, and $\sigma$ is its standard deviation The most probable diameter is given by $d_{\mathrm{mp}} = d_0\exp(\sigma^2)$, the mean diameter $\langle d\rangle = d_0\exp(\sigma^2/2)$, and higher moments $\langle d^n\rangle = d_0^n\exp(n^2\sigma^2/2)$. Taking size distribution into account the magnetization curve is given by:

$$M(H) = \int_0^\infty M(d,\ H)P(d)\mathrm{d}d \tag{10}$$

Chantrell *et al*. (1978) used expansions of the Langevin function together with the log normal distribution to obtain the following expressions for median diameter, $d_0$, and standard deviation, $\sigma$, from a magnetization curve of a polydisperse system.

$$\sigma = \frac{1}{3}\sqrt{\ln\frac{3\chi}{M_{\mathrm{s}}/H_0}} \tag{11a}$$

$$d_0 = \left(\sqrt{\frac{\chi}{3M_{\mathrm{s}}H_0}}\,\frac{18kT}{\pi M_{\mathrm{d}}}\right)^{\frac{1}{3}} \tag{11b}$$

where $\chi$ is the initial susceptility of the fluid and $1/H_0$ is the extrapolation to $M=0$ of the straight line obtained for high fields when plotting $M=f(1/H)$. Measured values of magnetization for dilute ferrofluids are in good agreement with the superparamagnetic relationship when the distribution of particle size is taken into account. Dipole–dipole interaction between particles elevates the low field portion of the magnetization curve for ferrofluids having parameter $\mu_0 M_{\mathrm{d}}^2 V/kT \approx 30$ or greater.

Temperature dependence of magnetization is of interest in problems of thermal convection. The pyromagnetic coefficient $K=-\partial M/\partial T$ depends on domain magnetization, fluid expansion coefficient, particle volume fraction, and thermal disorientation which can be modeled with the Langevin function.

### 6.2 *Anomalous Susceptibility*

The initial susceptibility $\chi = M/H$ of ferrofluid containing noninteracting particles can be computed from the expansion of Eqn. (8) as $L(\gamma) = M/M_{\mathrm{s}} = \gamma/3$ where $M_{\mathrm{s}}$ is the saturation magnetization of the ferrofluid and $a$ is the Langevin argument. Thus $\chi = \pi\mu_0 d^3 M_{\mathrm{d}} M_{\mathrm{s}}/18kT$ where $M_{\mathrm{d}}$ is the domain magnetization of the magnetic particles. For a concentrated phase of 12 nm magnetite particles with $\mu_0 M_{\mathrm{s}} = 0.1T$ the value of $\chi$ is 3.27. Polydisperse ferrofluid samples posess susceptibilities that are consistent with this estimate. However, as seen previously, values of $\chi$ in the droplets of a phase-separated sample are more than an order of magnitude larger. An *in situ* measurement based on elongation behavior of a droplet as a function of applied magnetic field intensity provides an elegant means for measuring the susceptibility as discussed in the following.

Using ionic ferrofluid the elongated deformation is obtained in fields of very low intensity, of the order of $120\,\mathrm{Am}^{-1}$ (1.5 Oe). Above a threshold value of the magnetic Bond number, $B_{\mathrm{m}} = \mu_0 H^2 R_0/\sigma_{\mathrm{t}}$, where $R_0$ is radius of an initially spherical drop and $\sigma_{\mathrm{t}}$ interfacial tension, the drop experiences an elongational shape instability characterized by a steep jump of its aspect ratio. The S-shape curve, see Fig. 5(b) can be fitted to a theoretical expression assuming an ellipsoidal prolate shape allowing susceptibilitiy $\chi$ and $\sigma_{\mathrm{t}}$ to be deduced. The minimum susceptiblity to achieve the hard transition occurs at about $\chi = 18$. For this data $\chi = 75 \pm 10$ and $\sigma = 9 \pm 2 \times 10^{-7}\,\mathrm{Nm}^{-1}$ with $R_0 = 6.5\,\mathrm{mm}$.

Subjected to a rotating magnetic field, the drops first elongate and spin, develop arms reminiscent of starfish, and undergo other transitions depending on field rotational frequency and intensity.

### 6.3 *Nonequilibrium Magnetization*

The vectorial magnetization, $M_0$, in equilibrium with steady magnetic field, $H$, in motionless fluid is aligned in the direction of $H$ and possesses magnetization magnitude $M_0$ given, for example, by the Langevin relationship. However, in the presence of time-varying magnetic field magnitude or orientation the magnetization, $M$, lags behind the field and differs from $M_0$. Models have been developed (Shliomis 1974, Martsenyuk *et al*. 1973) to treat this behavior which has importance to dynamic flows of ferrofluids.

Measurement of the frequency response of magnetization of a ferrofluid yields information concerning the relaxation mechanism (Fannin *et al*. 1990).

## 7. *Viscosity of Ferrofluid*

### 7.1 *Viscosity in Absence of Field*

In 1906, Einstein derived the earliest theory for noninteracting spheres suspended in a liquid based on the flow field of pure rate-of-strain perturbed by the presence of the sphere. The resulting formula relates the mixture viscosity, $\eta$, to the carrier fluid viscosity,

$\eta_0$, and solids fraction, $\phi$, in the form $\eta/\eta_0 = 1 + 5\phi/2$. This relationship has been extended by Batchelor to second order in concentration. For higher concentrations, a parameterized expression may be assumed of the form $\eta/\eta_0 = 1/(1 + a\phi + b\phi^2)$ with insistence that the expression (i) reduce to the Einstein relationship for small values of $f$ so that $a = -5/2$; (ii) the suspension becomes effectively rigid at a concentration, $\phi_c$, indicative of close packing (0.74 for close packed spheres); and (iii) core particles of volume fraction $\phi$ coated with dispersing agent of thickness $\delta$ occupies volume fraction $\phi(1 + \delta/r)^3$ where $r$ is radius of the core particle. Combining these relationships results in the expression:

$$\frac{\eta - \eta_0}{\phi\eta} = \frac{5}{2}\left(1 + \frac{\delta}{r}\right)^3 - \left(\frac{5\phi_c/2 - 1}{\phi_c^2}\right)\left(1 + \frac{\delta}{r}\right)^6 \phi \quad (12)$$

If particles have a tendency to cluster and form a gel network, the value of $\phi_c$ is less than 0.74. For $\phi_c$ less than 0.4 the coefficient of the last term in Eqn. (12), and hence the slope of a plot of $(\eta - \eta_c)/\phi\eta$ vs. $\phi$ changes sign, a phenomenon that has been observed for certain ferrofluids.

### *7.2 Viscosity in Magnetic Field*

When a magnetic field is applied to a ferrofluid that is sheared, the magnetic particles in the fluid tend to remain aligned in the direction of the orienting field and viscous dissipation in the fluid increases. A theoretical treatment (Shliomis 1974) for dilute suspensions of particles with large Néel time constant and accounting for the Brownian rotational motion gives

$$\frac{\Delta\eta}{\eta} = \frac{3}{2}\phi\left(\frac{\gamma - \tanh\gamma}{\gamma + \tanh\gamma}\right)\sin^2\beta \quad (13)$$

where $\gamma$ is the Langevin parameter, $\beta$ the angle between the magnetic field, $H$, and the fluid vorticity, $\mathbf{\Omega} = \nabla \times \mathbf{v}$, where $\mathbf{v}$ is the fluid velocity vector. The vorticity is twice the local average spin rate of the colloid. Magnetic particles rotate freely when the rotational and magnetic axes are aligned with the local field direction but are hindered otherwise. In laminar flow through a circular tube (Poiseuille flow) the vorticity magnitude is constant on concentric circles in a cross-section normal to the axis of the tube. For field oriented parallel to the axis, $\sin^2\beta = 1$ while for perpendicular orientation of the field relative to the tube axis, averaging over $\beta$ gives $\langle \sin^2\beta \rangle = 1/2$. Hence, for any applied magnetic field intensity, $\Delta\eta_{||} = 2\Delta\eta_{\perp}$. As seen in Fig. 8, the theoretical curves (solid lines) agree well with the experimental data of McTague (1969) for a dilute suspension of polymer-stabilized cobalt particles in toluene.

In alternating, linearly polarized magnetic field, the viscosity of a ferrofluid can exhibit a substantial reduction, i.e., a negative viscosity component (Shliomis and Morozov 1994). The particles of the ferrofluid act as tiny motors rotating faster than the vorticity spin rate thus helping to propel the fluid.

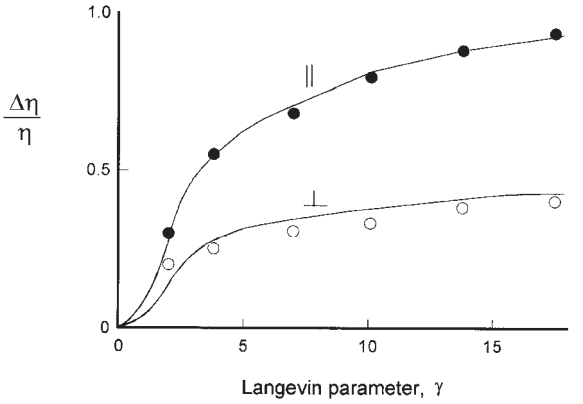

***Figure 8***
Magnetoviscosity of a dilute ferrofluid containing particles of elemental cobalt. Data of McTague (1963) compared to theory (after Shliomis and Raikher 1980).

## *8. Other Physical Properties*

Mass density and specific heat of ferrofluids is estimated as the volumetric average of particle and matrix liquid values assuming surfactant to possess properties of the carrier liquid. Pour point and vapor pressure can be estimated as that of the carrier liquid. Surface tension at ambient temperatures of sterically-stabilized aqueous ferrofluid is reduced from that of water ($72\,\mathrm{mNm^{-1}}$) to a typical value of $26\,\mathrm{mNm^{-1}}$, most likely due to free surfactant concentrated at the air interface. Interfacial tension for ferrofluids in various organic alkanes and esters ranges typically from 20 to $32\,\mathrm{mNm^{-1}}$ depending on the carrier.

The thermal conductivity, $\lambda$, of a composite consisting of particles in a matrix fluid is described by the Maxwell formula obtained by comparing the thermal field with the analogous electrical field and it is assumed that ferrofluids can be described in this manner also.

$$\frac{\lambda}{\lambda_c} = \frac{2\lambda_c + \lambda_p + 2\phi_p(\lambda_p - \lambda_c)}{2\lambda_c + \lambda_p - \phi_p(\lambda_p - \lambda_c)} \quad (14)$$

where $\lambda_c$ is thermal conductivity of the carrier solution, $\lambda_p$ the thermal conductivity of the particles, and $\phi_p$ the particle volumetric concentration. Solids conductivity may differ significantly from that of the carrier, e.g., for $\gamma$-$Fe_2O_3$ and perhaps magnetite $\lambda_p \approx 6\,\mathrm{W\,m^{-1}\,K^{-1}}$ while for an oil $\lambda_c \approx 0.13\,\mathrm{W\,m^{-1}\,K^{-1}}$. Thus, the solids volumetric concentration must considerably affect the

thermal conductivity of the ferrofluid. Data of magnetite-in-kerosene ferrofluid show a range $1.0 < \lambda/\lambda_c < 2.0$ with maximum concentration of $\phi = 0.2$. Magnetic field oriented normal to the temperature gradient does not affect $\lambda$.

Ferrofluid solutions when sufficiently dilute or in a thin enough layer transmit a light beam, and the normally isotropic fluid becomes optically anisotropic in an applied magnetic field, $H$. Properties of interest include birefringence, dichroism, and Faraday rotation.

Birefringence and dichroism in homogeneous samples is attributed to the shape anisotropy of particles and possibly correlations between neighbors. The influence of an individual particle depends on the orientation of its axis relative to the electric field of the incident light ray. Analysis that averages over orientations yields a dependence on applied field intensity that is the same for both phenomena (Shliomis and Raikher 1980).

$$\frac{n_{||} - n_{\perp}}{\Delta n_{\infty}} = \frac{K_{||} - K_{\perp}}{\Delta K_{\infty}} = 1 - \frac{3L(\gamma)}{\gamma} \qquad (15)$$

where $n_i'$ and $K_i$ are components of refractive index and adsorption coefficient, respectively. Figure 9 illustrates the favorable comparison of data and predictions for a sterically-stabilized ferrofluid. Using birefringence detection with a sample having volumetric particle fraction of less than $10^{-3}$ as a sensor, the viscosity of carrier liquids was measured with an accuracy of 5% over a viscosity range of seven decades (Bacri *et al.* 1985). The viscosity of the solutions was negligibly changed by presence of the particles, less than 2.5 parts per thousand using the Einstein relationship. Bibette (1993) produced a monodisperse emulsion of oil base ferrofluid droplets in an aqueous carrier and optically measured force vs. distance characterizing the electrostatic double layer surrounding the droplets. Modulation of the applied magnetic field was used to control the attraction between droplets, hence their separation distance.

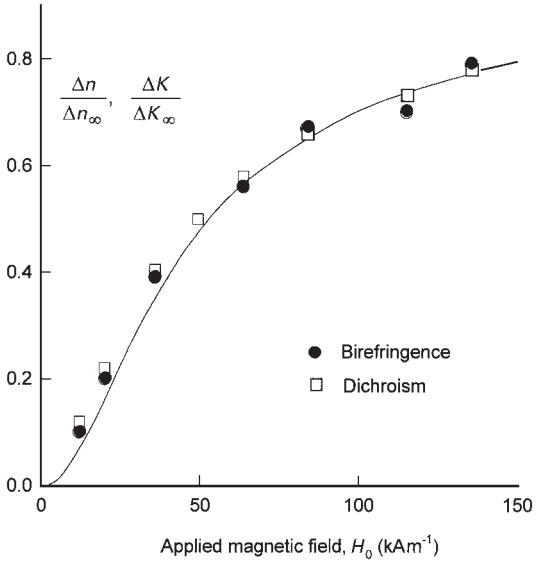

***Figure 9***
Dependence on magnetic field of birefringence and dichroism for a hydrocarbon base ferrofluid compared to theory.

## 9. *Status and Future Directions*

Scientific understanding of ferrofluids as a material has progressed greatly. Proceedings of the International Conferences on Magnetic Fluids (Elsevier, North-Holland, Publishers) are a rich source of information including bibliographies of patents and the literature. The influence of magnetic and thermal fields on the hydrodynamics of ferrofluids, i.e., ferrohydrodynamics, is highly developed. Commercial applications of ferrofluids range from tribology to instrumentation to densimetric separation of minerals, and many other uses are in stages of research. Materials research challenges for the future include: development of stable fluids having larger saturation moments, conjugation of ferrofluid particles with protein species for drug delivery and medical imaging, development of ferrofluid inks in various colors, ferrofluids possessing greater monodispersity, stable ferrofluids in liquid metal carrier, and ferrofluid composites with tailored properties.

# Ferrofluids: Magnetic Properties

The magnetic properties of ferrofluids are dominated by the intrinsic magnetic properties of the particles themselves. These are governed by dynamical effects due to Néel relaxation in the solid and Brownian motion in the fluid, and influenced by the interparticle interaction.

## *1. Single-domain Particles*

The particles have diameters in the range of typically 2–20 nm. The size is generally below the critical limit, dependent on the specific ferromagnet, where a magnetic domain structure can form, and so the particles can be considered as single domain. Because of the nanometer-scaled size, finite-size effects are significant. Surface effects influence the intrinsic properties (e.g., magnetization, magnetocrystalline anisotropy). The breaking of symmetry results in site-specific surface anisotropy; the reduced number of magnetic neighbors and specific electronic and structural features lead to magnetic disorder and weakened exchange coupling, with possible effects on atomic moments. All phenomena depend on the surface microstructure and can vary with the surroundings.

Volume effects influence the behavior of the exchange-coupled spin system against excitation. The particle volume, $V$, is small enough for coherent spin reversal (Stoner–Wohlfarth particle), at least on a macroscopic viewing scale. Because all the spins rotate in unison, except perhaps near the surface, they can be dealt with collectively via the particle moment $\boldsymbol{m}$. Its magnitude is given by

$$\boldsymbol{m} = M_s V \tag{1}$$

where $M_s$ is the intrinsic magnetization, which is the magnetic moment per unit volume. It can often be considered as constantly neglecting its thermal variation. The orientation of $\boldsymbol{m}$ with respect to the lattice is determined by the total magnetic anisotropy energy, which results generally from bulk magnetocrystalline, magnetostatic (shape), and global macroscopic surface anisotropies. It can often be considered uniaxial and is then given by

$$E = KV\sin^2\theta \tag{2}$$

where $K\,(>0)$ is the effective anisotropy energy density, generally in the range $10^4$–$10^6\,\mathrm{J\,m^{-3}}$, and $\theta$ is the angle with respect to the symmetry (easy) axis.

Since the anisotropy energy decreases with volume, the energy barriers separating the easy directions can be comparable to the thermal energy, $kT$, even below room temperature; here, $k$ is Boltzmann's constant and $T$ the temperature. $\boldsymbol{m}$ is then no longer fixed in the lattice, unlike in large crystals, but fluctuates

among the easy directions. Néel performed the first calculation of the relaxation time and this thermoactivated phenomenon is called Néel or superparamagnetic relaxation. The corresponding magnetic behavior is called superparamagnetism.

A particle responding to a magnetic field rotates its moment. In a solid, the rotation occurs inside the particle (Néel relaxation). In a ferrofluid, it can also occur by bulk rotation (Brownian rotational diffusion). The relaxation rates are generally different and the two processes can often be treated separately.

## 2. Néel Relaxation

In a uniform magnetic field $\boldsymbol{H}$ of strength $H$, the free energy of an isolated uniaxial particle with anisotropy barrier $E_B = KV$, fixed in space, is given by

$$E = E_B \sin^2\theta - \mu_0 mH(\cos\theta\cos\psi + \sin\theta\sin\psi\cos\varphi) \quad (3)$$

where $\mu_0$ is the permeability of free space, $\psi$ the angle between the easy axis (unit vector $\boldsymbol{e}$) and field, and $\varphi$ the longitude of $\boldsymbol{m}$ relative to the plane $(\boldsymbol{e},\boldsymbol{H})$. $H_K = 2E_B/\mu_0 m$ is the anisotropy field. The energy has a bistable form if the field is not too large, i.e., $H < H_c(\psi)$ with $1 \geqslant H_c/H_K \geqslant 1/2$. In Brown's model, the equation of motion is given by the Gilbert–Landau–Lifshitz equation

$$\begin{aligned} 2\tau_{N0}\frac{d\boldsymbol{m}}{dt} &= \frac{\mu_0}{kT}\left[m\zeta^{-1}\boldsymbol{m}\times\boldsymbol{H}_e + (\boldsymbol{m}\times\boldsymbol{H}_e)\times\boldsymbol{m}\right] \\ \tau_{N0} &= \frac{m}{2\gamma kT}(\zeta^{-1}+\zeta) \end{aligned} \quad (4)$$

where $\gamma$ is the gyromagnetic ratio ($1.7\times10^{11}\,s^{-1}\,T^{-1}$), and $\zeta$ ($\approx 10^{-1}$–$10^{-2}$) the dimensionless damping factor of the precession of $\boldsymbol{m}$ in the effective field $\boldsymbol{H}_e = -\mu_0^{-1}\partial E/\partial\boldsymbol{m} + \boldsymbol{h}(t)$, where $\boldsymbol{h}(t)$ is a random white-noise field. The probability density of $\boldsymbol{m}$ orientations obeys a Fokker–Planck equation, as is the case for Brownian motion.

The effective time to surmount the barrier is given by $\tau_N = 2\tau_{N0}\sum_{n=1}^{\infty} A_n/\lambda_n$, where $\lambda_n$ is the $n$th eigenvalue, and $A_n$ its amplitude. The lowest ($\neq 0$) eigenvalue, $\lambda_1$, is associated with the overbarrier mode, and higher ones with intrawell modes. Only the former is frequently considered and then $\tau_N = 2\tau_{N0}/\lambda_1$. If the field is parallel to the easy axis, the energy barrier is $E_B(1\pm h)^2$ with $h = H/H_K$, and $\tau_N$ is given by

$$\begin{aligned} \alpha = \frac{E_B}{kT} \ll 1, \quad \tau_N &= \tau_{N0}\left(1 - \tfrac{2}{5}\alpha + \tfrac{48}{875}\alpha^2 + \tfrac{2}{5}\alpha^2 h^2\right)^{-1} \\ \alpha \gg 1, \quad \tau_\pm &= \tau_{N0}\pi^{1/2}\alpha^{-3/2}\left[(1-h^2)(1\pm h)\right]^{-1} \\ &\quad \times \exp[\alpha(1\pm h)^2], \\ \tau_N^{-1} &= \tau_+^{-1} + \tau_-^{-1} \end{aligned} \quad (5)$$

$\tau_+^{-1}$ and $\tau_-^{-1}$ are the probabilities per unit time of $\boldsymbol{m}$ reversal from the lower to upper minimum and vice versa, respectively. For $H = 0$, $\tau_N$ is well approximated for all barrier heights by

$$\tau_N = \tau_{N0}\{2\alpha[\pi^{-1/2}\alpha^{3/2}(\alpha+1)^{-1} + 2^{-\alpha-1}]\}^{-1}(e^\alpha - 1) \quad (6)$$

For $\alpha \gg 1$, $\tau_N$ is often written as $\tau_N = \tau_0 e^\alpha$, where the factor $\tau_0$ is of the order of $10^{-9}$–$10^{-11}$ s.

## 3. Brownian Rotational Diffusion

If $\boldsymbol{m}$ is blocked in the lattice, along the easy axis ($\theta = 0$), the free energy is

$$E = -\mu_0 mH\cos\psi \quad (7)$$

There is no precessional motion. The equation of motion for Brownian rotation is given by

$$2\tau_{B0}\frac{d\boldsymbol{m}}{dt} = \frac{\mu_0}{kT}[(\boldsymbol{m}\times\boldsymbol{H}_e)\times\boldsymbol{m}], \qquad \tau_{B0} = \frac{3V_h\eta}{kT} \quad (8)$$

where $V_h$ is the hydrodynamic volume of the particle, and $\eta$ ($N\,s\,m^{-2}$) the kinematic viscosity of the carrier. The longitudinal, $\tau_{B\parallel}(\tau_B)$, and transverse, $\tau_{B\perp}$, relaxation times are given by

$$\begin{aligned} \tau_{B\parallel} &= \frac{\tau_{B0}\left[\xi - 2L(\xi) - \xi L^2(\xi)\right]}{L(\xi)} \\ \tau_{B\perp} &= \frac{\tau_{B0}2L(\xi)}{\xi - L(\xi)} \end{aligned} \quad (9)$$

with

$$\xi = \frac{\mu_0 mH}{kT}$$

where $L(\xi) = \coth\xi - 1/\xi$ is the Langevin function. For $\xi \ll 1$, $L(\xi) = \xi/3$, so $\tau_{B\parallel} = \tau_{B\perp} = \tau_{B0}$. For $\xi \gg 1$, $L(\xi) = 1 - 1/\xi$ and $\tau_{B\parallel} = \tau_{B\perp}/2 = \tau_{B0}/\xi$. Equations (7)–(9) also apply to the solid-state process (with $\tau_{N0}$ replacing $\tau_{B0}$) if the influence of the anisotropy is negligible ($H \gg H_K$).

## 4. Behavior in Zero Field

A moment rotating by both processes has the effective relaxation time $\tau_{eff}$ given by

$$\frac{1}{\tau_{eff}} = \frac{1}{\tau_N} + \frac{1}{\tau_B} \quad (10)$$

so the process with the shorter time is dominant. In general, $\tau_{N0} < \tau_{B0}$, implying a critical volume $V_c$ satisfying $\tau_N = \tau_B$ (e.g., for $\tau_{N0}/\tau_{B0} = 10^{-2}$ and $H = 0$, $V_c \approx 8\,kT\,K^{-1}$). Smaller particles will relax mostly by Néel and larger ones by Brownian process. In a zero field, $\tau_N$ is in the range of approximately $10^{-10}$–$10^{20}$ s, and $\tau_B$ of $10^{-8}$–$10^{-4}$ s, so $\tau_{eff}$ is in the range

$10^{-10}$–$10^{-4}$ s. A moment will appear blocked or time-averaged to zero depending on whether $\tau_{\text{eff}}$ is longer or shorter, respectively, than the measuring time, $t_{\text{m}}$. Every moment is time-averaged on the scale for d.c. magnetization measurements, where $t_{\text{m}}$ is typically 1–100 s, and so a ferrofluid has no spontaneous magnetization. Moreover, after the removal of the field the system is demagnetized within a time $t \ll t_{\text{m}}$, so ferrofluids are intrinsically perfectly reversible in terms of their d.c. magnetic properties. If particle rotation is frozen out, the relaxation time can reach a geological scale. Under given experimental $(t_{\text{m}}, T)$ conditions, a particle can appear unmagnetized $(\tau_{\text{N}} < t_{\text{m}})$ or magnetized $(\tau_{\text{N}} > t_{\text{m}})$ depending on its size and anisotropy $(KV)$.

## 5. *D.c. Magnetization and Initial Susceptibility*

When the measuring time is longer than the relaxation time, the system is at thermodynamic equilibrium and Boltzmann statistics can be applied. If $\tau_{\text{B}} < \tau_{\text{N}}$ ($\tau_{\text{B}} < \tau_{\text{N}} < t_{\text{m}}$ or $\tau_{\text{B}} < t_{\text{m}} < \tau_{\text{N}}$), the Néel relaxation is of no consequence and Eqn. (7) leads to the magnetization given by

$$M = \frac{M_s \int_0^{\infty} \cos\psi \, \mathrm{e}^{-E/kT} \sin\psi \, \mathrm{d}\psi}{\int_0^{\infty} \mathrm{e}^{-E/kT} \sin\psi \, \mathrm{d}\psi} = M_{\text{s}} L(\xi) \qquad (11)$$

If $\tau_{\text{N}} < \tau_{\text{B}}$ ($< t_{\text{m}}$), which can occur only in small fields, the system is at equilibrium on the Brownian time scale (Eqn. (3), $M(\psi)$); the easy axis orientation ($\psi$) is changed after a Brownian event and so the magnetization at global equilibrium will be $M = \frac{1}{2}\int_0^{\pi} M(\psi)\sin\psi \mathrm{d}\psi$, which reduces for $\xi \ll 1$ to $M = M_s\xi/3$. For $\xi \gg 1$, there is no Néel relaxation $(H > H_{\text{K}})$ and $M = M_s(1 - 1/\xi)$ as a first approximation. Langevin's law of paramagnetism describes the result in each case. By analogy with spins, the equilibrium behavior is called superparamagnetic. The initial (low-field) susceptibility follows a Curie law

$$\frac{\mu_0 M_s V H}{kT} \ll 1, \quad \chi_0 = \frac{M}{H} = \frac{\mu_0 M_s^2 V}{3kT} \qquad (12)$$

If there are $n$ similar particles per unit volume in the sample, the sample magnetization is $M^* = nM$. In practice, it is necessary to take the size distribution into account. Experimental devices measure the magnetic moment, so $M^* = C_v \langle M \rangle$, where $C_v$ is the volume fraction of particles, and $\langle M \rangle$ the average particle magnetization given by

$$\langle M \rangle = \frac{1}{Z} \int_0^{\infty} M(V) V f(V) \mathrm{d}V$$
$$Z = \int_0^{\infty} V f(V) \mathrm{d}V \qquad (13)$$

where $f(V)$ is the volume distribution function. If all particles satisfy the conditions for the low- and high-field approximations of the Langevin function, the magnetization is given by

$$\text{low field} \quad \langle M \rangle = \frac{\mu_0 H M_s^2}{3kTZ} \int_0^{\infty} V^2 f(V) \mathrm{d}V \qquad (14)$$

$$\text{high field} \quad \langle M \rangle = M_s \left[1 - \frac{kT}{\mu_0 H M_{\text{s}} Z}\right] \qquad (15)$$

where $M_{\text{s}}$ is the average intrinsic magnetization. The data exhibit no remanence and coercivity and show $H/T$ superposition (Fig. 1). In principle, one can make use of the magnetization curve to determine the parameters of the size distribution.

Below the melting temperature of the carrier, the moments will gradually block with decreasing temperature, according to the distribution of energy barriers. A blocking temperature $T_B$ is defined for a particle of volume $V$ as the temperature at which $\tau_{\text{N}} = t_{\text{m}}$. In very small fields, $T_{\text{B}} = KV/k\ln(t_{\text{m}}/\tau_0)$ for $\alpha \gg 1$. If the easy axes are randomly oriented, for

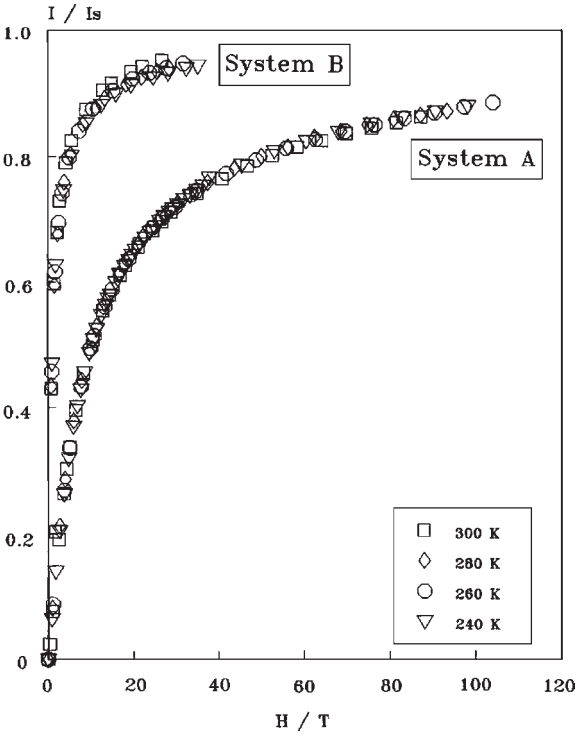

***Figure 1***

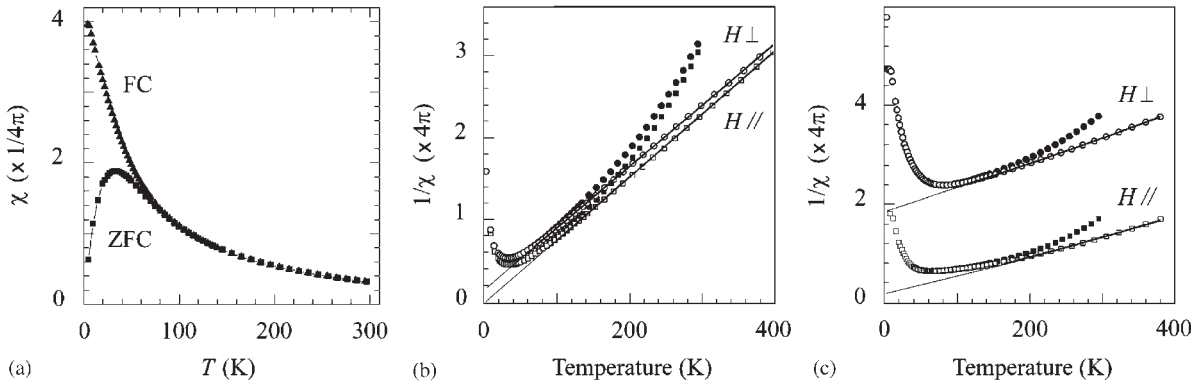

***Figure 2***
Thermal variation of the initial susceptibility ($\chi$) for polymerized $\gamma$-$Fe_2O_3$ ferrofluids. Applied field $H = 800\ \mathrm{A\ m^{-1}}$. (a) Field-cooled (FC) and zero-field-cooled (ZFC) susceptibilities for a dilute sample. (b) Inverse ZFC susceptibility for parallel or perpendicular geometry; and (c) Concentrated sample. Experimental data (filled symbols); corrected (open symbols) for the thermal variation of the intrinsic magnetization. Volume fraction of particles (a, b) 0.0075, (c) 0.195. Average diameter 7.7 nm. (Unpublished data courtesy of M. Nogués).

$T > T_B$ (unblocked state) the particle susceptibility is equal to $\chi_0$. For $T < T_B$ (blocked state), it is given by $\chi_1 = \mu_0 M_s^2/3K$. Thus, for a broad volume distribution, the susceptibility will be

$$\chi(T, t_m) = \frac{\mu_0 M_s^2}{3kTZ}\int_0^{V_c} V^2 f(V)\,dV + \frac{\mu_0 M_s^2}{3KZ}\int_{V_c}^{\infty} V f(V)\,dV \qquad (16)$$

with $V_c$ such that $T_B(V_c) = T$. The fraction of unblocked particles decreases with temperature so that the $\chi$ versus $T$ curve has a maximum. The temperature $T_{max}$ at maximum is proportional to the average blocking temperature according to the type of volume distribution function.

The thermal variation of the initial susceptibility is commonly studied by measurements at very low field of the in-phase a.c. susceptibility $\chi'_{ac}(\nu) = dM/dH$ with $\nu$ the frequency, and d.c. susceptibility $\chi = M/H$ (Fig. 2(a)). The d.c. susceptibility measured after cooling the sample in zero field (ZFC susceptibility) shows a maximum, like $\chi'_{ac}$. The d.c. susceptibility measured after cooling the sample under field (FC susceptibility) grows continuously with decreasing temperature, splitting from the ZFC curve at $T_{sp} > T_{max}$, and finally saturating below some temperature $T_{sat}$. $T_{sp}$ and $T_{sat}$ correspond to the largest and smallest $T_B$ value, respectively. For $T > T_{sp}$, the system is at equilibrium. For $T < T_{sp}$, it is in a non-equilibrium state.

In the blocked state, any change of the magnetic field is followed by a time variation of the magnetization, e.g., both the ZFC and remanent ($M_r$) magnetizations are time dependent. For a single particle with relaxation time $\tau_N$ ($\alpha \gg 1$), an exponential time decay

$$M_r(t) = M_r(0)\exp\frac{-t}{\tau_N} \qquad (17)$$

was predicted by Néel. For a volume distribution, $M_r(t) = (1/Z)\int_0^{\infty} M_r(t, V) V f(V) dV$. A decay of the form $M_r(t) = A - S\ln(t)$ is usually found, but deviations can be observed depending on the experimental conditions (e.g., recording time of the relaxation) and sample characteristics. The blocked state gives rise to bulk-like hysteresis cycles, affected by particle size and anisotropy, responsible for the difference in saturation, remanence and coercive force $H_c$. For uniaxial anisotropy, when all the moments are blocked, $M_r = M_s/2$ and $H_c = H_K/2$ if the easy axes are randomly oriented, and $M_r = M_s$ and $H_c = H_K$ if they are aligned parallel to the field. An orientation texture can easily be induced by freezing a ferrofluid under field.

## 6. *A.c. Susceptibility*

The a.c. susceptibility, $\chi(\omega) = \chi'(\omega) - i\chi''(\omega)$, with $\omega = 2\pi\nu$ the angular frequency, is determined by the moments able to follow the small a.c. field $H = H_0 e^{i\omega t}$. Frequencies of interest for ferrofluids range from hertz to gigahertz, i.e., up to ferromagnetic resonance. For a uniaxial particle where the moment deviates slightly from the easy axis, the resonant condition is $\omega = \gamma\mu_0 H_K$. Far below resonance, for a random assembly of particles with volume $V$ and relaxation time $\tau$, the particle magnetization is given by

$$M(t) = H_0[\chi_0 - (\chi_0 - \chi_\infty)e^{-t/\tau}] \qquad (18)$$

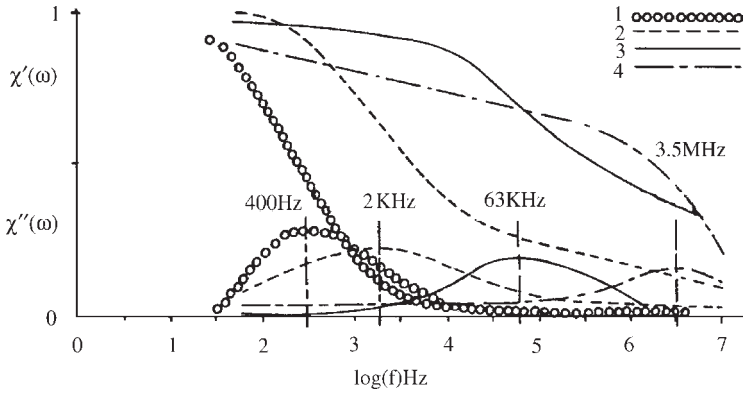

***Figure 3***
Normalized plots of the real and imaginary parts of the a.c. susceptibility against frequency for cobalt ferrite (1,3) and magnetite (2,4) ferrofluids. Median particle radius of (1–3) 5 nm, (4) 4.5 nm. (Reprinted with permission from Fannin 1994; © Elsevier Science B.V.)

where $\chi_\infty$ is the high-frequency susceptibility. The Fourier transform gives the susceptibility according to Debye's theory

$$\chi(\omega) = \frac{\chi_0 + \mathrm{i}\omega\tau\chi_\infty}{1 + \mathrm{i}\omega\tau}$$

$$\chi'(\omega) = \chi_\infty + \frac{\chi_0 - \chi_\infty}{1 + \omega^2\tau^2}$$

$$\chi''(\omega) = \frac{(\chi_0 - \chi_\infty)\omega\tau}{1 + \omega^2\tau^2} \qquad (19)$$

$\chi'(\omega)$ falls monotonically with increasing $\omega$, whereas $\chi''(\omega)$ has a maximum at $\omega\tau = 1$ (Fig. 3). This enables one to determine the effective relaxation time and particle size in a ferrofluid in a relatively simple way.

A single loss peak will be found if the relaxation time is distributed continuously, in the range 1–100 MHz when the Néel mechanism dominates, and much lower when the Brownian process prevails. For a random assembly of particles, $\chi(\omega)$ can be described in terms of its parallel, $\chi_\parallel(\omega)$, and perpendicular, $\chi_\perp(\omega)$, components according to

$$\chi(\omega) = \frac{\chi_\parallel(\omega) + 2\chi_\perp(\omega)}{3} \qquad (20)$$

$\chi_\parallel(\omega)$ and $\chi_\perp(\omega)$ refer (Eqn. (19)) to longitudinal and transverse relaxation times, respectively. With increasing frequency, $\chi_\parallel(\omega)$ remains purely relaxational in character. $\chi_\perp(\omega)$ is associated with resonance, which corresponds to $\chi'_\perp(\omega)$ going negative. From the frequency dependence of $\chi(\omega)$ in the range 100 MHz−10 GHz, parameters such as $H_K$, $K$, and $M_\mathrm{r}(t)$ can be determined.

## 7. *Interparticle Interaction Effects*

The magnetic dipolar interparticle interaction always exists in a particle assembly. In a ferrofluid, its consequences can range from liquid-like short-range order to highly anisotropic chain configurations as observed in large applied fields. The energy of particle $i$ due to interaction with all other particles is given by

$$E_i = -\mu_0 \boldsymbol{m} \bullet \sum_{i \neq j} \boldsymbol{H}_{ij}, \quad \boldsymbol{H}_{ij} = \frac{3(\boldsymbol{m}_j \bullet \boldsymbol{r}_{ij})\boldsymbol{r}_{ij} - \boldsymbol{m}_j}{4\pi d_{ij}^3} \qquad (21)$$

where $\boldsymbol{H}_{ij}$ is the magnetic field seen by particle $i$ due to the interaction with particle $j$, and $\boldsymbol{r}_{ij}$ and $d_{ij}$ are the unit vector and distance defining the vector connecting the centers of the two particles with moments $\boldsymbol{m}_i$ and $\boldsymbol{m}_j$. The interaction energy adds to the individual anisotropy energy. The particle energies are interdependent and the whole system tends to minimize its magnetostatic energy. A ferrofluid system, unconstrained topologically, will partition itself into an ensemble of subsystems with low magnetostatic energy.

Relaxation in the particles can be assumed blocked and the leading parameter is $\lambda = \mu_0 m^2 / 4\pi D_\mathrm{h}^3 kT$ with $D_h$ the hydrodynamic particle diameter, neglecting size distribution. The stability of the suspension of particles limits the value of $\lambda$. No spatial correlation occurs if $\lambda \lesssim 1$. Clustering develops with growing $\lambda$ and when $\lambda$ is large enough, all particles are aggregated at equilibrium, as shown by Monte Carlo simulations. Short linear chains (dimers, trimers) predominate at small $\lambda$ values. Bending and branching appear when $\lambda$ increases. At medium values, closed magnetic configurations prevail. For large $\lambda$ values, the cluster structure is more and more isotropic and dense, with the orientation of the moments tending to be randomized. In large applied

fields, the spatial order becomes anisotropic. The orientation effect of the field strengthens the interactions favoring chain-like configurations, which give rise to the anisotropic magneto-optical properties of ferrofluids.

The interactions influence the magnetic properties especially in low applied fields. They cause deviations from the Langevin behavior (Figs. 2(b) and (c)). The equilibrium magnetization is given by the Langevin law, referring to the effective field, $H_{\text{eff}}$, seen by the particle, which is not equal to the applied field, $H_{\text{app}}$, in the presence of interaction. Since the sample is magnetized, boundary phenomena give rise to demagnetizing field effects. The demagnetizing field is constant inside the sample if this is an ellipsoid with an axis parallel to the applied field. The field exterior to the particles is then given by

$$H_{\text{ext}} = H_{\text{app}} - N_{\text{e}} C_v M \tag{22}$$

with $N_{\text{e}}$ ($0 \leqslant N_{\text{e}} \leqslant 1$) the demagnetizing factor of the sample. The measured susceptibility $\chi_{\text{app}} = M/H_{\text{app}}$ depends on the geometrical experimental parameters, unlike $\chi_{\text{ext}} = M/H_{\text{ext}}$.

Different models have been proposed for estimating $H_{\text{eff}}$ as a function of $H_{\text{ext}}$. They all lead to first order, with a varying range of applicability, to the same formula for the initial susceptibility

$$\chi_{\text{ext}} = \chi_0(1 + N_{\text{i}} C_v \chi_0) \tag{23}$$

where $N_{\text{i}} = 1/3$. This agrees with experimental results, after correcting for size distribution and thermal variations of $M_{\text{s}}$ and $C_v$, and with numerical simulations for $\chi_0^* = C_v\chi_0 \lesssim 3$. In the limit $\chi_0^* \ll 3$, the susceptibility takes a Curie–Weiss form; it is in no way indicative of a magnetic phase transition. For $\chi_0^* \gtrsim 3$, correlations cannot be neglected and Eqn. (23) does not hold; the influence of the microstructure ($\chi_0^* \approx 8\lambda C_v$) no longer reduces to a concentration effect and Monte Carlo simulations are in practice the only reliable way of modeling. Since the texture varies with field and temperature ($\lambda$), the magnetic behavior of ferrofluids can be extremely complex. In real systems, clustering of physicochemical origin may bring extra complexity.

The interactions affect the Brownian dynamics (Fig. 3), especially because a cluster is a rotating Brownian object, with relaxation time proportional to the volume. They modify the dynamics in the particles depending on the topology and relative magnitudes of the anisotropy and interaction energies. In random solid systems, for weak enough interactions, the dynamics can still be described in the framework of the Néel relaxation. The interactions increase the energy barrier. In the Dormann *et al*. (1997) model, valid when all (most) moments are above or near their blocking temperature, the increase for particle $i$ is approximately given by

$$E_{\text{Bint}}(i) = \sum_j q_{ij} L\frac{q_{ij}}{kT}, \quad q_{ij} = \frac{\mu_0}{4\pi} m_i m_j \frac{3\cos^2\xi_{ij} - 1}{d_{ij}^3} \tag{24}$$

where $\xi_{ij}$ is an angle parameter of $\boldsymbol{r}_{ij}$. For strong enough interactions, the behavior will become cooperative in type. In any case, typical features (e.g., aging effect on the magnetization relaxation) of correlated disordered systems, such as spin–glass systems, will be observed if the experimental conditions (temperature, time window) are suitably chosen. In ferrofluids, the dynamics in aggregated particles influences the lifetime of their association.

## 8. Summary

The theoretical models of magnetic dynamics in ferrofluids and main macroscopic experimental features have been outlined. The main difference between Néel and Brownian relaxations lies in their timescales. It is the key to the specific properties of ferrofluids, i.e., a perfectly soft behavior (irrespective of particle size, concentration, and aggregation), an orientational texture under field, and a spatial texture caused by the magnetic interparticle interaction.

## Ferrofluids: Neutron Scattering Studies

The investigation of the internal structure of magnetic fluids is often carried out by indirect techniques like magnetization measurement or *ex situ* investigations, e.g., the electron micrography of specially prepared fluid samples. This causes strict limitations concerning the interpretation of the fluid microstructure itself as well as of the dependence of macroscopic properties of the fluids on microscopic structural changes.

A possibility to overcome these restrictions is the use of neutron scattering to explore microstructural properties of magnetic fluids. In contrast to normal light, scattering neutrons are able to penetrate ferrofluid samples of reasonable thickness and to give appropriate scattering intensities on experimentally practicable time scales. The intensity of neutrons scattered by a ferrofluid contains an additional anisotropic magnetic part besides the usual nuclear scattering. This magnetic part of the scattering intensity $I_m$ depends on the relative orientation between the scattering vector $\vec{q}$, the neutron polarization $\vec{p}$, and the magnetization of the fluid sample $\vec{m}$ respectively:

$$I_m \propto \{(\vec{q} \times \vec{p}) \cdot (\vec{q} \times \vec{m})\}^2 \tag{1}$$

If unpolarized neutrons are used—and thus the first bracket becomes a constant factor—the scattering intensity of magnetic scattering is anisotropic depending on the relative orientation between scattering vector and sample magnetization:

$$(\vec{q} \times \vec{m})^2 = \left\{ \begin{array}{l} 0 \text{ if } \vec{q} \parallel \vec{m} \\ \\ 1 \text{ if } \vec{q} \perp \vec{m} \end{array} \right\} \tag{2}$$

For an unmagnetized sample the $(\vec{q} \times \vec{m})^2$-term equals 2/3 and the scattering becomes isotropic as it can be seen from Fig. 1. In particular, magnetic neutron scattering allows direct access to the magnetic microstructure and thus to the solutions of questions like magnetic size distribution or cluster and chain formation of magnetic particles. Details concerning the possibility to distinguish between nuclear and magnetic scattering will be discussed in the forthcoming sections.

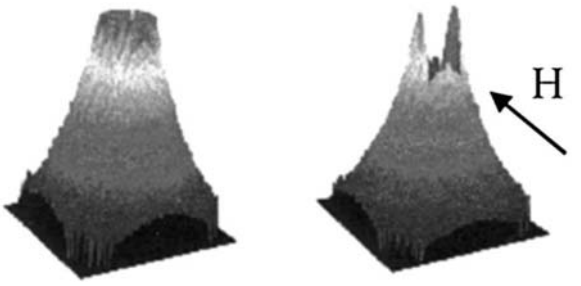

***Figure 1***
Typical small angle scattering signal from an unmagnetized ferrofluid (left) and from a fluid under influence of a field H in the depicted direction (right) (after Odenbach 2000).

### *1. Selection of Experimental Method*

The choice of the particular neutron scattering method to be used is determined by the size of the scattering units and the main goal of the investigation itself. The typical particle size range for the particles suspended in a magnetic fluid—which is usually between 5 nm and 30 nm—requires a range of q-vectors to be examined between:

$$\begin{aligned} q_{\min} &= \frac{2\pi}{d_{\max}} \approx 0.2 \text{Å}^{-1} \text{ and} \\ q_{\max} &= \frac{2\pi}{d_{\min}} \approx 1 \text{Å}^{-1} \end{aligned} \tag{3}$$

For thermal neutrons with a wavelength $\lambda$ of about 6Å to 10Å, which are usually used for the experiments, this corresponds to scattering angles $\theta$ defined by

$$\sin(\theta) = \frac{\lambda q}{4\pi} \tag{4}$$

in the range between 5° and 25°. That means that the method usually chosen for ferrofluid investigations is small angle neutron scattering (SANS). For details on SANS experiments the reader should refer to the basic textbooks by Guinier (1963) and Egelstaff (1965). Figure 2 shows the principal set up for a SANS experiment with magnetic fluids. The sample is subjected to a collimated neutron beam transmitted through the fluid. The scattered neutrons are usually detected

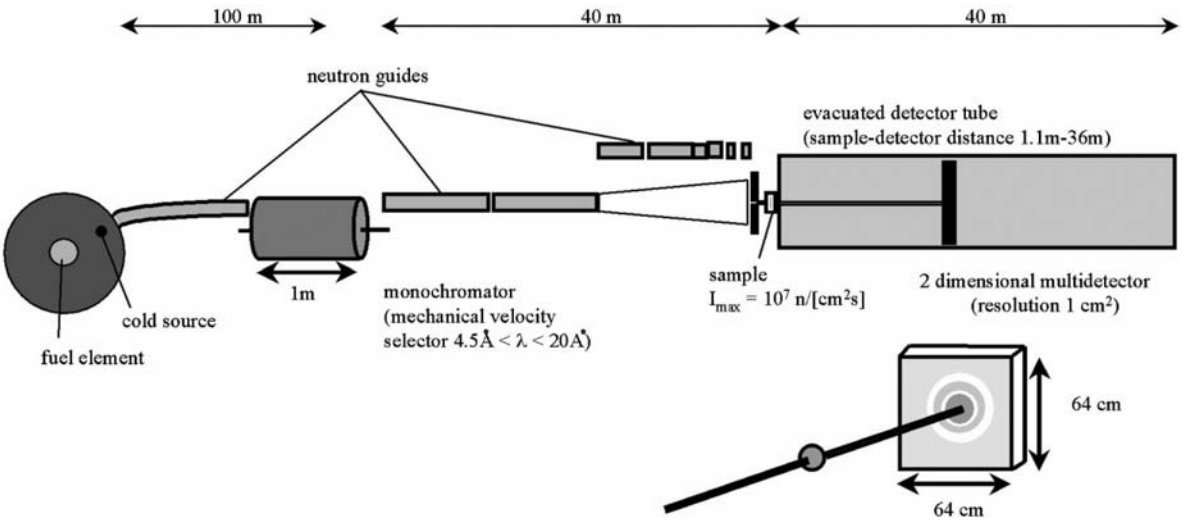

***Figure 2***

using a two-dimensional array detector. The detector—sample distance can be altered to vary the maximum momentum transfer detectable. To avoid reduction of scattering intensity, the neutron path to the sample and from the sample to the detector is guided through vacuum tubes.

SANS experiments can be carried out using polarized as well as unpolarized neutrons, providing different kind of information, as can be seen from Eqn. (1). Some basic experimental questions will be discussed, followed by the experiments with unpolarized neutrons that represent the major amount of experimental work performed. Finally, experiments with polarized neutrons and other experimental techniques will be outlined.

## 2. *Nuclear Scattering and Contrast Variation*

As was already mentioned, neutron scattering on magnetizable materials provides an anisotropic part of scattering intensity as a result of the interaction between the neutrons magnetic moment and the magnetization of the sample.

Besides this, the most important part of scattering intensity will usually be made by conventional nuclear scattering. The total cross-section for nuclear scattering is composed from the coherent $\sigma_{coh}$, incoherent $\sigma_{inc}$, and absorption $\sigma_{abs}$ scattering cross-sections of the particles material, the surfactant, and the solvent. The scattering cross-sections for the most important elements contained in a ferrofluid are given in Table 1.

***Table 1***
Scattering cross-sections for relevant elements in barns.

| Element | $\sigma_{coh}$ | $\sigma_{inc}$ | $\sigma_{abs}$ |
|---|---|---|---|
| Fe | 1.86 | 0.46 | 1.4 |
| H | 1.76 | 79.7 | 0.19 |
| D | 5.59 | 2.01 | $5 \times 10^{-4}$ |
| O | 4.23 | 0.01 | $1 \times 10^{-4}$ |
| C | 4.52 | 0.98 | $3 \times 10^{-3}$ |

Essential for scattering experiments is the relation between the coherent scattering providing the signal and incoherent scattering and absorption leading to unwanted noise and signal reduction. For the metallic particles the coherent scattering cross-section is dominant compared to the incoherent part and only weak absorption occurs leading to only small reduction of the scattered intensity. For surfactant and carrier liquid, one has to distinguish between deuterated and nondeuterated material. If nondeuterated substances are used, the scattering behavior will be dominated by the incoherent scattering due to the hydrogen atoms. In this case the scattering from the surfactant and the carrier liquid will dominate the incoherent scattering of the whole sample investigated. The scattering from the particles will be just a small additional part over a strong incoherent noise and thus detection may be difficult. Furthermore, the maximum thickness of the sample in the direction of the beam will be reduced

due to the incoherent scattering by hydrogen. Experiments (Odenbach *et al.* 2000) have shown that the scattering intensity rises by a factor of approximately three if deuterated carrier liquids are used and the necessary counting time for a given sample thickness and for reasonable statistics can be furthermore reduced due to the improvement of the signal/noise ratio in the case of absence of hydrogen.

Beside this, the partial replacement of hydrogen by deuterium allows special experimental approaches providing additional information about the ferrofluid sample. If one defines the excess scattering from the particles over the scattering from the carrier liquid as the scattering contrast (Cebula *et al.* 1983b), one can change the scattering intensity by variation of the scattering from carrier liquid and surfactant. The optimization of the contrast between particles and carrier solvent provides optimum statistics of the signal and ensures that the scattered signal is dominated by the internal particle structure of the ferrofluid. By comparison of scattering intensities from a fluid with deuterated surfactant with that from one having conventional surfactant, information about the thickness of the surfactant layer can be obtained. The best way to do that is the use of a Guinier plot, i.e., a plot of the logarithm of scattered intensity over the square of $q$. This plot provides a linear relation for small q-vectors with a slope proportional to the mean size of the scattering units. Thus in the first case a Guinier plot provides the core size of the particles, in the second case it reflects the size including the surfactant.

## 3. *SANS Experiments for Determination of Size Distribution*

Size distribution determination for the particles in a magnetic fluid can be done by electron microscopy or magnetic measurement. In the first case a sample must be prepared by a process that may modify the size distribution, while the second method provides values that strictly depend on the underlying magnetic theory, in particular the question of interaction between the particles can cause serious problems.

From Eqns. (3) and (4) it is seen that the scattering angle depends on the size of the scattering structures, i.e., in the case of a ferrofluid on the size of the particles

$$\sin(\theta) = \frac{\lambda}{2d} \tag{5}$$

A monodisperse colloid would provide a SANS signal which would directly allow the determination of the particle size from a Guinier plot. For a polydisperse system the situation becomes more difficult, since multiple signal structures are superimposed. Under these conditions a model is needed to fit the data and to obtain the size distribution. Most often

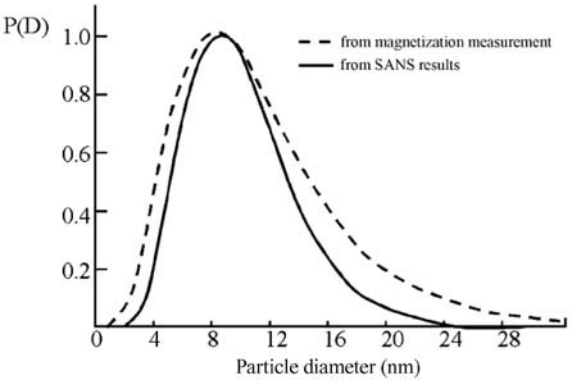

***Figure 3***
The comparison between particle size distributions measured with conventional magnetization measurement and by SANS. The discrepancy is explained by the neglection of field-induced interaction of the particles in magnetization measurement analysis (after Upadhyay *et al.* 1993).

the usual log normal distribution is used as base model for the fits, but newly developed fitting software at several neutron sources allows more model-independent determination of the distribution. The experimental results obtained in SANS studies show various deviations from the distributions determined with conventional methods like magnetization measurement that shed a light on some basic problems in the understanding of magnetic fluids. In some experiments (e.g., Potton *et al.* 1983) an expansion of the size distribution to larger radii was obtained from the SANS data compared to magnetization measurement, while Upadhyay *et al.* (1993) observed a narrower distribution in neutron experiments (Fig. 3).

The explanations for these discrepancies are usually taken from the lack of knowledge about basic data of the fluids themselves. While the narrower distribution is explained by field-induced magnetic interaction between the particles in magnetization measurement, not accounted for in the data evaluation of these measurements, the expansion to larger radii could be explained by the difference between the bulk saturation magnetization and that of small particles (Söffge *et al.* 1981). Furthermore, the assumption of spherical particles which is usually used when fitting the neutron data together with the considerably large errors of neutron scattering data in general could also lead to discrepancies. Thus it is seen that the underlying model for the data evaluation and the assumptions within as well as the accuracy of the data obtained are of significant influence on the results obtained. While the models used can only be improved on the basis of new experimental results, the quality of the scattering data must be optimized

(e.g., by appropriate choice of deuterated carrier liquids) to avoid additional uncertainties.

## 4. SANS Experiments for Observation of Cluster Formation

While SANS methods are only an alternative in determining particle size distribution, they provide a unique tool if the formation and development of clusters and cluster like structures of magnetic particles are considered. Aggregation of particles forms structures—determining the scattering process—which have sizes in the order of several hundred nm. Thus the intensity scattered by these structures will be found at even smaller scattering angles of the order of $1^\circ$ and less. Even the best small angle scattering experiments available nowadays reach with such requirements the edge of their technological possibilities. Nevertheless the influence of the scattering from large structures changes the line shape of the small angle scattering signal even at higher angles easily available in experiments. Such changes can then be taken to obtain information on formation of multiparticle aggregates in magnetic fluids.

In this way, Cebula *et al.* (1983a) investigated the appearance of cluster formation in ferrofluids containing cobalt particles. They found a strong dependence of the scattering signal on the volume fraction of particles at zero field indicating the appearance of cluster formation due to magnetic dipole—dipole interaction. Furthermore, they found interference peaks when a magnetic field was applied, indicating the appearance of ordered structures like chains aligned with the magnetic field direction. Finally reduction of temperature, resulting in a reduction of thermal motion, lead to an anisotropy at $H = 0$, also indicating formation of aggregates and chains. Thus these experiments showed clearly that SANS is a powerful tool for the *in situ* observation of aggregation phenomena in ferrofluids without disturbing effects due to drying in sample preparation for electron micrography.

Extended work on aggregation formation in magnetite-based ferrofluids was carried out by Rosman *et al.* (1990). They combined the SANS measurement in variable magnetic fields with the already discussed contrast variation method providing them with the particle size distribution and the structure of the surfactant layer of the fluids under investigation. Here again the mentioned differences between conventional and neutron scattering methods appeared. Even at low volume fraction and in comparably weak magnetic fields of about 100 mT they found a formation of thin chains of particles in the direction of the applied field. Higher volume concentration enabled formation of three-dimensional rods in field direction. The interparticle distance obtained from the scattering data gave rise to the assumption that the surfactant layers are in contact in the aggregates.

Even larger structures can be observed in ferrofluid mixtures (Hayter *et al.* 1989) when macromolecules are dispersed in a ferrofluid. These nonmagnetic molecules act as magnetic voids in the liquid and arrange to macroscopic structures in presence of magnetic fields. The neutron diffraction patterns obtained show an anisotropy that corresponds to these macrostructures. In this case the neutron diffraction experiments were used to prove the possibility of alignment of nonmagnetic macromolecules by means of magnetic fluids.

## 5. SANS Experiments with Polarized Neutrons

During the discussion of neutron scattering data obtained from ferrofluids with unpolarized neutrons, it became clear that anisotropies in the scattering pattern can be due to magnetic effects (see Eqn. (1)) as well as due to formation of structures. The use of polarized neutrons can be a powerful help to distinguish between these two kind of anisotropies and thus to eliminate the nuclear scattering background completely. To do so the fluid sample is subjected to a beam of polarized neutrons and a polarization analysis—distinguishing between neutrons scattered with spin flip and those scattered without—is carried out after the scattering process. Coherent nuclear scattering, giving information about the structural phenomena like aggregation by measuring the particle number density, does not flip the neutrons spin. In contrast, the magnetic scattering—which is caused by the component of magnetization perpendicular to $\vec{q}$—causes spin flip for those components of magnetization which are perpendicular to the field, while the parallel one gives nonflip scattering. Therefore measurement of scattered intensity with $\vec{q}$ parallel and perpendicular to the applied field makes it possible to distinguish between nuclear and magnetic scattering signals. This technique has been used by Pynn *et al.* (1983) to analyze the interparticle structure in a cobalt ferrofluid.

The previously discussed problem of the influence of polydispersity on the SANS signal can also be reduced by the use of polarized neutrons (Nunes 1988). Furthermore, a detailed analysis of nuclear and magnetic scattering intensities and of the respective size distributions obtained can shed a light on the existence of magnetically dead layers.

## 6. Other Experimental Approaches

Up to now we have outlined the use of neutron scattering for determination of structure and agglomeration processes in magnetic fluids using SANS techniques. Beside this, there are a couple of experiments taking neutron scattering for other experimental

goals or using alternative scattering techniques. For example SANS experiments have been used to investigate diffusion phenomena in magnetic fluids (Odenbach *et al*. 1995) by determination of the spatial variation of magnetic scattering anisotropy. Since the anisotropy is proportional to magnetization of the fluid and since this is a measure for the concentration of particles at given magnetic field strength, one can determine the spatial variation and time dependence of concentration in a ferrofluid subjected to a magnetic field gradient. Other SANS experiments have shown that it is possible to use the anisotropy as a measure for local variations of flow velocity in a ferrofluid (Odenbach *et al*. 1999). The shear in the fluid changes the mean alignment of the particles with the magnetic field direction and thus reduces the apparent magnetization in a certain sample volume leading to a change of anisotropy.

In the characterization of a temperature-sensitive magnetic fluid the disappearance of magnetic scattering for temperatures above the Curie point has been used to distinguish between magnetic and nuclear scattering, avoiding the loss of intensity connected with the spin flip method discussed above (Upadhyay *et al*. 1997).

Finally, powder diffraction with polarized neutrons was used as an alternative method to determine the size distribution of the particles and to get information about magnetically-disordered layers (Lin *et al*. 1995).

### 7. Outlook

It has been discussed that neutron scattering can be a helpful tool to investigate the microstructure of magnetic fluids, the structure of particles and surfactants and the formation of clusters, aggregates, and chains. From this it is astonishing that the amount of work done in this field is not as high as one would expect considering the potential of the method. A possible reason for this could be based on the fact that shortly after the first efforts in this field the two major neutron sources in Europe, providing sufficient intensity for ferrofluid experiments—the high flux research reactors at ILL in Grenoble and at KFA in Jülich, were out of order for approximately five years for maintenance reasons. Now, after restart of both sources, the activities on neutron scattering experiments with ferrofluids have been reactivated and new results are expected in the future. In particular the investigation of structure formation in the presence of magnetic field and shear flow—which is the microscopic reason for the appearance of non-Newtonian effects in ferrofluids—is expected to become a vivid field of interest.

## Ferrofluids: Preparation and Physical Properties

A ferrofluid, or magnetic fluid as it is also commonly referred to, consists of a stable colloidal suspension of single-domain nano-sized particles of ferri- or ferromagnetic materials in a carrier liquid. A wide range of carrier liquids have been employed, and many ferrofluids are commercially available to satisfy particular

applications, e.g., in rotary vacuum lead-throughs, it is essential that the carrier liquid has a very low vapor pressure. In other applications, temperature—either high, low, or both—may be a critical consideration. Theoretically it should be possible to produce dispersions in any liquid thereby being able to tailor the requirements of viscosity, surface tension, temperature and oxidative stability, vapor pressure, stability in hostile environments, etc., to the particular application in mind, whether it be technological or biomedical (see *Ferrofluids: Applications*).

In order to achieve a stable colloidal suspension, and in this context stability refers to situations where the ferrofluid is subjected to a magnetic field, magnetic field gradient, and/or gravitational field, the magnetic particles generally have to be of approximately 10 nm in diameter. Particles of this size, whether they are ferrite or metal, possess a single magnetic domain only, i.e., the individual particles are in a permanent state of saturation magnetization.

As a result, a strong long-range magnetostatic attraction exists between individual particles which would inevitably lead to agglomeration of the particles and subsequent sedimentation unless a means of achieving a repulsive interaction can be incorporated. A repulsive mechanism (see *Ferrofluids: Introduction*) can be achieved by coating the particles with a surface-active material (surfactant) to produce an entropic repulsion or by incorporating a charge on the surface of the particles thereby producing an electrostatic repulsion. In the case of liquid–metal carriers, no such interaction has yet been achieved to produce a stable suspension.

The various methods by which small magnetic particles can be prepared and subsequently colloidally dispersed is described in this article. The preparation of particles and ferrofluids has been the subject of numerous patents and research publications. A comprehensive bibliography of this information can be found updated in each of Proceedings of the International Conference on Magnetic Fluids (ICMF), under the following authors Zahn and Shenton (1980), Charles and Rosensweig (1983), Kamiyama and Rosensweig (1987), Blums *et al.* (1990), Cabuil *et al.* (1993), Bhatnagar and Rosensweig (1995). Reviews of the subject have been given by Rosensweig (1979, 1985, 1988), Charles and Popplewell (1980), Martinet (1983) and Scholten (1978).

## 1. Preparation of Nano-sized Magnetic Particles

The preparation of nano-sized magnetic particles can be conveniently considered under two headings; one dealing with metal particles and the other with ferrites.

### *1.1 Metal Particles*

There are a number of methods of producing small magnetic metallic particles, the commonest of which for ferrofluid preparation being the decomposition of organometallic compounds. In addition, reduction of solutions of metal salts and other miscellaneous methods are available. The decomposition of organometallic compounds will be discussed in most detail as it is the easiest and most versatile method of producing metal particles suitable for ferrofluids. In most of these methods, the presence of a surfactant is crucial. By selecting an appropriate surfactant, it has been shown (Charles and Wells 1990) to be an effective method of controlling particle size.

There are two major advantages of using ferrofluids based on metallic particles, such as cobalt and iron particles. First, these metals have high saturation magnetizations compared with ferrites and second, they can be produced easily with very narrow size distributions. However, there is also a major drawback which has restricted their use in most commercial applications and that is their poor resistance to oxidation and subsequent loss of magnetic properties. Only by maintaining these fluids in an inert atmosphere can these fluids possess an extended lifetime.

#### *(a) Decomposition of organometallic compounds*

In the 1960s, several groups of workers (Thomas 1966, Hess and Parker 1966) reported the production of colloidal-sized cobalt particles by the thermolysis of dicobalt octa-carbonyl in hydrocarbon solutions containing polymeric materials. The process is very simple in that it only involves refluxing a solution of the carbonyl, usually in toluene, until the reaction is complete, with the formation of cobalt metal particles. Thomas (1966) showed that the particles possess a very narrow size distribution ideal for the production of stable colloids. The particles also possess an f.c.c. structure instead of the b.c.c. structure of bulk cobalt. The absence of a polymer in the thermolysis leads to the formation of large particles ($>100$ nm). A detailed investigation by Hess and Parker (1966) of the presence of different copolymers of acrylonitrile-styrene in the reaction solution showed that the greater the concentration of polar groups along the polymer chain, the smaller the size of the particles formed.

It was Smith (1981) who proposed that the reaction is polymer-catalyzed, which results in the formation of a polymer–carbonyl complex which then decomposes to form elemental cobalt. Papirer *et al.* (1983) showed that the decomposition could also be catalyzed by the presence of surfactants. They investigated the evolution of carbon monoxide during the decomposition in the presence of diethyl-2-hexyl sodium sulphosuccinate (Manoxol-OT) and in its absence, both experiments carried out as a function of temperature. The results were consistent with the presence of "micro-reactors" and a diffusion mechanism to control the growth. The higher the temperature used, the smaller the particles produced. During the

process of thermolysis in toluene, the presence of $Co_4(CO)_{12}$ was identified as an intermediate.

However, the overall reaction mechanism is complex but it seems likely that a carbonyl complex and/or microreactors are formed which subsequently decompose to produce cobalt particles. Charles and Wells (1990) investigated methods to control the size of the cobalt particles formed by the use of a variety of surfactants and combinations of surfactants. By taking aliquots of the reaction mixture as the reaction proceeded and making observations using electron microscopy, they observed the presence of clusters or microreactors for the first half hour of a four-hour reaction but no particles. Subsequently, observations showed the presence of particles only. They were able to consistently produce particles with median diameters in the range 5 to 15 nm. The median diameter refers to a lognormal volume distribution (see Sect. 1.3).

In many of the papers quoted so far, little information has been presented concerning the saturation magnetization of the particles compared to that of the bulk. Charles and Wells (1990) found the saturation magnetization of the particles to be consistently lower (75%) than that of the bulk value of 17900 Gauss (1.79 T). This result is in agreement with the work of Hess and Parker (1966). There are several possible reasons for this, namely oxidation, spin-pinning/canting, or poor crystallization. Experiments where care had been taken to avoid oxidation still showed the reduced saturation magnetization. However, evidence from x-ray diffraction indicated that the particles were poorly crystallized or amorphous with similar results being obtained for iron particles produced by a similar process (Wonterghem *et al.* 1986). X-ray diffraction and Mössbauer studies indicated the presence of carbon in the particles which is thought responsible for the poorly crystallized state.

The particles, when annealed, showed an x-ray pattern consistent with $\alpha$-Fe and $\chi$-$Fe_5C_2$. Some researchers, using transmission electron diffraction, have reported that the particles produced by thermolysis have a crystalline structure. Whether this is a true indication of the structure of the particles or that annealing has taken place in the electron beam is not known. Measurements of the magnetic anisotropy of cobalt particles have been undertaken by several groups of workers (Chantrell *et al.* 1980, Charles and Wells 1990).

Iron particles of colloidal dimensions can also be produced by thermolysis (Wonterghem *et al.* 1986); in this case of iron pentacarbonyl in decahydronaphthalene. Particle size is again controlled by the presence of surfactants. The actual structure of the particles is open to question. Some groups have reported a crystalline structure (Kilner *et al.* 1984), whilst others (Wonterghem *et al.* 1986) reported an amorphous structure which undergoes crystallization on annealing.

(Hoon *et al.* 1983) have reported the preparation of colloidal nickel particles by the irradiation of nickel carbonyl with ultraviolet light and by the reduction of nickelocene. The particles were reported to have an f.c.c. structure from transmission electron diffraction.

Nakatani and Furubayashi (1990) and Nakatani *et al.* (1993) have prepared iron nitride particles by two methods. First, by a plasma CVD reaction of iron pentacarbonyl and nitrogen gas and second, by heating a solution of iron pentacarbonyl in kerosene containing a surfactant through which a constant stream of ammonia is passed. The crystal structure observed is $\varepsilon$-$Fe_3N$.

It is also possible to prepare alloy particles of the transition metals by the thermolysis of mixed-metal organometallic compounds in the presence of surfactants. Lambrick *et al.* (1985, 1987) prepared organometallic compounds from which particles of Fe–Co and Ni–Fe alloys with median diameters $\sim 8$ nm were obtained. The saturation magnetizations of the particles are 84% of that of the bulk values.

*(b) Reduction of metal salts in aqueous solution*

Much of the work on the formation of particles by the reduction of metal salts in aqueous solution using reducing agents such as sodium hypophosphite or sodium borohydride stemmed from an interest in producing particles suitable for magnetic recording media. The particles produced were typically of micron size, which precluded their use in ferrofluids because of their large magnetic moments and consequent strong magnetostatic interactions.

However, there have been a few reports of the formation of particles of nanometer size which could be used in ferrofluids. The solutions used in the preparation contain the salts of ferromagnetic elements, a reducing agent, complexing agents, and buffers to control the pH during reaction. The formation of particles is induced by the addition of $PdCl_2$ to the solution. By the introduction of water-soluble viscosity-increasing materials, it has been shown (Akashi and Fujyama 1969) that particle size can be reduced so that the particle can remain in stable suspension. There have been a few other reports of the formation of such particles. Harada *et al.* (1972) have reported the formation of Co-P particles, using sodium hypophosphite as reducing agent, in aqueous solutions containing protein or synthetic polypeptides. Similar studies on Fe-P particles have also been undertaken.

The at.% of phosphorus or boron in the particles is very dependent on the conditions used. Above a critical concentration of boron, phosphorus, and indeed carbon, the particles possess an amorphous structure very similar to structures produced by rapid-quench techniques. The incorporation of phosphorus, boron, and carbon is a disadvantage in one respect, in that the saturation magnetization of the particles may be

significantly reduced. Small acicular particles of cobalt have been prepared using this method, performed in the presence of a uniform magnetic field (Charles and Issari 1986).

*(c) Inverse microemulsion techniques*

Numerous papers have been published on the preparation of small nano-sized metal particles, some of which are ferromagnetic, via the use of reverse micelles. The stimulus for much of this work has been an interest in the production of small-particle catalysts. A reverse micelle can be described as a water-in-oil microemulsion in which two immiscible liquids are stabilized by a surfactant. As it is a three-component system, a triangular phase diagram of the three-component system is used to describe the various structures other than microemulsions that may be formed. For detailed information on micelles and particle formation, the reader is recommended to study a review edited by Pileni (1989). The method of preparation of particles involves the preparation of two microemulsions, one containing an aqueous solution of a metal salt or mixture of metal salts and the other an aqueous solution of a reducing agent, e.g., sodium borohydride.

By simply mixing the two in the appropriate ratio, metal particles, in which some boron is usually incorporated, are produced within the micelles. Because of the incorporation of boron, the particles often have an amorphous structure. Using pure surfactants, the micelle size distribution is very narrow, with the result that the particles themselves also possess a narrow particle size. It has been shown by Lopez-Quintela and Rivas (1992) that it is possible to subsequently coat the metal particles formed with another metal using a further microemulsion. This process is of particular interest in that by the use of an appropriate second metal it may be possible to overcome the recurring problem of oxidation of ferromagnetic particles of iron, cobalt, etc.

*(d) Miscellaneous methods*

Fine particles of most of the metallic elements can be produced by evaporation of the metals in an inert gas atmosphere. The size of the particles so produced is very dependent on the gas used and its pressure. As was the case using the reduction of aqueous solutions of metal salts, the same stimulus for this work was the production of micron-sized particles suitable for magnetic recording.

However, ferrofluids have been prepared this way containing particles of iron, cobalt, or nickel by the vacuum evaporation on to a running oil substrate containing a surfactant (Nakatani *et al.* 1987). The particles produced by this method are very small ($\sim$2 nm in diameter). On heating the product to 270 °C in an argon atmosphere for a few minutes, the particle size can be increased. Fluids produced by this method are gravitationally stable.

This method has also been used to produce dispersions of particles of gadolinium and transition metal alloys in mercury. Unfortunately, these fluids are not colloidally stable despite attempts to stabilize the dispersions with metallic additives.

Spark erosion has been used to produce ferrofluids. A wide range of particle sizes is produced, the smaller particles of which are suitable for dispersion to form a ferrofluid. The method suffers from disadvantages in that the process is slow and the particle distribution is very wide. However, it does have an advantage in that novel particles with similar properties to the bulk can be produced, e.g., TbFeB, which possess a large magnetostriction.

### *1.2 Ferrite Particles*

Ferrites may possess a normal or inverse spin structure. Detailed reviews of the structures and magnetic properties of ferrites have been given by Dormann and Nogues (1990). The name spinel is given to those ferrites which have the formula $MFe_2O_4$ (where M is a divalent ion) and which have the cubic crystal structure of the mineral spinel ($MgAl_2O_4$). The oxygen atoms are arranged in layers in such a way that there are two types of interstitial sites, tetrahedral (A) sites and octahedral (B) sites. The net magnetic moment of each ferrite is determined by the moment of each cation, the arrangement of the cations in the A and B sites, and the interaction between cations.

The most commonly used ferrites in commercial ferrofluids are magnetite ($FeO.Fe_2O_3$) and maghemite ($\gamma$-$Fe_2O_3$). Because magnetite can be oxidized to maghemite with only a relatively small reduction in moment, the actual structure of the particles in commercial and other ferrofluids usually involves the presence of both ferrites in an undefined ratio. In magnetite, the moment of the two $Fe^{3+}$ ions are split between an A site and a B site and are antiferromagnetically coupled so that the moments cancel, whereas the $Fe^{2+}$ ion situated on the B site gives rise to the overall moment. This opposite and unequal arrangement of the moments gives rise to ferrimagnetism.

The original method of producing ferrofluids based on ferrites is attributed to Papell (1965). The method involved wet-grinding ferrites in a ball mill in the presence of a suitable surfactant until the ferrite is in a colloidal state. Centrifugation was usually employed to remove larger particles, which could lead to agglomeration and sedimentation. Many other workers subsequently studied and used this method. However, this process usually takes a very long time ($\sim$1000 hours) and it is mainly for this reason that the process has been superceded by a rapid and simple method involving the coprecipitation of metal salts in aqueous solution using a base. This method is the subject of the next section. No further reference will be made to wet grinding.

*(a) Coprecipitation method*

The coprecipitation method for the preparation of particles of magnetite, maghemite, and substituted ferrites suitable for use in ferrofluids is now well established and has been the subject of many patents and publications (see Introduction to this article *Ferrofluids: Preparation and Physical Properties*). Because the process is usually carried out at room temperature, the cation distribution on the A and B sites may not conform to the distribution in bulk-annealed crystals of the same material. Nevertheless, it is well established by x-ray diffraction that the particles formed are crystalline. Further, their magnetic characteristics with regard to magnetic crystalline anisotropy and Curie temperature are not that far removed from that of the bulk crystals.

For most technological applications, the carriers used are nonaqueous. Thus, the colloidal suspension is usually stabilized by coating the particles with a surfactant. In aqueous colloidal suspensions, surfactants can also be used to stabilize the system but suspensions can also be stabilized by the presence of a charge on the particles. The latter method has been studied extensively by Massart (1981) and his coworkers (Bacri *et al.* 1990, Bee *et al.* 1995). As magnetite and maghemite are the most commonly used materials, the discussion of the coprecipitation method is divided into two sections, one involving these materials and the other, substituted ferrites.

*(b) Magnetite and maghemite particles*

In the case of magnetite, particles can be prepared from the coprecipitation of hydroxides from an aqueous solution of $Fe^{2+}$ and $Fe^{3+}$ in the mole ratio of approximately 1:2 using a base (Khalafalla and Reimers 1973). The reaction is complex and involves the conversion of the hydroxide particles to magnetite. Oxidation of $Fe^{2+}$ leads to the stoichiometry of the particles not being purely magnetite, which can be circumvented by adjusting the ratio of the $Fe^{2+}$ and $Fe^{3+}$ concentrations.

Some oxidation of the particles themselves may occur during the preparation or may subsequently oxidize over a period of time to maghemite ($\gamma$-$Fe_2O_3$). However, oxidation appears to be of little consequence in most technological application as the oxidation has little effect, if any, on the colloidal stability, and results in only a relatively small decrease in the magnetic moment of the particles, at most 10%. In cases where maghemite is preferred, it is a relatively simple process to oxidize the particles of magnetite by heating the particles to 90 °C for thirty minutes in a 0.34 M solution of ferric nitrate (Bee *et al.* 1995).

The co-precipitation process is an extremely versatile method of producing ferrite particles in that particles of different size and magnetic properties may be prepared by simply controlling the experimental conditions. (Massart and Cabuil 1987) have shown that control of the mole fraction ratio of $Fe^{3+}$:$Fe^{2+}$, their concentrations, nature and concentration of the alkali medium can enable particles to be prepared of the desired size. This work has been extended by Davies *et al.* (1993) to include studies of the effect of precipitation temperature on particle size, the effect of heating the precipitate in the alkaline medium, and the effect of addition of surfactant to the reaction mixture.

They have shown that the particle size increases when uncoated particles are heated in the alkaline medium and that the extent of this increase depends on the temperature to which the particles are heated. For an increase in precipitation temperature (between 2 °C and 90 °C) and without subsequent heating in the alkali media, an increase in particle size is observed. The effect of changing the initial $Fe^{3+}$:$Fe^{2+}$ molar ratio from 2:1 to 1.5:1 and also changing the bases (KOH, NaOH and $NH_4OH$) have been shown to have an effect on the particle size.

The particle size distribution obtained on changing these various parameters is attributed to changes in the nucleation and growth rate, which in turn depend on the relative supersaturation of the solute, $S$, the rate of nucleation, $R_N$, and the critical size for formation of a particle, $r^*$. The clustering of molecules and subsequent particle precipitation depends on the relative supersaturation of the solute, where the relative supersaturation is the ratio of the activity of the solute in the supersaturated solution to that at equilibrium. A level of supersaturation, $S$, exists below which nucleation is slow and above which $R_N$ increases rapidly. Nuclei below a critical size, $r^*$, may either dissolve or grow, but above which nuclei grow and precipitation occurs.

Expressions for $r^*$ and $R_N$ are given by Walbridge (1987) which depend on the interfacial tension and free energy of dilution per unit volume of the precipitating phase. During the precipitation, the supersaturation level falls and the rate of nucleation, $R_N$, decreases. It follows that with an increase in $S$, the critical size, $r^*$, decreases. Consequently, as nucleation is occurring, the supersaturation level falls and the critical size increases. As $r^*$ increases, the smaller particles dissolve preferentially resulting in a narrower size distribution (Ostwald ripening). Particle growth may also occur whereby smaller particles adhere to the larger particles, thereby promoting growth.

In addition to simple straightforward precipitation, it is possible to produce particles using the microemulsion technique as described in 1.1(c) (Gobe *et al.* 1984).

*(c) Substituted ferrites*

Coprecipitation is not only a very versatile method of producing particles suitable for ferrofluids but it also enables one to produce a wide range of substituted ferrites. The $Fe^{2+}$ ion is simply replaced or partially

replaced by another or combination of divalent metal ions such as $Co^{2+}$, $Mn^{2+}$, $Ni^{2+}$, $Zn^{2+}$, etc. Ions of other valency, e.g., $Li^{+}$ can also be used to prepare substituted ferrites. Numerous papers and patents have been published on this subject. See the references given in the Introduction to this article (*Ferrofluids: Preparation and Physical Properties*). The method of precipitation of the particles is essentially the same as that used to prepare magnetite. Thus it is not important that details of individual preparations be given here, except to say that in some cases the precipitate needs to be hydrotheramally aged to facilitate the conversion of the precipitated hydroxides to the ferrite.

The interest in substituted ferrites stems from differences in the magnetic properties of these materials (Dormann and Nogues 1990). For example, in the case of cobalt ferrites, the magnetocrystalline anisotropy can be very high (Davies *et al.* 1995) so even for nano-sized particles, the magnetic moment is "blocked." Other ferrites, which have relatively low Néel temperatures ($\sim 100\,^{\circ}C$) and thus high thermomagnetic coefficients at these temperatures, have been used in studies of thermomagnetic convection (Fujita *et al.* 1990) and heat transfer (Nakatsuka *et al.* 1990).

### *1.3 Particle-size Distribution*

An important parameter in characterization of fluids is knowledge of the particle-size distribution in ferrofluids. It is not only a pointer to the likely stability of the fluid in the presence of a magnetic field gradient but also is a means of monitoring the reproducibility of the method of particle preparation. It is an obvious advantage to have a narrow particle-size distribution since large particles, which may adversely affect the performance of the fluid, are absent.

Particle-size distribution is best monitored by using transmission electron microscopy. However, another method based on measurement of the magnetization curve of the fluid is particularly convenient (Chantrell *et al.* 1978). To obtain the particle size, the saturation magnetization of the particles is needed. Use of the bulk value may lead to erroneous values, particularly in the case of ferromagnetic particles where values of the saturation magnetization of the particles and bulk can differ greatly. The method also assumes that the particle-size distribution can be described by a log-normal volume distribution (O'Grady and Bradbury 1983). This distribution has been found to be a good representation for most systems studied whether they are based on metallic or ferrite particles.

X-ray diffraction and use of the Debye-Scherrer expression is a satisfactory pointer to the particle size for well-crystallized particles. This method is obviously of no value for particles such as some of the metal particles, which have an amorphous structure.

## *2. Preparation of Ferrofluids*

For most applications low viscosity, low vapor pressure, and chemical inertness are desirable for the carrier liquid and surfactant. Scholten (1978) gives a review of the chemical and physical problems associated with these parameters and lists the advantages and disadvantages associated with different carrier liquids.

### *2.1 Using Metal Particles*

One drawback exists in producing ferrofluids containing metal particles using the methods described in Sect. 1.1; in those cases where a surfactant is chosen to produce particles of a particular size, that surfactant may not be compatible with the carrier liquid needed for a particular application. Although the surfactants used in the preparation can be removed prior to dispersion in another carrier liquid containing an appropriate surfactant, this is not always an easy option. Thus, sometimes a compromise has to be made. To achieve compatibility between the surfactant and carrier liquid, one may have to be flexible in one's choice of particle size, which is dictated by the surfactant used in the preparation of the particles.

Alternatively, sometimes it is possible to achieve a stable colloid by the addition of a secondary surfactant. Transfer of the coated particles to the carrier of choice is best facilitated by rotary evaporation under reduced pressure of the solvent used in the preparation, in the presence of the carrier liquid. The volume of the latter dictates the value of the saturation magnetization of the ferrofluid. This value will in turn be dictated by the requirements of viscosity for particular applications. For particles of iron, cobalt, and $Fe_3N$, saturation magnetizations of 2000 Gauss (0.2 T) are feasible (Scholten 1983), representing a volume fraction of the metal particles between 10% and 20%.

### *2.2 Using Ferrite Particles*

#### *(a) Surfactant-stabilized particles*

Various methods of coating particles prior to dispersion in a carrier liquid have been described but all are basically the same with small differences in procedure. As an example of one method, magnetite can be coated with oleic acid by adding the acid to the precipitated phase in alkaline solution at pH $\sim$9.5. The mixture is usually left stirring for approximately one hour after which time it is heated to $95\,^{\circ}C$ to facilitate the conversion of hydroxides formed to ferrite. After cooling, the product is acidified to pH 5.0 using nitric acid. The oleate ion produced chemisorbs strongly on to the magnetite particles, and the precipitate coagulates and falls out of solution. The coagulation may also be accompanied by the appearance of a thin film of oleic acid on the surface of the supernatant liquid

which is unadsorbed oleate ions reconverted to oleic acid in acid solution.

Sufficient oleic acid must be added to form a monolayer coverage (Davies *et al*. 1993). The supernatant liquid can be decanted and the agglomerated hydrophobic precipitate of coated particles washed several times to remove salts such as nitrates and sulfates. Water and any physisorbed oleic acid can be removed by washing with acetone. By adding the appropriate carrier liquid to the acetone-wet slurry and gently heating, the acetone and any residual water can be removed leaving a colloidal dispersion of magnetite. If any aggregates are present it may be necessary to centrifuge the fluid or subject the fluid to a high-gradient magnetic field separator (HGMS) (O'Grady *et al*. 1986). If the washing procedure with water has not been carried out carefully, the presence of small quantities of micron-sized particles of salt may be present, which must be filtered.

Using this method with the appropriate surfactant it is possible to produce stable colloids in low vapor pressure carriers such as diesters (Wyman 1984), polyphenyl ethers (Bottenberg and Chagnon 1982), silicone oils (Chagnon 1982), hydrocarbons (Khalafalla and Reimers 1973), perfluorocarbons, perfluoropolyethers, etc.

Stable water-based fluids can be produced by this method by the addition of a variety of secondary surfactants to oleate-coated particles (Shimoiizaka *et al*. 1978).

As with fluids prepared from metal particles, the limiting value of saturation magnetization of ferrite-based fluids depends on the desired viscosity of the fluids. Fluids with magnetization up to approximately 1000 Gauss (0.1 T) can be prepared (Scholten 1983), which represents approximately 25 vol.% of ferrite. Most ferrites have saturation magnetizations at 20 °C up to a maximum value of 5000 Gauss (0.5 T).

*(b) Ionically stabilized particles*

Massart (1981) developed the method of producing stable colloidal dispersions in alkaline and acidic aqueous media. He and his coworkers have subsequently made extensive and detailed studies of such dispersions, e.g., Bacri *et al*. (1990), Bee *et al*. (1995).

The production of particles of magnetite and maghemite, the latter produced by oxidizing magnetite particles in ferric nitrate solution (see Sect. 1.2(b)), are produced using a similar method to that already described. The particles produced by this method are macroions in which the electric changes are due to specific adsorption of the amphoteric hydroxyl group. In an alkaline medium, the particles are negatively charged and in an acidic medium, positively charged. These particles can be stabilized in water by the presence of low-polarizing counter-ions such as $N(CH_3)_4^+$ in alkaline medium, or $ClO_4^-$ in acidic medium. Strongly polarizing counter-ions lead to flocculation.

For the -OH ligand, the point-of-zero-charge (PZC) occurs at approximately pH = 7.5. The small surface-charge density in this region of pH precludes the formation of a stable colloidal suspension. Using $OH^-$ ligands, stable suspensions are restricted to pH values outside the range 6–10. Massart and co-workers (Bacri *et al*. 1990) overcame this problem by modifying the nature of the surface charges by substituting the -OH surface ligands by citrate ligands. In so doing, they were able to synthesize stable fluids in the pH range 3–11.

### *2.3 Assessment of Colloidal Stability*

In many applications of magnetic fluids, such as exclusion seals, loudspeakers, etc. (see *Ferrofluids: Applications*), the fluids are subjected to large magnetic fields and field gradients. It is thus of paramount importance that the fluids are free from the presence of large agglomerates or large particles so that fluid stability can be maintained and sedimentation averted. A review of the role that aggregation plays in determining the properties of magnetic fluids has been presented by Charles (1988) as well as the various techniques by which aggregation can be studied, both experimentally and theoretically.

The stability of a fluid can be best monitored by simply measuring the saturation magnetization of the fluid and the magnetic particle size (Chantrell *et al*. 1978) before and after subjecting the fluid to a strong magnetic field gradient. An effective and simple way of studying the effect of a magnetic field gradient on colloidal stability is by the use of a high-gradient magnetic field separator (HGMS) (O'Grady *et al*. 1986). Other methods to monitor the presence of agglomerates and large particles include ac-susceptibility measurements (Fannin *et al*. 1987), light scattering (Beresford and Smith 1973), or small-angle neutron scattering (SANS) (Cebula *et al*. 1983).

A simple method to undertake routine and reproducible measurements of stability and thereby make meaningful comparisons between different fluids is by means of a system based on a Colpitts oscillator (Bissell *et al*. 1984). In this method, a long (15 cm) narrow tube is filled with ferrofluid. Measurements of inductance along the length of the tube enable variations in the concentration of the particles to be monitored. Application of a magnetic field gradient allows a comparison of the concentration profile to be made before and after exposure.

## *3. Physical Properties of Ferrofluids*

An overview of the requirements for the stability of ferrofluids and some of the basic magnetic and physical properties is given in *Ferrofluids: Introduction*. The ferrohydrodynamics of ferrofluids, including such processes as convection, mass, and heat transfer, are

discussed in *Ferrohydrodynamics*. Magneto-optic effects have been discussed by Scholten (1980), and thermal conductivity studies made by Popplewell *et al*. (1982).

For many applications of ferrofluids, a knowledge of the saturation magnetization of the fluid, initial magnetic susceptibility, viscosity, operating temperature range, surface tension, and thermal conductivity are required. Much of this information is to be found in Table 2.4 of the monograph by Rosensweig (1985).

In this section, because of their important role in technological applications, discussion of the physical properties will be confined to the viscosity of ferrofluids in the presence of an applied field, and phase separation.

### *3.1 Viscosity*

In the absence of an applied field, a ferrofluid has rheological properties similar to any other colloidal suspension. A colloidal suspension will exhibit a viscosity greater than that of the pure carrier liquid due to the presence of suspended particles, increasing the energy dissipation during viscous flow. In ferrofluids, where unbound dispersants are present, the viscosity will also be enhanced.

The viscosity of the suspension depends on the volume fraction, $\varphi$, of the coated particles, which for $\varphi < 0.1$ follows the well-known Einstein relation

$$\eta_f/\eta_o = (1 + 2.5\alpha\varphi) \qquad (1)$$

where $\eta_f$ is the viscosity of the fluid, $\eta_o$ is that of the carrier, and $\alpha$ is a factor dependent on the shape of the particles, which is unity for spheres.

The above relation is not valid for higher concentrations and so various other relations have been proposed which all, more or less, describe the $\varphi$-dependent viscosity satisfactorily. De Bruyn (1960) proposed the following relationship for spherical particles.

$$(\eta_f - \eta_o)/\eta_f = 2.5\varphi - (2.5\varphi_c - 1)\varphi^2/\varphi_c^2 \qquad (2)$$

where $\varphi_c = 0.74$ represents a critical concentration at which the liquid becomes solid. In the case of ferrofluids, $\varphi$ represents the volume fraction of coated particles. In situations where the particles are acicular, then the coefficient in Eqn. (1) can increase significantly and thereby the viscosity, which in most applications is to be avoided.

Experimental and theoretical studies of the viscosity in the presence of a magnetic field have been reported. The magnetic field dependence of the viscosity is dependent on whether the magnetic moments within the suspended particles are "blocked" or are free to rotate within the time scale of the measurements, i.e., superparamagnetic. In a situation where the moments cannot rotate freely, the magnetic moments in the fluid are subjected to a torque $\boldsymbol{\mu} \times \mathbf{H}$ where $\boldsymbol{\mu}$ is the magnetic moment of a particle and $\mathbf{H}$ is the applied field. As a result, the moments tend to align with the direction of the field with the result that it changes the state of rotation of the particles causing increased viscous dissipation.

When the fluid vorticity and magnetic field are parallel, the particle can rotate freely and thus the viscosity of dilute suspensions should be unaffected. When perpendicular, the viscosity should increase and reach an asymptotic value for high fields at which the particles are prevented from rotating. If the moments were completely free to rotate within the particle (superparamagnetism) then the field effects would be negligible in either orientation. Good agreement was found between the experimental observations of McTague (1969) and the theoretical calculations of Shliomis (1974). Shliomis showed that non-Newtonian behavior, i.e., shear thinning, should occur.

In the case of concentrated suspensions or poorly dispersed systems where agglomeration is prevalent, shear thinning can be pronounced. Studies by Rosensweig *et al*. (1969) of the field- and shear-dependent viscosity of ferrofluids showed a significantly greater enhanced viscosity with field than predicted by Shliomis. These results were attributed to the presence of agglomerates.

### *3.2 Field-induced Agglomeration and Phase Separation*

In most technological applications, the presence of field-induced agglomeration is to be avoided as it will ultimately lead to sedimentation and failure of the device. For good well-dispersed systems, the problem of field-induced agglomeration is not a problem. This is well established by the fact that ferrofluids have operated successfully for long periods in devices in which strong fields are present and where shear is absent which could otherwise break up agglomerates.

In certain applications, field-induced agglomeration is a property that is essential, for example, for the observation of magnetic domain boundaries (Jones and Puchalska 1979), and for the observation of magneto-optic effects, e.g., birefringence, in ferrofluids (Scholten 1980).

Theoretical studies using Monte Carlo methods have been carried out by Chantrell *et al*. (1982) to investigate the effects of particle interaction on chaining in ferrofluids (see *Ferrohydrodynamics*).

In any device employing a ferrofluid, it is essential that the ferrofluid remains stable under all conditions of operation. However, it has been reported by Bacri and Salin (1982), Rosensweig and Popplewell (1991) and others that a phase separation into liquids of different concentrations can occur. In this phenomenon, the concentrated phase consists of droplets

which in the presence of a field are elongated in the field direction. In the case of field-induced phase separation, removal of the field causes break-up of the droplets into small droplets, which subsequently disappear by diffusion. This phenomenon has been studied theoretically by Cebers (1983) and Buyevich and Ivanov (1992) using a thermodynamic model, Sano and Doi (1983) using a lattice-gas model, and Berkovsky *et al*. (1987) using a cell model. Coexistence curves, in which the concentrated phase and dilute phase of the ferrofluid in the presence of a magnetic field as a function of dipole–dipole interactions, have been presented. For small particles, in which the dipole–dipole interactions are small, no phase-separation occurs in very strong fields.

If large particles are present then phase-separation can occur in zero field. Factors, other than a magnetic field, which may induce a phase transition include lowering of the temperature, variation of free surfactant concentration for sterically stabilized particles, and an increase of ionic strength for electrostatically stabilized fluids. Bacri *et al*. (1990) have studied magnetic field-induced phase separation, ionic-strength induced phase separation and the reversibility of phase separation and the effect of polydispersity. Coexistence curves have been presented. Recent studies have been made by Rosensweig and Popplewell (1991) of the influence of concentration and temperature on the magnetic field-induced phase transition of surfactant-stabilized fluids. They observed phase separation for which a coexistence curve was produced.

One of the problems in any analysis of phase separation is how to distinguish between fluids in which the particles are well-dispersed, i.e., no agglomerates present, and those in which agglomerates, too small to be seen optically, are nevertheless present. In the latter case, the presence of a field will transform the agglomerates from having no resultant moment (flux closure) to one in which a large moment is present. In these circumstances, chaining will arise leading to the presence of elongated structures, which, on removal of the field, will break up and disappear.

Whether phase separation exists or agglomerates are present in a fluid, both effects are unwelcome when it comes to consider fluids for use in devices. These problems can be circumvented by the use of fluids in which the particles are small and agglomeration negligible.

## Ferrohydrodynamics

Ferrohydrodynamics describes the study of the flow behavior of magnetic fluid media. The basic equations of ferrohydrodynamics are introduced. The basic equations of hydrodynamics of a magnetic fluid

consist of three conservation laws of mass, momentum and energy which differ from those of ordinary fluid by the inclusion of a magnetic tensor which is known as the Maxwell stress tensor. The momentum equation is constructed by two different treatments depending on the particle size dispersed in the base liquid. In the case of relatively small particles which behave superparamagnetically, the magnetization of the magnetic fluid is treated as being collinear with the magnetic field. On the other hand, in the case of relatively large particles, it is necessary to treat the fluid as a micropolar fluid.

Pipe flow problems are explained as representative examples of ferrohydrodynamics. The effect of uniform and nonuniform magnetic fields on steady pipe flow resistance of laminar and turbulent flow states is described. The experimental data for laminar flow show a large increase in the flow resistance due to the applied magnetic field which means that the particles in a fluid partially aggregate in the applied magnetic field even in a flowing state. Gas–liquid two-phase flow and oscillatory flow characteristics in a pipe are also taken up in the application of stationary and alternating magnetic fields.

Finally, the ordinary fluid flow around a circular cylinder coated with a magnetic fluid film is described to clarify the drag reduction mechanism of the flow around a blunt body.

## 1. Basic Equations of Ferrohydrodynamics

### 1.1 Magnetic Body Force

If the local magnetization vector is collinear with the local magnetic field vector in any volume element, Eqn. (1) for the magnetic stress tensor in magnetic fluids can be obtained in the general form (Rosensweig 1985):

$$T_{ij} = -\left\{ \mu_0 \int_0^H \left( \frac{\partial M v}{\partial v} \right)_{H,T} \mathrm{d}H + \frac{\mu_0}{2} H^2 \right\} \delta_{ij} + B_i H_j \quad (1)$$

where $M$ is magnetization, $H$ the magnetic field, $B$ the magnetic flux density, $v$ the specific volume ($\mathrm{m^3 kg^{-1}}$), $\delta_{ij}$ the Kronecker delta, and $\mu_0$ the permeability of free space which has the value of $4\pi \times 10^{-7}\ \mathrm{Hm^{-1}}$. In Cartesian coordinates, $j$ is a component of the vectorial force per unit area, or traction, on an inflinitesimal surface whose normal is oriented in $i$ direction.

The magnetic body force density is given by $\mathbf{f}_\mathrm{m} = \nabla \cdot \mathbf{T}$. Its component are represented by:

$$f_i = (\nabla \cdot \mathbf{T})_j = \sum_i \frac{\partial T_{ij}}{\partial x_i} \quad (2)$$

The vector expression for the magnetic body force may be written as:

$$\mathbf{f}_\mathrm{m} = -\nabla \left\{ \mu_0 \int_0^H \left( \frac{\partial M v}{\partial v} \right)_{H,T} \mathrm{d}H \right\} + \mu_0 (\mathbf{M} \cdot \nabla) \mathbf{H} \quad (3)$$

### 1.2 Quasi-stationary Hydrodynamics

To analyze the magnetic fluid flow, it is necessary to formulate a momentum equation for magnetic fluids which was first proposed by Neuringer and Rosensweig (1964). They considered the limiting case that the relaxation time for magnetization is zero; that is, the magnetization $\mathbf{M}$ is collinear with the magnetic field $\mathbf{H}$. Collinearity is a good approximation for sufficiently small size particles which behave superparamagnetically. The direction of magnetic moment $\mathbf{M}$, then, rotates freely within the solid particle.

The system of ferrohydrodynamics equations is described as follows. The continuity equation is:

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{u}) = 0 \quad (4)$$

the equation of motion is

$$\rho \frac{\mathrm{D}\mathbf{u}}{\mathrm{D}t} = -\nabla p + \mu_0 (\mathbf{M} \cdot \nabla) \mathbf{H} - \rho \mathbf{g} + \eta \nabla^2 u \quad (5)$$

the energy equation is

$$\rho c \frac{\mathrm{D}T}{\mathrm{D}t} + \mu_0 \left( \frac{\partial M}{\partial T} \right)_H \frac{\mathrm{D}H}{\mathrm{D}t} = \nabla \cdot (\kappa \nabla T) + \mathbf{\Phi} \quad (6)$$

the Maxwell equation is

$$\nabla \times \mathbf{H} = \mathbf{j} \approx 0,\ \nabla \cdot \mathbf{B} = 0 \quad (7)$$

the equation of state is

$$p = p(\rho,\ T) \quad (8)$$

and the expression of magnetization $M$ is

$$M = M_0(\rho,\ T,\ H) \quad (9)$$

where $\mathbf{u}$ is the flow velocity, $\eta$ the fluid viscosity, $c$ the specific heat, $\kappa$ the thermal conductivity, and $\Phi$ the viscous dissipation energy.

The boundary condition at a boundary between two different media as illustrated in Fig. 1 is obtained as follows. From Eqn. (1), the traction on a surface element with unit normal $\mathbf{n}$ is:

$$\mathbf{n} \cdot T_{ij} = -\mathbf{n} \left( \mu_0 \int_0^H \frac{\partial M v}{\partial v} \mathrm{d}H + \frac{\mu_0}{2} H^2 \right) + \mathbf{n} \cdot \mathbf{BH} \quad (10)$$

The difference in this magnetic stress across an interface between media is a force oriented along the normal which may be expressed as:

$$[\mathbf{n} \cdot \mathbf{T}] = \mathbf{n}[T_{nn}] = \mathbf{n} \left( \mu_0 \int_0^H \frac{\partial M v}{\partial v} \mathrm{d}H + \frac{\mu_0}{2} M_n^2 \right) \quad (11)$$

The square brackets denote the difference between the quantities across the interface.

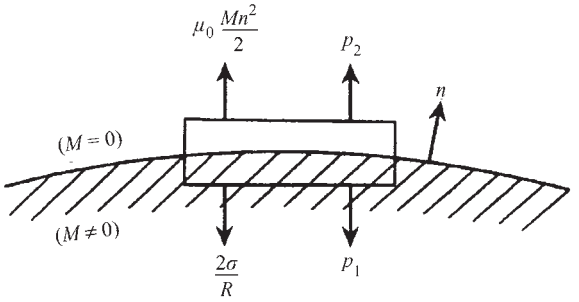

***Figure 1***
Balance of forces in the boundary condition.

### *1.3 Treatment as Micropolar Fluids*

If a magnetic fluid includes relatively large particles, the relaxation time for magnetization of the fluid is determined by Brownian rotation. In this case, the particles can be considered as rigid magnetic dipoles; that is, one can assume that the magnetic moment of a particle changes its orientation only for rotation of the particle itself. Then, the presence of an external magnetic field results in the prevention of the rotation of the particle and in the appearance of the mechanism of rotational viscosity.

The basic equations in this case were derived using the treatment of micropolar fluids by Shliomis (1967) and Shaposhinikov and Shliomis (1975). The fluid is treated as a fluid with internal angular momentum. The volume density of internal angular momentum is denoted by

$$\mathbf{S} = I\omega \tag{12}$$

Here $I = 8\pi r^5 \rho_s n/15$ is the sum of moments of inertia of the sphere particle per unit volume and $\omega$ is the angular velocity of their ordered rotation, where $r$ is the particle radius, $\rho_s$ the particle density and $n$ is the number density of the particles:

$$\rho\frac{\mathrm{D}\mathbf{u}}{\mathrm{D}t} = -\nabla p + \mu_0(\mathbf{M}\cdot\nabla)\mathbf{H} + \eta\nabla^2\mathbf{u} + \frac{1}{2\tau_\mathrm{s}}\nabla\times(\mathbf{S} - I\boldsymbol{\Omega}) \tag{13}$$

$$\frac{\mathrm{D}\mathbf{S}}{\mathrm{D}t} = \mu_0(\mathbf{M}\times\mathbf{H}) - \frac{1}{\tau_\mathrm{s}}(\mathbf{S} - I\Omega) + \gamma\nabla^2\mathbf{S} \tag{14}$$

Here $\boldsymbol{\Omega} = (1/2)\nabla\times\mathbf{u}$ is angular velocity of fluid, $\gamma = 2r^2/(3\tau_\mathrm{B})$ is diffusion coefficient, $\tau_\mathrm{s} = r^2\rho_\mathrm{s}/(15\eta_0)$ is the relaxation time of particle rotation, and $I/2\tau_\mathrm{s}$ is the rotational viscosity. To obtain a closed system of equations, it is necessary to add the equation for $\mathrm{D}\mathbf{M}/\mathrm{D}t$ to Eqns. (13) and (14); that is

$$\frac{\mathrm{D}\mathbf{M}}{\mathrm{D}t} = \omega\times\mathbf{M} - \frac{1}{\tau_\mathrm{B}}\left(\mathbf{M} - M_0\frac{\mathbf{H}}{|H|}\right) \tag{15}$$

where $\tau_B$ is relaxation time of Brownian motion, and $M_0$ the equilibrium magnetization of magnetic fluid. Eqns. (4), (6)–(9) and (13)–(15) form a complete system of equations.

## *2. Pipe Flow Problems*

The pipe flow problems of magnetic fluids in an applied magnetic field are very important in basic studies of the hydrodynamics of magnetic fluids, which is closely related to the development of engineering applications such as energy conversion systems, viscous dampers and actuators (Kamiyama 1992). Therefore, the various pipe flow problems have been investigated.

### *2.1 Theoretical Analysis of Steady Laminar Flow*

*(a) Flow in an axial magnetic field*

Let us consider the steady laminar pipe flow in an axial magnetic field $H_z(z)$ and apply the basic equations derived in Sect. 1.3 for the micropolar fluid. If the particle radius is on the order of $10^{-8}$ m (10 nm), then the values of $\tau_\mathrm{s}$ becomes the order of $10^{-11}$ s and hence the left-hand side and the third term on the right-hand side of Eqn. (14) may be neglected. Therefore, eliminating $\mathbf{S}$ from Eqns. (13) and (14), Eqn. (13) reduces to

$$\frac{\mathrm{d}p}{\mathrm{d}z} = \eta\frac{1}{r}\frac{\mathrm{d}}{\mathrm{d}r}\left(r\frac{\mathrm{d}u_z}{\mathrm{d}r}\right) + \mu_0 M_z\frac{\mathrm{d}H_z}{\mathrm{d}z} - \frac{\mu_0}{2r}\frac{\partial}{\partial r}(rM_rH_z) \tag{16}$$

Also, the following relations are obtained:

$$M_r = \frac{\Omega\tau_\mathrm{B}M_z}{1 + \dfrac{\mu_0\tau_\mathrm{s}\tau_\mathrm{B}M_zH_z}{I}} \tag{17}$$

and

$$u_z\frac{\partial M_z}{\partial z} = \frac{1}{\tau_\mathrm{B}}\left\{M_0 - M_z - \frac{(\Omega\tau_\mathrm{B})^2M_z}{\left(1 + \dfrac{\mu_0\tau_\mathrm{s}\tau_\mathrm{B}M_zH_z}{I}\right)^2}\right\} \tag{18}$$

Here, the equilibrium magnetization $M_0$ is assumed to be expressed by the Langevin function $L$; that is,

$$M_0 = nmL(\xi) \tag{19}$$

where $L(\xi) = \coth\xi - \xi^{-1}$, $\xi = \mu_0 mH/kT$. In the case of a uniform magnetic field, the second terms on the right-hand side of Eqn. (16) and on the left-hand side of Eqn. (18) vanish (Kamiyama *et al.* 1979).

(1) Solution in the case of $\Omega\tau_\mathrm{B} \ll 1$

Under the condition that the rotary Péclet number $P_\mathrm{er} = 2\Omega\tau_\mathrm{B} \ll 1$ holds, the following relation is obtained from Eqn. (18),

$$M_z \approx M_0 \tag{20}$$

Now, let us introduce the following dimensionless quantities:

$$\begin{aligned} r^* &= \frac{r}{r_0} \qquad z^* = \frac{z}{r_0} \\ u_z^* &= \frac{u_z}{u_0} \qquad h^* = \frac{H_z}{H_{\max}} \\ M_z^* &= \frac{M_z}{M_{0\max}} \qquad p^* = \frac{pr_0}{\eta u_0} \\ L^* &= \frac{L(\xi)}{L(\xi_{\max})} \qquad A = \frac{\mu_0 \tau_s \tau_B H_{\max} M_{0\max}}{I} \end{aligned} \tag{21}$$

Here $r_0$ is the pipe radius and $u_0$ is the mean flow velocity. Then, Eqn. (16) is expressed as

$$\frac{\mathrm{d}\rho^{*\prime}}{\mathrm{d}z^*} = \frac{2}{r^*}\left(1 + \frac{\Delta\eta}{\eta}\right)\frac{\mathrm{d}u_z^*}{\mathrm{d}r^*} \tag{22}$$

where

$$\begin{aligned} \Delta\eta &= \frac{3}{2}\phi\eta_0 \frac{Ah^*L^*}{1 + Ah^*L^*} \\ p^{*\prime} &= p^* - \frac{\mathrm{r}_0 nkT}{\eta u_0} \ln(\xi^{-1} \sinh\xi) \end{aligned} \tag{23}$$

where $\phi = (4/3)\pi a^3 n$ is volumetric concentration of particles, $a$ is the particle radius and $\eta_0$ is the viscosity of the solvent of the magnetic fluid.

Applying the boundary condition $u_z^* = 0$ at $r^* = 1$ to Eqn. (22), we obtain the solution:

$$u_z^* = \frac{\dfrac{\mathrm{d}p^{*\prime}}{\mathrm{d}z^*}(r^{*2} - 1)}{4\left(1 + \dfrac{\Delta\eta}{\eta}\right)} \tag{24}$$

Eqn. (24) shows that the Poiseuille flow of a Newtonian fluid has an apparent viscosity of $\eta_e = \eta + \Delta\eta$. Applying the continuity equation, the velocity profile is also represented by:

$$u_z^* = 2(1 - r^{*2}) \tag{25}$$

Integrating Eqn. (22), the pressure difference between two arbitrary points $z_1^*$ and $z_2^*$ in the applied magnetic field region is given by:

$$\begin{aligned} p_1^* - p_2^* = &- \frac{r_0 nkT}{\eta u_0} |\ln(\xi^{-1} \sinh\xi)|_{z_1^*}^{z_2^*} \\ &+ 8(z_2^* - z_1^*) + 8\int_{z_1^*}^{z_2^*} \frac{\Delta\eta}{\eta}\,\mathrm{d}z^* \end{aligned} \tag{26}$$

The first term on the right-hand side of Eqn. (26) is the static pressure difference due to the magnetic body force, the second and third terms correspond to the pressure drop due to friction loss without magnetic field and additional loss with magnetic field, respectively.

(2) Solution in the case of $\Omega\tau_B \sim 1$

It is very difficult to solve Eqn. (16) directly in the case of $P_{er}(=2\Omega\tau_B) \geqslant 1$. However, an approximate solution is obtained by putting

$$M_z^*(r^*,\ z^*) = M_0^*(z^*)\delta(r^*,\ z^*) \tag{27}$$

Then, the solution of Eqn. (16) is obtained as:

$$\frac{\mathrm{d}u_z^*}{\mathrm{d}r^*} = \frac{r^*}{2\left(1 + \dfrac{\Delta\eta}{\eta}\right)}\left\{\frac{\mathrm{d}p^*}{\mathrm{d}z^*} - \frac{r_0\mu_0 M_{0\max} H_{\max}}{\eta u_0}\delta L^*(\xi)\frac{\mathrm{d}h^*}{\mathrm{d}z^*}\right\} \tag{28}$$

where

$$\Delta\eta = \frac{3}{2}\phi\eta_0 \frac{Ah^*L^*\delta}{1 + Ah^*L^*\delta} \tag{29}$$

It is clear from Eqns. (28) and (29) that the apparent viscosity depends on the flow shear rate $\dot{\Omega}$; that is, the magnetic fluid shows the non-Newtonian fluid property.

*(b) Flow in a transverse magnetic field*

In a similar treatment in the case of an axial magnetic field, the solution of Eqn. (16) is obtained for the case where $P_{er}(=2\Omega\tau_B) \ll 1$ as:

$$\begin{aligned} \frac{\mathrm{d}p^{*\prime}}{\mathrm{d}z^*} = &\left(1 + \sin^2\theta\,\frac{2\Delta\eta}{\eta}\right)\frac{\mathrm{d}^2 u_z^*}{\mathrm{d}r^{*2}} \\ &+ \left(1 + \cos^2\theta\,\frac{2\Delta\eta}{\eta}\right)\frac{\mathrm{d}u_z^*}{r^* dr^*} \end{aligned} \tag{30}$$

where

$$\Delta\eta = \frac{3}{4}\phi\eta_0 \frac{Ah^*L^*}{1 + Ah^*L^*} \tag{31}$$

The increase in the apparent viscosity $\Delta\eta$ in a transverse magnetic field is just half of that in a longitudinal magnetic field.

### *2.2 Steady Pipe Flow Resistance in Laminar and Turbulent Flows*

In the case of ordinary Newtonian fluid, the pressure drop in a laminar pipe flow is expressed by using the pipe friction coefficient $\lambda(=2d\Delta p/\rho u_0^2 l)$ with $\lambda = 64/Re$, where $Re = \rho u_0 d/\eta$, $d = 2r_0$ is the pipe diameter, and $l$ is the pipe length between measuring points of $\Delta p$. Experimental studies of the flow in the axial and transverse magnetic fields were carried out using a similar technique to the ordinary fluid (Kamiyama *et al.* 1979, 1983, 1987).Typical experimental results are sketched in Fig. 2. Figure 2 shows clearly that the pressure increases with the field strength $H$ in the entrance region of magnetic field, due to the magnetic body force, and decreases in the outlet region. Moreover, the pressure drop caused by friction loss is larger in an applied magnetic field than in no

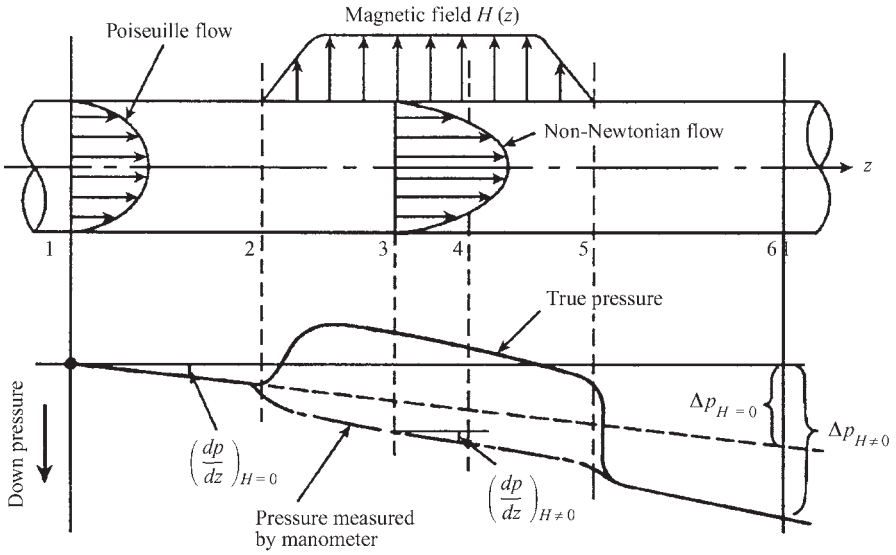

***Figure 2***
Typical experimental result of pressure distribution measured by transducer and manometer.

magnetic field. The true pressure distribution shows the profile as indicated by solid line in Fig. 2. However, if the pressure in the magnetic field region is measured by a manometer outside the magnetic field, the pressure difference in the manometer indicates only the pressure drop due to pipe friction loss shown by the chain line. In such a case, the magnetic pressure also acts on the fluid in the connecting tube across the magnetic field and cancels the magnetic static pressure in the pipe.

Now, we would like to examine in some detail the pressure distribution measured by the manometer using the test tube in the axal magnetic field distribution as shown in Fig. 3 where the pressure coefficient $C_p$ along the pipe axis is plotted

$$C_p = \frac{p - p_1}{\rho u_0^2/2} \tag{32}$$

where $p_1$ is the pressure at the upstream reference point. It is clearly shown that a peculiar pressure drop occurs at the edge of the imposed magnetic field. The following loss coefficients may be defined from Fig. 3:

$$\zeta = \lambda_0 \frac{l_1 + l_3}{d} + \lambda_H \frac{l_2}{d} + \zeta_{in} + \zeta_{out} \tag{33}$$

where $\lambda_H$ denotes the resistance coefficient in uniform magnetic field and $\lambda_0$ in the absence of magnetic field. $\zeta_{in}$ and $\zeta_{out}$ are loss coefficients in nonuniform magnetic field regions at the inlet and outlet. Since the pressure gradient is supposed to be nearly constant in

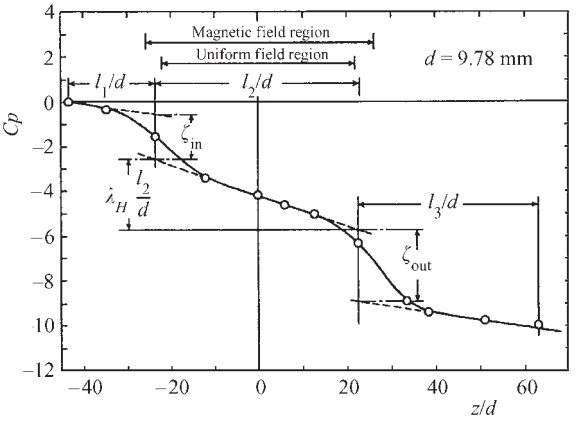

***Figure 3***
Measured pressure distribution along the pipe axis measured by manometer.

the uniform field region, the resistance coefficient $\lambda_H$ was estimated. The relation between the resistance coefficient $\lambda$, which corresponds to $\lambda_H$ and the modified Reynolds number $Re^*$ is shown in Fig. 4 where

$$\lambda = \frac{64}{Re^*} \quad \text{and} \quad Re^* = \frac{\rho u_0 d}{\eta + \Delta\eta} \tag{34}$$

It is clear that in the laminar flow regime the resistance coefficient $\lambda$ increases with the intensity of magnetic flux density $B$. In particular, the coefficient $\lambda$ for water-based fluid is much larger than that for

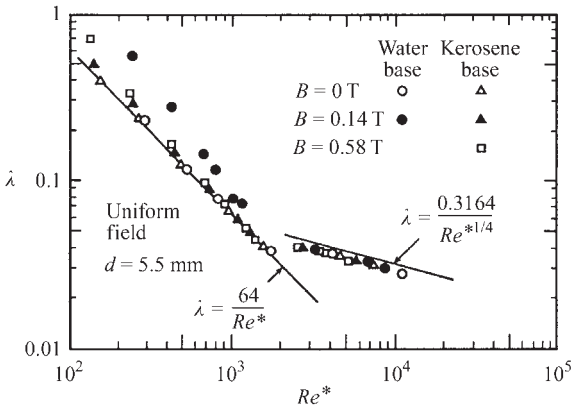

***Figure 4***
Effect of magnetic field on the relation of resistance coefficient $\lambda$ versus Reynolds number $Re^*$ in a uniform magnetic field.

kerosene-based fluid. On the other hand, $\lambda$ for turbulent flow is not influenced by the application of magnetic field; it has a slightly lower value compared to the Blasius formula as a Newtonian fluid.

Since it is observed that the large pressure drop occurs at the nonuniform field region, it is important to examine the effect of nonuniform magnetic field on the flow resistance. An experimental study was, therefore, done to clarify the effect of nonuniform magnetic field on the flow resistance. The nonuniform magnetic field distribution was generated by adjusting the pole gap of the electromagnet as shown in Fig. 5. Figure 6 shows the experimental results of the pressure change $\Delta p'_{1-2}$ against mean flow velocity at several values of current $I$ supplied to the electromagnet for both water-based and kerosene-based fluids. $\Delta p'$ denotes the pressure drop over the pipe length $L$:

$$\Delta p' = \lambda \frac{L}{d} \rho \frac{u_0^2}{2} \tag{35}$$

In this case, subscript 1–2 denotes the change between the locations $z_1$ and $z_2$ in Fig. 5. The theoretical values obtained from Eqn. (26), modified for the transverse magnetic field, are also shown in Fig. 5. The experimental values for the kerosene-based fluid agree well with the predicted ones as indicated in Fig. 5. On the other hand, it is easy to see that the experimental values for the water-based fluid are much larger than the predicted ones.

Measurements of the flow resistance were also made for other pipes with variable cross-sectional area such as venturi and long orifice tubes (Kamiyama *et al.* 1987).

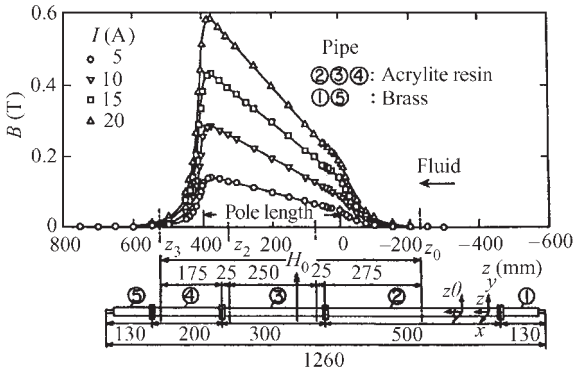

***Figure 5***
Distribution of magnetic flux density in the test section.

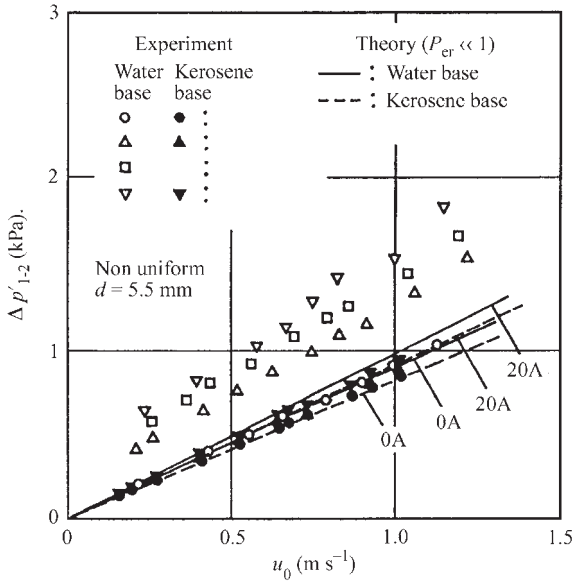

***Figure 6***
Pressure difference as a function of mean flow velocity.

## *2.3 Unsteady Flow*

### *(a) Oscillatory pipe flow characteristics*

The unsteady pipe flow problem is also important in relation to development in the application to magnetic fluid dampers and actuators. As an example of unsteady pipe flow problems, oscillatory flow in a straight pipe in a transverse magnetic field is considered here. Theoretical analysis of the oscillatory flow is made under the assumption that the shape of aggregated particles in the magnetic fluid is a rigid prolate spheroid as shown in Fig. 7 (Tsebers 1974). When the basic equations are simplified by the same

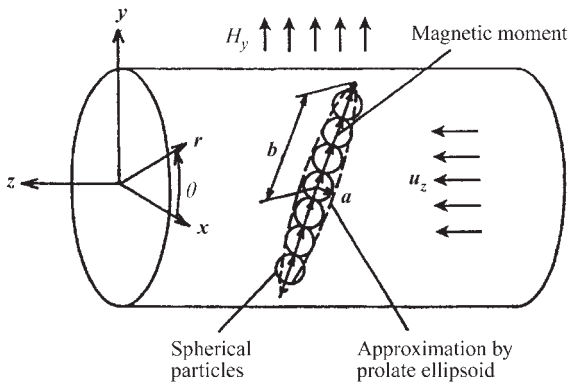

***Figure 7***
Model of aggregated particles in a magnetic field.

procedure as for steady flow in Sect. 2.1, the following dimensionless equation is obtained:

$$W^2\left(\frac{\mathrm{d}u^*}{\mathrm{d}t^*}\right) = -\frac{\mathrm{d}p^{*\prime}}{\mathrm{d}z^*} + \left(1+\frac{2\Delta\eta_1}{\eta}\right)\frac{\partial^2 u^*}{\partial r^{*2}} + \left(1+\frac{2\Delta\eta_2}{\eta}\right)\frac{\partial u^*}{r^*\partial r^*} + \left(1+\frac{2\Delta\eta_3}{\eta}\right)\frac{\partial^2 u^*}{r^{*2}\partial\theta^2} \tag{36}$$

together with the boundary conditions

$$r^*=1: \quad u^*=0; \quad r^*=0: \quad \frac{\mathrm{d}u^*}{\mathrm{d}r^*}=0 \tag{37}$$

Here, $W=r_0/\sqrt{\omega\rho/\eta}$ is Womersley number,

$$p^{*\prime} = p^* - \frac{nkT}{\eta\omega}\ln(\xi^{-1}-\sinh\xi),$$

$$\Delta\eta_1 = \frac{\alpha}{8}\left[\left\{\frac{\xi-\tanh\xi}{\xi+\tanh\xi}+\lambda\left(3L_2-\frac{L_3}{\xi}\right)\right\}\sin^2\theta + \frac{\lambda}{\xi}\left(2L_1-\frac{L_2}{\xi}\right)\right]$$

$$\Delta\eta_2 = \frac{\alpha}{8}\left[\left(\frac{\xi-\tanh\xi}{\xi+\tanh\xi}+\lambda L_2\right)\cos^2\theta + \lambda\left(2L_2-\frac{L_3}{\xi}\right)\sin^2\theta + \frac{\lambda}{\xi}\left(2L_1-\frac{L_2}{\xi}\right)\right]$$

$$\Delta\eta_3 = \frac{\alpha}{8}\left[\left\{\frac{\xi-\tanh\xi}{\xi+\tanh\xi}+\lambda\left(3L_2-\frac{L_3}{\xi}\right)\right\}\cos^2\theta + \frac{\lambda}{\xi}\left(2L_1-\frac{L_2}{\xi}\right)\right] \tag{38}$$

and

$$\alpha = \frac{4\phi\eta_0}{3}\frac{1-\delta^4}{(2-\delta^2)\dfrac{\delta^2}{\sqrt{1-\delta^2}}\ln\dfrac{1+\sqrt{1-\delta^2}}{\delta}-\delta^2}$$

is the rotational friction per unit fluid volume and

$$\begin{aligned} L_1&=\coth\xi-\xi^{-1} & L_2&=1-\frac{3}{\xi}\\ L_3&=L_1-\frac{5L_2}{\xi} & \lambda&=\frac{1-\delta^2}{1+\delta^2}\\ \delta&=\frac{a}{b}=\frac{1}{Nu} & r^*&=\frac{r}{r_0}\\ z^*&=\frac{z}{r_0} & u^*&=\frac{u}{u_0}\\ p^*&=\frac{p/\eta u_0}{r_0} & t^*&=\omega t \end{aligned} \tag{39}$$

where $u_0$ is the amplitude of oscillating mean flow velocity and $Nu$ is the number of aggregated particles.

When the oscillating flow rate is given, the velocity distribution is obtained by solving Eqn. (36) using difference calculus. Also, fluctuating pressure difference between two points in a pipe is expressed by Eqn. (40):

$$\Delta\bar{p}^{*\prime} = -u_0^*\int_0^{l^*}\frac{\mathrm{d}z^*}{\dfrac{1}{\pi}\iint U^* r^*\,\mathrm{d}r^*\,\mathrm{d}\theta} \tag{40}$$

where $U^*=u^*/(\mathrm{d}p^{*\prime}/\mathrm{d}z^*)$, $l^*=l/r_0$, and $l$ is the length between two measuring points in a pipe.

Figure 8 shows the calculated results of the effect of magnetic field on the pressure difference in the pipe compared with the experimental data obtained by using the water-based magnetic fluid with 20% mass concentration of particles (Shimada and Kamiyama 1993). The vertical axis shows the increase rate of the pressure difference of the first mode oscillatory flow between two pressure transducers installed apart for 160 mm apart with an applied magnetic field. The abscissa is the Womersley number. The Reynolds number $Re$ is defined as $2r_0u_0/\nu$, where $\nu$ is the kinematic viscosity. $I=20$ A is the current supplied to the electromagnet which produces a nonuniform magnetic field with $H_{\max}=120\,\mathrm{kAm^{-1}}$. The results show that the fluctuating pressure difference increases with the magnetic field strength especially at low Womersley numbers. The scatter of the experimental data is shown with error bands in Fig. 8. Theoretical analysis can also explain the experimental results well by assuming that the aggregated particle number $Nu$ depends on the Womersley number.

*(b) Pulsating flow characteristics*

As another example of the unsteady pipe flow, we consider here pulsating pipe flow, that is, the velocity

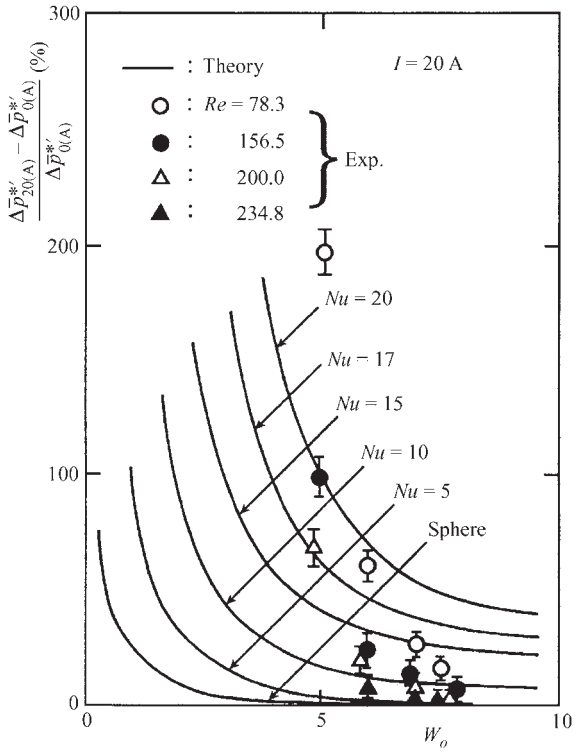

***Figure 8***
Increase rate of pressure difference versus Womersley number.

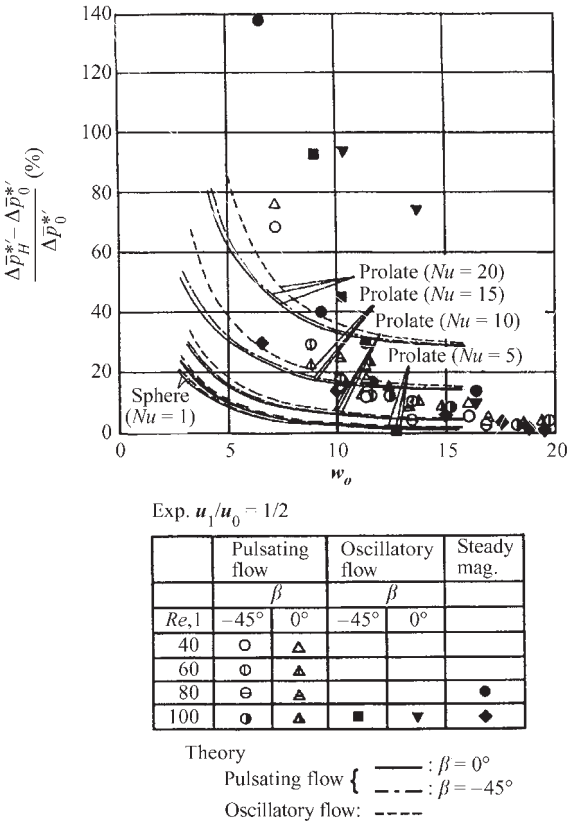

***Figure 9***
Comparison of pressure difference between pulsating and oscillatory flows.

of the fluid is composed of steady and oscillatory flow ($u_0 + u_1$) in a pulsating magnetic field ($H_0 + H_1$). Eqn. (36) is solved numerically by assuming that each time-varying variable is expanded in a series of number $n(= 1, 2 \ldots n)$ and then ordering the resulting terms with respect to the power of $n$ (Shimada and Kamiyama 1994). Time-varying velocity profiles in a circular pipe are obtained as a function of the Womersley number $W$ and the magnetic field parameter. Generally speaking, it is clear from the numerical calculations that the velocity profiles are mainly influenced by $W$ in the same way as the ordinary fluid flow; for smaller $W$, the velocity profile is parabolic-like and for larger $W$, it becomes a profile with a maximum near the wall.

Figure 9 shows the results calculated for increasing rate of pressure difference with the application of pulsating magnetic field compared with the experimental results. The results in the case of the oscillatory flow both in the steady and the pulsating magnetic field are also shown for comparison, where $\beta$ denotes the phase difference between fluctuating velocity and magnetic field. It is easy to see that the experimental data for the pulsating flow are smaller than those for oscillatory flow in the pulsating magnetic field and this result is similar to the theoretical analysis. However, the experimental data also show that the difference in the oscillatory flow characteristics appears between the cases of the pulsating and steady magnetic field. The cause seems to be the complicated effect of the magnetic field on the particles aggregation in the unsteady flow state.

### 2.4 *Gas–Liquid Two-phase Flow*

Gas–liquid two-phase pipe flow problems are closely connected with the development of a new energy conversion system utilizing magnetic fluid. The use of the gas–liquid two-phase flow is very effective in increasing the driving force of circulating fluid in this device.

#### *(a) Theoretical analysis*

Let us consider one-dimensional two-phase flow in the vertical pipe. Figure 10 shows schematically the system used in the theoretical analysis as well as in the experiment. A temperature sensitive magnetic

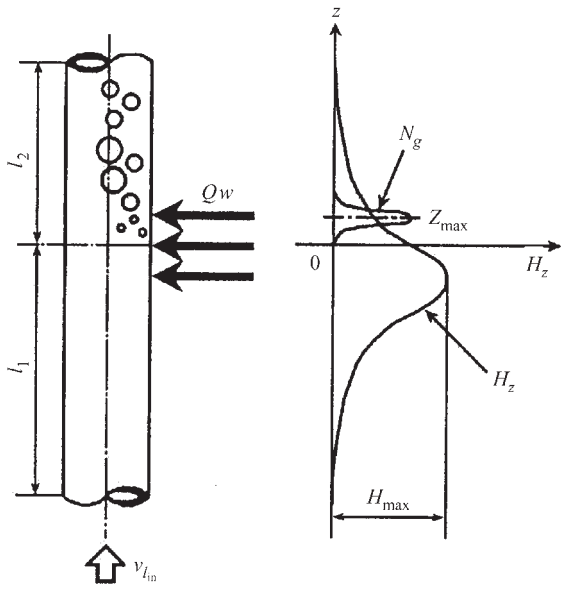

***Figure 10***
Analytical model of two-phase flow in a nonuniform magnetic field.

fluid is assumed to be heated passing through the point of the maximum magnetic field strength toward the downstream side region and boiled to form the gas–liquid two-phase flow. Under the above conditions, the governing equations of the boiling two-phase flow based on the thermal nonequilibrium two-fluid model are derived as follows (Kamiyama and Ishimoto 1995). The equations of continuity are:

$$\frac{\mathrm{d}}{\mathrm{d}z}(\rho_g v_g \alpha) = \Gamma_g$$
$$\frac{\mathrm{d}}{\mathrm{d}z}\{\rho_l v_l (1-\alpha)\} = \Gamma_l \tag{41}$$

where $\alpha$ is the void fraction, $v$ is the velocity, and $\Gamma$ is the phase generation rate. The subscript g and l denote gas and liquid phase respectively. $\Gamma_g$ and $\Gamma_l$ are expressed by

$$\begin{aligned} \Gamma_g = -\Gamma_l = \Gamma_{(e)} - \Gamma_{(c)} \quad & \text{for } T_l \geqslant \bar{T}_l \\ = 0 \quad & \text{for } T_l \leqslant \bar{T}_l \end{aligned} \tag{42}$$

where $\bar{T}_l = (T_{l_{in}} + T_s)/2$, $T_{l_{in}}$ is the liquid-phase temperature at the inlet section ($z = -l_1$) and $T_s$ is the evaporation temperature. $\Gamma_{(e)}$ and $\Gamma_{(c)}$ are the mean evaporation and condensation rates (Dobran 1988) and are given by

$$\begin{aligned} \Gamma_{(e)} = \varepsilon_{(e)}^{-\frac{1}{3}} A_1 (1-\alpha)\rho_l \alpha (\bar{T}_l R_G)^{\frac{1}{2}} \left(\frac{T_l - \bar{T}_l}{T_s}\right) \quad & \text{for } T_l \geqslant \bar{T}_l \\ = 0 \quad & \text{for } T_l < \bar{T}_l \end{aligned} \tag{43}$$

$$\begin{aligned} \Gamma_{(c)} = \varepsilon_{(c)}^{-\frac{1}{3}} A_2 (1-\alpha)\rho_g \alpha (T_s R_G)^{\frac{1}{2}} \left(\frac{T_s - T_g}{T_s}\right) \quad & \text{for } T_g \leqslant T_s \\ = 0 \quad & \text{for } T_g > T_s \end{aligned} \tag{44}$$

where $\varepsilon_{(e)}$ and $\varepsilon_{(c)}$ are the relaxation parameters for the evaporation and the condensation and $R_G$ is the gas constant. The variables $A_1$ and $A_2$ are proportional to the contact area between the gas and liquid phases. They include the effect of the number density of the vapor bubbles generation $N_g[1/(\mathrm{m}^3\mathrm{s}^{-1})]$ which is assumed to have normal distribution in the region of $z = 0-2z_{max}$. The combined momentum equation is:

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{d}z}\{\rho_g \alpha v_g^2 + \rho_l (1-\alpha) v_l^2\} = & -\frac{\mathrm{d}p_l}{\mathrm{d}z} - (1-\alpha)\rho_l g \\ & + (1-\alpha)\mu_0 M_z \frac{\mathrm{d}H_z}{\mathrm{d}z} \\ & + \Gamma_g (v_g^{(i)} - v_l^{(i)}) \\ & - \frac{32\{\eta_g \alpha v_g + \eta_l (1-\alpha) v_l\}}{d^2} \end{aligned} \tag{45}$$

where $g$ is acceleration of gravity and suffix $(i)$ denotes the interface between the gas and liquid phases.

To consider the effect of slip and radial expansion of the bubbles, the equation of motion for the gas phase is replaced here by the translational motion of a single bubble (Ishimoto *et al.* 1994). The equation of motion for the gas phase is:

$$\begin{aligned} \frac{4}{3}\pi \bar{R}^3 \rho_g v_g \frac{\mathrm{d}v_g}{\mathrm{d}z} = & -\frac{4}{3}\pi \bar{R}^3 \frac{\mathrm{d}p_l}{\mathrm{d}z} - \frac{4}{3}\pi \bar{R}^3 \rho_g g \\ & - F_D - F_{VM} - F_B \end{aligned} \tag{46}$$

where $\bar{R}$ is the mean radius of the bubble defined by Eqn. (51) below. $F_D$ is the drag force, $F_{VM}$ is the virtual mass force considering the expansion of the bubble, and $F_B$ is the Basset term which takes into account the effect of deviation in a flow pattern from the steady state.

The energy equations for the gas and liquid phases expressed as follows:

$$\frac{\mathrm{d}}{\mathrm{d}z}\left\{\rho_g \alpha v_g \left(h_g + \frac{v_g^2}{2}\right)\right\} = -\rho_g \alpha v_g g + \Gamma_g h_g^{(i)} + q_g^{(i)} a^{(i)} \tag{47}$$

$$\begin{aligned} & \frac{\mathrm{d}}{\mathrm{d}z}\left\{\rho_l (1-\alpha) v_l \left(h_l + \frac{v_l^2}{2}\right)\right\} \\ & \quad = -\rho_l (1-\alpha) v_l g + \Gamma_l h_l^{(i)} + q_l^{(i)} a^{(i)} \\ & \qquad - (1-\alpha)\mu_0 T_l \left(\frac{\partial M_z}{\partial T_l}\right)_H v_l \frac{\mathrm{d}H_z}{\mathrm{d}z} + Q_w \end{aligned} \tag{48}$$

where $q_g^{(i)}$ and $q_l^{(i)}$ are the heat fluxes through the gas–liquid interface ($q_g + q_l = 0$). $h_g^{(i)}$ and $h_l^{(i)}$ are the respective enthalpies as the interface. $a^{(i)}$ is the interface area concentration and $Q_w$ is the heat transfer rate per unit volume. It is assumed that the energy transfer is caused by the heat transfer between an isothermal spherical bubble and the surrounding liquid. With the assumption of a spherical bubble with an equivalent radius $\bar{R}$, the expression for $a^{(i)}$ is obtained as $a^{(i)} = 3\alpha/\bar{R}$ (Kataoka 1986).

To close the basic equations in this system, the following three equations are introduced.

The equation of the ideal gas law:

$$\frac{p_g}{\rho_g} = R_G T_g \tag{49}$$

where $R_G$ is the gas constant.

The equation of the pressure balance between the gas and liquid phases:

$$p_g - p_l = \frac{2\sigma}{\bar{R}} \tag{50}$$

where $\sigma$ denotes the surface tension in the liquid phase.

The mass conservation equation for the single gas bubble:

$$\frac{4}{3}\pi \frac{d}{dz}(\rho_g \bar{R}^3) = \frac{d}{dz}\left(\frac{\sum \Gamma_g}{\sum N_g}\right) \tag{51}$$

where $N_g$ is the number density of the generation of the vapor bubbles.

*(b) Experimental study*

An experimental study to measure precisely the liquid phase pressure, the temperature, and the mean velocity was conducted using a test loop tube, the inner diameter and the total length of which are 8.0 mm and 3.3 m, respectively. Taking advantage of the high permeability of an ultrasonic wave in the magnetic fluid, the ultrasonic imaging technique was applied to the investigation of a boiling two-phase flow in the magnetic field.

Figure 11 shows a schematic diagram of the experimental set-up for the boiling two-phase flow of the magnetic fluid. The ultrasonic wave probe is closely attached to the flow pipe through the gel pad. The ultrasonic wave echo visualizes a bubble in the magnetic fluid. The magnetic fluid is heated by a YAG laser, with a constant heat flux passing through the point of the maximum magnetic field strength toward the downstream side.

Figure 12 shows the experimental results of the pressure distribution in the liquid phase, $\Delta p_{lT}$ compared with the numerical analysis. $\Delta p_{lT}$ is the pressure difference at the inlet section of the applied magnetic field region and is defined by $\Delta p_{lT} = p_l - \rho_l g(l_2 - z) - p_{l_{in}}$.

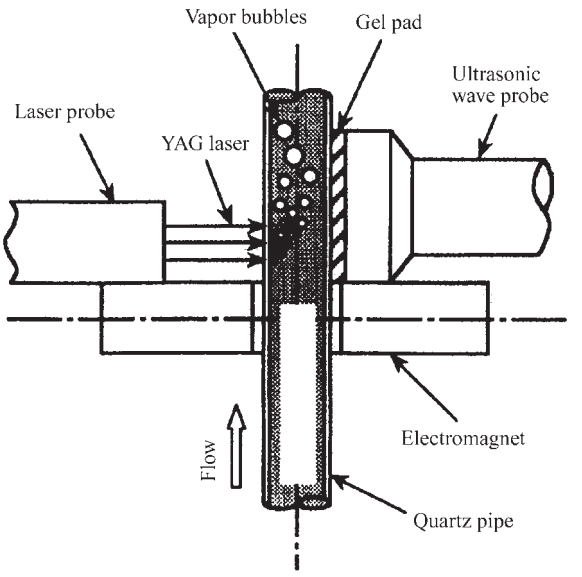

***Figure 11***
Experimental set-up for two-phase flow in a magnetic field.

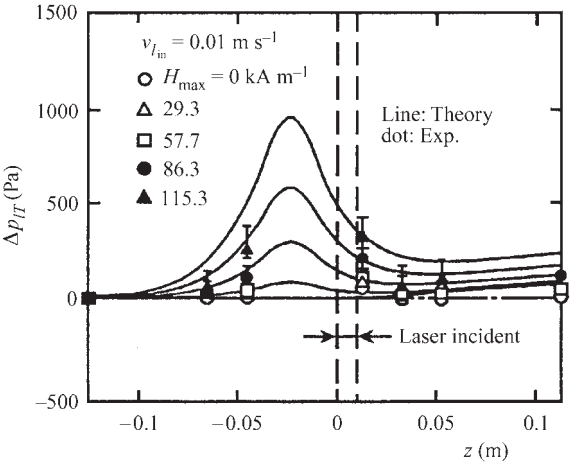

***Figure 12***
Pressure distribution in liquid phase as a function of $z$ coordinate for different magnetic field strength.

The measured pressure distribution agrees reasonably with the numerical results. Also, because of the appearance of the gas phase and the temperature increase after passing through the heated region, $\Delta p_{lT}$ at the exit position increases with the maximum magnetic field strength $H_{max}$. These experimental and theoretical results explain the effectiveness of the two-phase flow in increasing the driving force of the magnetic fluid flow in a nonuniform magnetic field.

### 3. Flow Around a Blunt Body Coated with a Magnetic Fluid

To reduce the drag and enhance the heat transfer by controlling flow separation in the flow around a blunt body, the magnetic fluid coating on a solid body is investigated. A cylinder coating is made by using a permanent magnet cylinder magnetized transverse to its axis or an electrically conducting cylinder carrying the electric current. The magnetic field keeps the magnetic fluid as the coating which has a constant thickness (its radius = $a$). The shape of this coating changes under the action of the viscous flow as shown in Fig. 13.

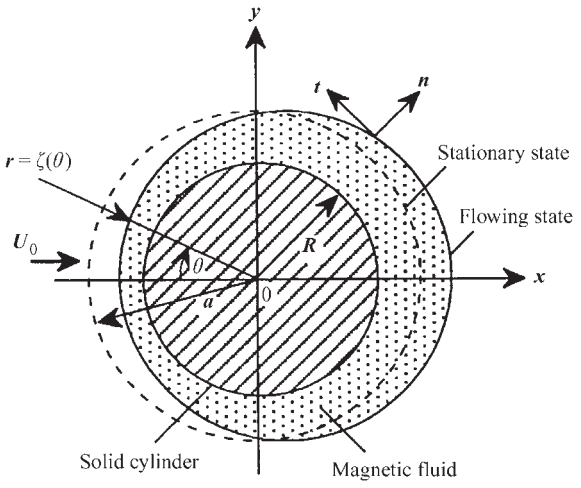

*Figure 13*
Flow past a circular cylinder coated with a magnetic fluid.

The numerical calculation of this flow problem with a transforming the boundary shape was carried out using a new finite element method technique and compared with experimental data (Krakov and Kamiyama 1995). Figure 14 shows the calculated results of a drag reduction ratio $G$ as a function of the initial radius ratio $a/R$ in the case when the viscosity ratio of the outer fluid ($\eta_2$) and the magnetic fluid ($\eta_1$) equals 100. The Reynolds number is defined as $Re = \rho_2 U_0 2R/\eta_2$. The experimental data were obtained by free fall of a cylindrical permanent magnet coated with the magnetic fluid in silicon oil (Berkovsky *et al.* 1990). It is clear from Fig. 14 that the drag reduction with the film coating is effective in high viscous fluid flow around the blunt body.

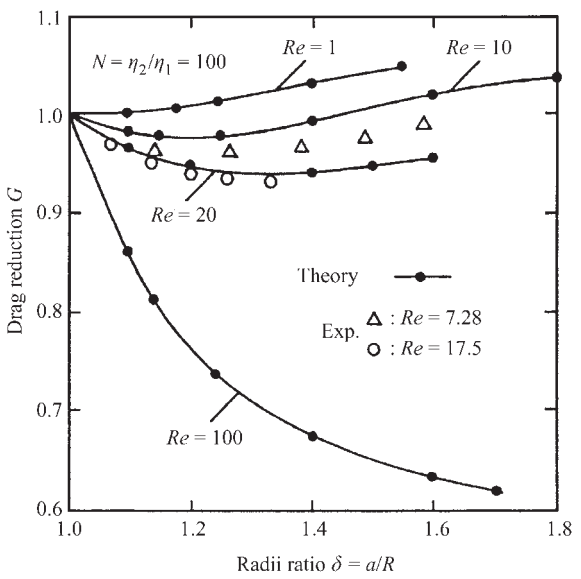

*Figure 14*
Drag reduction ratio as a function of radii ratio.

# Films and Multilayers: Conventional Superconducting

Thin-film multilayers are artificially fabricated materials that consist of thin slabs of various materials deposited sequentially on a substrate. In general, when the individual layer thicknesses are comparable with certain physical length scales for electronic interactions, the electronic transport takes on new characteristics which could be quite different from the electronic properties of the constituent layers. Superconductivity is one property particularly amenable to layered modifications due to its rather long coherence length in many materials.

The superconducting materials community has historically paid particular attention to films and multilayers, mostly for uncovering new superconducting mechanisms, but also in studying superconducting phenomena in "tunable" model systems. Superconducting thin films are also technologically important as they are a basis for superconducting electronics. Besides artificially structured multilayers, layered structures also exist naturally in transition-metal dichalcogenide superconductors such as $NbSe_2$ and high-$T_c$ cuprate superconductors such as $YBa_2Cu_3O_y$ and $Bi_2Sr_2CaCu_2O_y$ (see *High-temperature Superconductors: Thin Films and Multilayers*).

In this article the focus is on presenting a framework for understanding the physics of superconductivity in layered materials. The discussion centers on one of the interesting aspects of the layered superconductors which is their static anisotropic magnetic properties and dimensional cross-over. For more detailed reviews of materials systems involved see, for example, Ruggiero and Beasley (1984), Matijasevic and Beasley (1987), and Schuller *et al.* (1990). The phenomenological framework of Ginzburg–Landau (GL) that is presented here provides for a simple understanding of the macroscopic superconducting properties of multilayers. However, if the layering affects the fundamental interactions that bring about the superconductive electronic pairing, this picture will be inadequate, and a microscopic model is needed.

## 1. Types of Multilayers

Superconducting multilayer structures typically consist of two different layers which alternate in a one-dimensional layering lattice. One material is the primary superconductor (S) and the second material can be an insulator (I), another superconductor (S′), a normal metal (N), or a ferromagnet (F) (see Fig. 1). The wavelength of the modulation is usually denoted by $s$, with $s = d_S + d_X$, where $d_S$ and $d_X$ are the thicknesses of the superconducting and mediating layers, respectively. In reality materials issues are often more complicated, producing, for example, an interfacial layer which could be another superconducting phase, so that there are S/S′/N multilayers rather than simply S/N.

### 1.1 Superconductive Coupling

In practice there are two different mechanisms for Josephson coupling of superconductivity between the superconducting layers in a multilayer: pair tunneling and superconducting proximity effect coupling (extension of Cooper pairs into a normal metal). Pair

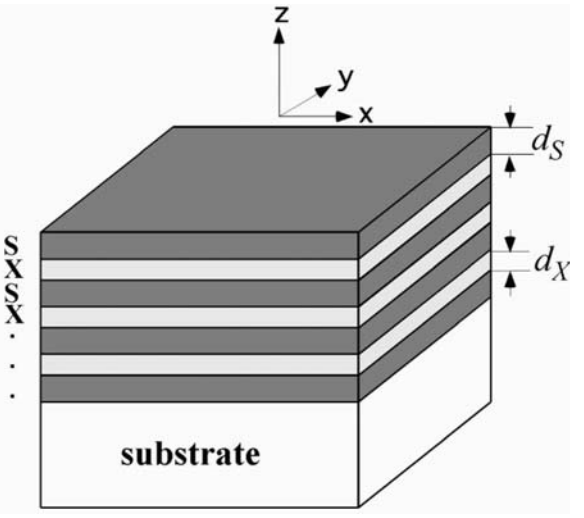

***Figure 1***
Schematic of a multilayer. X represents an insulator, a second superconductor S′, a normal metal N, or a ferromagnet F.

tunneling is relevant for the S/I systems and proximity effect for the others. Both couplings decay exponentially with the separation of the S layers, but the decay scale is different. For tunneling the range is typically 1–2 nm, while proximity effect coupling is typically at 10–1000 nm. Pair tunneling is temperature-independent, for example, so the details of the coupling are different in the two cases, but for many macroscopic properties the actual nature of the coupling is not relevant.

There has been increasing interest in superconductive coupling via ferromagnetic metallic layers. In the case of coupling through ferromagnetic materials the magnetic pair breaking reduces the coupling distance typically to about 1–10 nm. In a ferromagnet adjacent to a superconductor, the exponentially decaying superconducting pair function is presumed to oscillate, as was first suggested by Buzdin *et al.* (1982) and Radovic *et al.* (1988). This behavior is akin to the description of an oscillatory superconducting order parameter that is generated in the presence of an exchange field, described by the Fulde–Ferrell–Larkin–Ovchinikov (FFLO) effect (Fulde and Ferrell 1964, Larkin and Ovchinikov 1964).

The oscillating order parameter reveals itself in an oscillating $T_c$ as a function of $d_F$ and therefore is manifestly different from other types of couplings. Jang *et al.* (1995) and Mühge *et al.* (1996) have shown such behavior in two different S/F systems, but the experimental situation is not yet clarified. When the coupling is negative between the S layers it is presumed that there would be a $\pi$ phase shift between the superconducting layers to give a so-called $\pi$-junction. Subsequent reports by Ryazanov *et al.* (2001) have provided strong evidence for such an oscillatory superconducting wave function.

Figure 2 contrasts the different types of mediating layers and the relevant length scales for the coupling. The present discussion focuses on macroscopic thermodynamic properties of the superconducting

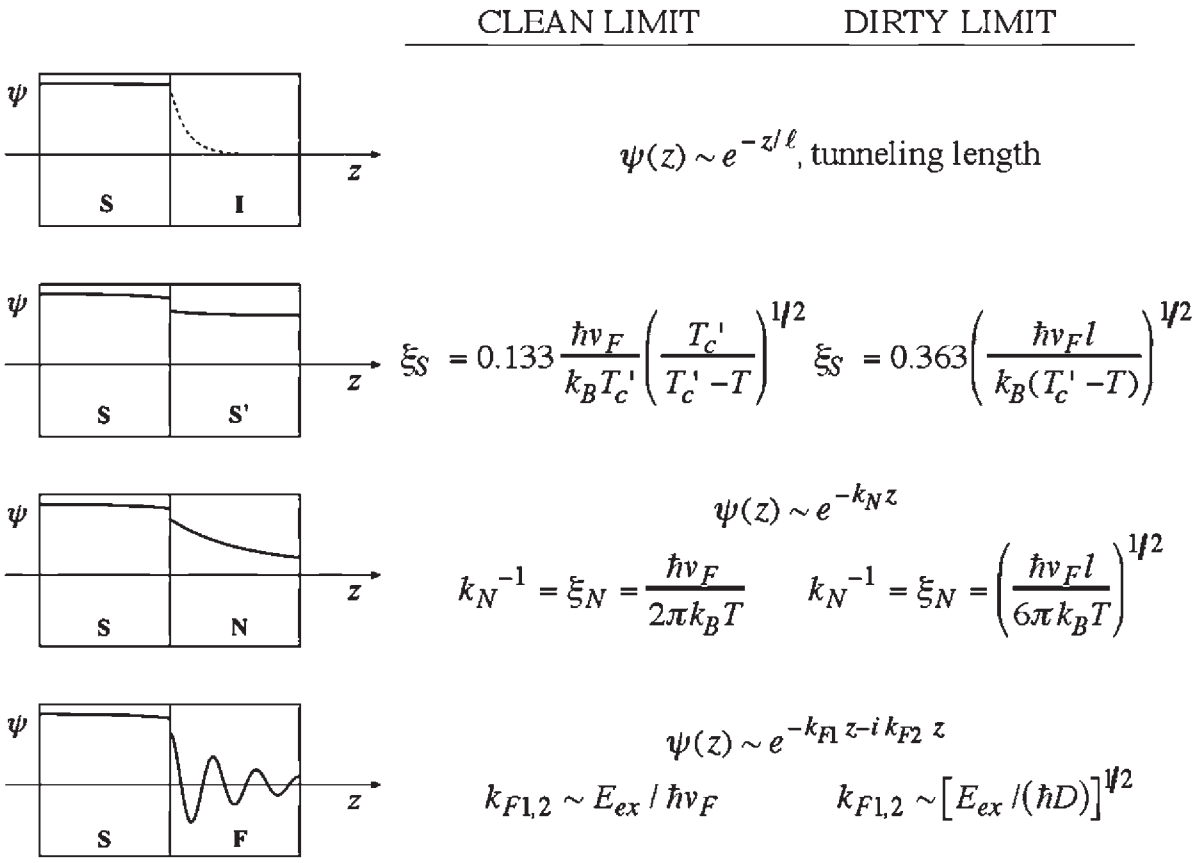

***Figure 2***
Comparison of the superconducting order parameter across various interfaces and their relevant length scales in the clean and dirty material limits. $T_c'$ is the transition temperature of the S′ superconductor, $v_F$ is the Fermi velocity, $l$ is the mean free path, $D$ is the diffusion constant, and $E_{ex}$ is the exchange splitting in the ferromagnet.

multilayer. For a discussion of, for example, electronic transport perpendicular to the layers see *Josephson Junctions: High-$T_c$*. A number of properties of superconducting multilayers have been studied experimentally, with transition temperature and upper critical fields being among the most commonly studied. When a conducting material is adjacent to the superconductor the overall $T_c$ can be reduced due to an averaging of the pairing function with the N or F layer. For the case of the magnetic material in contact with the superconductor, there is additional proximity-induced magnetic pair breaking in the S layers.

### *1.2 Dimensionality of Superconducting Multilayers*

Multilayer superconductors can be distinguished according to whether the individual superconducting layers are thick or thin compared with their intrinsic, i.e., intralayer, temperature-dependent GL coherence length $\xi(T)$. If the layer thickness $d_S > \xi(T)$ then the layers themselves are three-dimensional and exhibit bulk material properties. In this case the layering only introduces planar defects to the superconductor which could be of interest for flux pinning and critical currents when a registration of the vortex lattice occurs with the multilayer lattice. If $d_S < \xi(T)$, then the individual layers are two-dimensional. The behavior of the whole system will depend on the strength of the coupling across the mediating layers.

The dimensionality of a superconducting multilayer is not dependent on the detailed nature of the coupling, but can be described macroscopically by a coherence length in the direction perpendicular to the layers, called $\xi_z$. This perpendicular coherence length reflects the coupling between the S layers. For $\xi_z(T) \gg s$ the system will behave as a bulk anisotropic superconductor. For systems where the $\xi_z(T) \leqslant s$ one can expect a cross-over from three-dimensional to two dimensional behavior as a function of temperature when $\xi_z(T)$ reaches $\sim s$. This classification is summarized in Table 1. The theoretical model described below illustrates this cross-over behavior quantitatively.

***Table 1***
Classification of superconducting multilayers according to dimensionality.

| Length scale condition | Dimensionality of the system | Behavior of macroscopic superconducting properties |
|---|---|---|
| $\xi_S < d_S$ | 3D; weakly coupled | 3D isotropic |
| $\xi_S > d_S$, $\xi_z < s$ | 2D; weakly coupled | 2D single film-like |
| $\xi_S > d_S$, $\xi_z > s$ | Quasi-2D; strongly coupled | 3D anisotropic |

## *2. Magnetic Properties of Superconducting Multilayers*

The upper critical field phase boundary is one of the macroscopic properties that directly reflects on the size of the superconducting coherence length in the material and the dimensionality of superconductivity. Another example, which is not discussed here in detail, are the superconducting fluctuations above $T_c$, where the size of the volume for averaging the fluctuations is also $\xi(T)$.

### *2.1 Ginzburg–Landau Description of Anisotropic Superconductors*

The GL description of superconductivity follows the Landau theory for a two-component order parameter phase transition. The GL free energy of a superconductor in the presence of a magnetic field can be written as

$$F = F_0 + \int \left[ \alpha |\psi|^2 + \frac{\beta}{2}|\psi|^4 + \frac{1}{2m^*}\left| \left( \frac{\hbar}{i}\nabla - \frac{e^*}{c}\mathrm{A} \right)\psi \right|^2 + \frac{1}{8\pi}B^2 \right] \mathrm{d}^3 r$$

where $\alpha = \alpha'(T - T_c)$ and $m^* = 2m$, $e^* = 2e$, and upon variation with respect to $\psi$, the usual GL equation is obtained:

$$\alpha\psi + \beta|\psi|^2\psi + \frac{1}{2m^*}\left( \frac{\hbar}{i}\nabla - \frac{e^*}{c}\mathbf{A} \right)^2 \psi = 0 \qquad (1)$$

The GL formulation is often generalized to an anisotropic form where the mass $m^*$ is replaced by an effective-mass tensor, such as

$$\frac{\mathbf{1}}{\mathbf{m}^*} \equiv \begin{pmatrix} \frac{1}{m_x} & 0 & 0 \\ 0 & \frac{1}{m_x} & 0 \\ 0 & 0 & \frac{1}{m_z} \end{pmatrix} \qquad (2)$$

for a uniaxial system as a multilayer where $z$ axis is the symmetry direction.

Associated with this anisotropic mass tensor are the anisotropic GL coherence lengths and magnetic field penetration depths,

$$\xi_{x,z} \equiv \left( \frac{\hbar^2}{2|\alpha| m_{x,z}} \right)^{1/2} \quad \text{and} \quad \frac{1}{\lambda_{x,z}} = \left( \frac{4\pi e^* 2|\psi|^2}{c^2 m_{x,z}} \right)^{1/2}$$

In a layered superconductor $\xi_z(T)$ reflects the effective coupling across superconducting layers and not

an intrinsic property of a single layer. As $T \to T_c$ the coherence length always diverges and the superconductor inherently averages over many layers in a multilayer. This means that the anisotropic GL model described here is always applicable and $\xi_z(T)$ can be defined.

The upper critical field of a Type II superconductor is the field at which superconductivity is destroyed via a second-order phase transition. Theoretically it can be obtained by determining the temperature at which the linearized Eqn. (1),

$$\alpha\psi + \frac{1}{2m^*}\left(\frac{\hbar}{i}\nabla - \frac{e^*}{c}A\right)2\psi = 0 \tag{3}$$

in an applied magnetic field **H**, along the **z** direction, has a nontrivial solution. Using the Landau gauge, $\mathbf{A} = H_0\hat{\mathbf{y}}x$, and, separating variables, one obtains the following eigenvalue equation

$$\frac{\hbar^2}{2m^*}\left[-\frac{d^2}{dx^2} + \left(\frac{e^*Hx}{c}\right)^2\right]\psi = -\alpha\psi = \varepsilon(H)\psi \tag{4}$$

where $H_{c2}(T)$ is given by the implicit relation $\varepsilon(H) = -\alpha(T) = \hbar^2/[2m^*\xi(T)^2]$, where $\xi(T) = \xi(0)\sqrt{(T_c/T_c - T)}$. Equation (4) is equivalent to a Schrödinger equation of a harmonic oscillator with frequency $\omega_c = |e^*|H_0/m^*c$ and Landau levels. Hence, the lowest eigenvalue, corresponding mathematically to the highest field at which superconductivity can nucleate, is $\varepsilon(H) = \hbar e^* H/2m^*c$, from which it follows that

$$H_{c2} = \frac{\Phi_0}{2\pi\xi(0)^2}\frac{T_c - T}{T_c} \tag{5}$$

where $\Phi_0 = hc/e^*$ is the superconducting flux quantum. At $H_{c2}$ the density of vortices $\sim\xi^{-2}(T)$ is such that the superconductor becomes filled with normal cores of vortices.

From Eqn. (5) the temperature dependence of $H_{c2}$ is linear near $T_c$ for a three-dimensional superconductor. Note that it is the coherence lengths in the two directions perpendicular to the applied field $H$ that enter into Eqn. (5).

### 2.2 *Superconducting Thin Films*

In a superconducting thin film of thickness $d$, $T_c$ will usually decrease as $d$ is reduced due to changes in electronic interactions and reduced dimensionality. Neglecting these effects, however, and by treating $T_c$ and $d$ independently, one can solve Eqn. (3) for the case of a parallel magnetic field. The appropriate boundary condition for a free surface is

$$\left(\nabla - \frac{ie^*}{\hbar_c}\right)\psi \cdot \hat{\mathbf{n}} = 0,$$

where **n** is the unit vector normal to the surface. One can apply a solution (see Ketterson and Song 1999, for example) of the form $\psi = u(z)e^{ik_x x + ik_y y}$ and obtain

$$H_{c2\parallel} = \frac{\sqrt{12}\Phi_0}{2\pi\xi(T)d} \tag{6}$$

In comparison with Eqn. (5), one $\xi(T)$ factor is replaced with $d/\sqrt{12}$, and therefore the critical field has a square root temperature dependence instead of a linear one. These two behaviors are referred to as 2D (square root) and 3D (linear). In the perpendicular direction thin films have the critical field, $H_{c2\perp}$, the same as the bulk value of Eqn. (5).

### 2.3 *Superconducting Multilayers and Dimensional Crossover*

In a multilayer superconductivity can have either 2D or 3D character. These behaviors and their cross-over can be illustrated with a simple GL model. Lawrence and Doniach (1971) first described the modified GL free-energy functional of a series of superconducting layers which are Josephson coupled—a 1D Josephson lattice.

$$F = \sum_n \int d^2r \left[\alpha|\psi_n|^2 + \frac{\beta}{2}|\psi_n|^4 + \frac{1}{2m^*}\left|\left(\frac{\hbar}{i}\nabla - \frac{e^*}{c}\mathrm{A}\right)\psi\right|^2 + \eta|\psi_{n+1} - \psi_n|^2\right]$$

From the free energy functional the GL equation can be derived by variation as

$$\alpha\psi_n + \beta|\psi_n|^2\psi_n + \frac{1}{2m^*}\left(\frac{\hbar}{i}\nabla - \frac{e^*}{c}\boldsymbol{A}\right)^2\psi_n - \eta(\psi_{n+1} - 2\psi_n + \psi_{n-1}) = 0 \tag{7}$$

The first part of this equation is the 2D result, where individual layers are indexed with $n$. The second part represents the Josephson coupling energy, scaled by the coupling parameter $\eta$. In the limit of strongly coupled layers, i.e., when $\psi_n$ varies slowly across the layers, the solution is the same as the anisotropic GL, with the mass

$$m_z = \hbar^2/2s^2\eta$$

Within the LD model one can solve for arbitrary coupling of the layers, i.e., not assuming strong coupling. The linearized GL equation in a parallel magnetic field becomes

$$\left[-\frac{\hbar^2}{2m^*}\frac{d^2}{dx^2} + \frac{\hbar^2}{m_z^* s^2}\left(1 - \cos\frac{2eHxs}{\hbar c}\right)\right]\psi = -\alpha\psi$$

From this equation the critical field follows as

$$H_{c2\parallel} = \frac{\Phi_0}{2\pi s^2(1 - s^2/2\xi_z(T)^2)^{1/2}}\left(\frac{m_x^*}{m_z^*}\right)$$

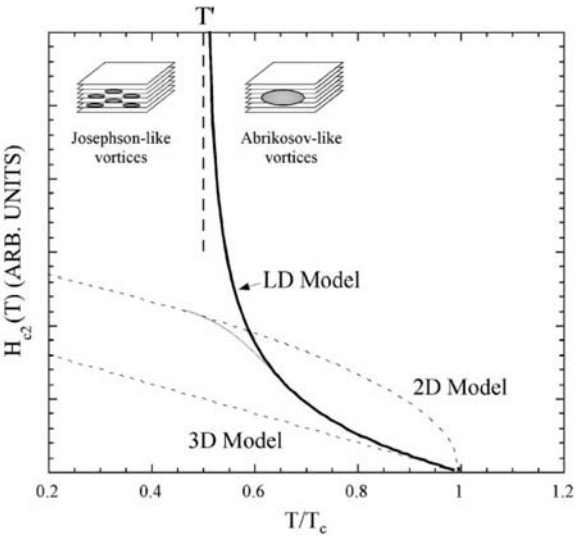

***Figure 3***
Temperature dependence of the upper critical field for the Josephson coupled Lawrence–Doniach (LD) model. Comparison is shown with the 3D GL and 2D GL models. In reality the critical field will not diverge at $T'$ as in the LD model, but will cross over to a 2D behavior. Below $T'$ vortices fit between the superconducting layers and become Josephson type. Above $T'$ vortices are averaging over several layers and are Abrikosov-type.

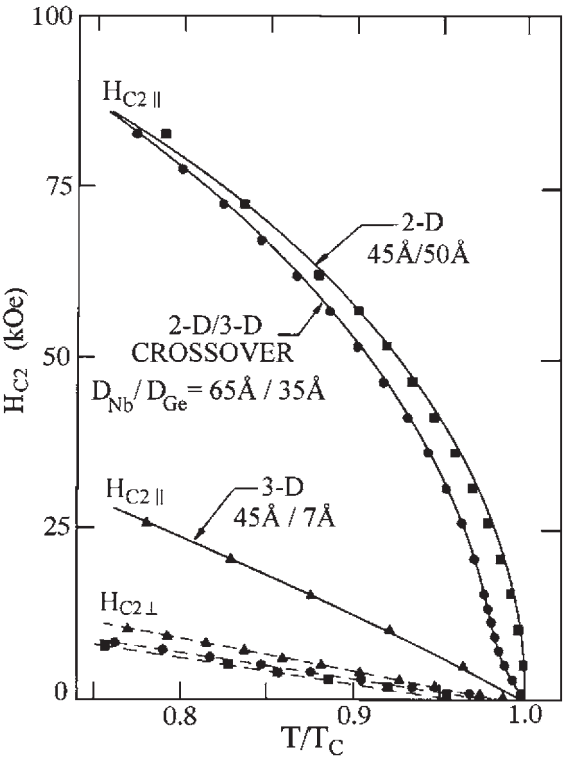

***Figure 4***
Upper critical fields near $T_c$ for Nb/Ge multilayers. As the Ge layer thickness increases the system evolves from 3D behavior to "crossover" behavior and finally to decoupled 2D. Solid lines are fits to the theory (after Ruggiero *et al.* 1980).

This equation leads to a divergence of the critical field at $T'$ defined by $\xi_z(T') = s/\sqrt{2}$ (see Fig. 3).

Above $T'$ the multilayer behaves as a 3D anisotropic superconductor. As the temperature is lowered the coherence length decreases its zero temperature value. When the coherence length becomes comparable to the spacing of the superconducting layers, the normal cores of the vortices can fit between the superconducting layers where they have a reduced pair-breaking effect. Hence the critical field will increase at this temperature and in the LD model the critical field becomes infinite. In reality the critical field will not diverge because it is limited by the single film value, such as that described above. However, the essential physics is captured in this simple model for dimensional crossover. Below $T'$ the vortices change from Abrikosov-like to Josephson-like when the X layers are nonsuperconducting.

Dimensional crossover was experimentally confirmed by a number of experimental reports. The first most compelling result was by Ruggiero *et al.* (1980). Other reports can be found in the reviews mentioned above. Ruggiero *et al.* studied Nb/Ge (S/I) multilayers as a function of different layer thicknesses in order to observe dimensional crossover. Figure 4 shows the upper critical field of several Nb/Ge multilayer samples with 3D, 2D, and crossover behavior. Later studies have observed the crossover more elaborately in S/N systems (see, for example, Banerjee *et al.* 1983).

### *2.4 Takahashi–Tachiki Effect in S/S′ Multilayers*

Takahashi and Tachiki (1986a, 1986b) examined the behavior of the upper critical field in S/S′ multilayers within a microscopic theory. For the case of widely differing diffusion constants, i.e., differing $\xi$, but with similar bulk $T_c$ of the two superconducting layers, they observed two possible solutions for nucleation of superconductivity. One solution is for nucleation of the superconducting order parameter in the dirty superconductor, here labeled S, and the other for nucleation of superconductivity in the clean superconductor, or S′, layers. The actual critical field will be the larger of the two solutions.

The Takahashi–Tachiki effect is a discontinuity in the parallel upper critical field exhibiting an upward curvature at low temperatures. This happens when

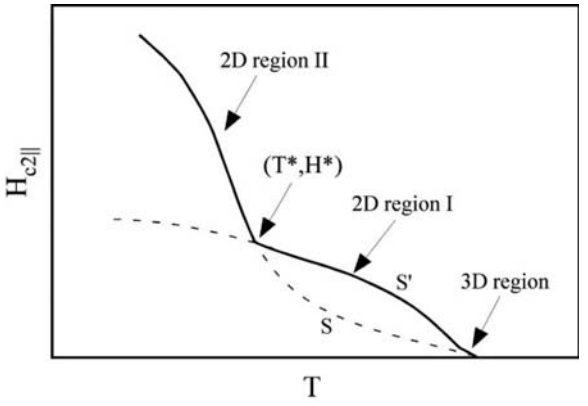

***Figure 5***
Schematic of the Takahashi–Tachiki effect (after Takahashi and Tachiki (1986b).

nucleation of superconductivity switches from S′ to S layers. Figure 5 illustrates the behavior of the critical field for a particular set of material parameters where this effect may be observed. The effect is only observed for a ratio of diffusion constants above a certain value, or equivalently above a minimum $\xi_{S'}/\xi_S$.

For temperatures very close to $T_c$ the parallel critical field has the usual linear 3D behavior. At some temperature below $T_c$ there is a crossover to 2D behavior with nucleation in the S′ layers. As the temperature decreases further and the coherence length becomes shorter than $d_S$, the order parameter is constrained inside the S layers and superconductivity behaves as it would in the bulk S material which has a high critical field. At $T^*$ superconductivity crosses over from being nucleated in the S′ to the S layers and there is a discontinuity in the critical field.

The theoretical prediction of the effect was subsequently experimentally confirmed in the Nb/NbTi multilayer system by Karkut *et al*. (1988). For the proper choice of materials, as in $Nb_{0.6}Ti_{0.4}$ and Nb, the two layers have similar $T_c$ but their diffusivities differ by a factor of 20. Karkut *et al*. observed an upturn in the parallel critical field at a particular temperature $T^*$ as predicted by the Takahashi–Tachiki theory.

## Fullerene Formation

Diamond and graphite constitute two natural crystalline forms of pure carbon. Their properties and characteristics are completely different, a fact that can be explained in terms of the way carbon atoms

bond to each other within the structure. For diamond, $sp^3$ hybridization prevails, four bonds from each carbon atom being directed towards the corners of a regular tetrahedron. The resulting three-dimensional network is extremely rigid, which is one reason for the hardness of diamond. In graphite, $sp^2$ hybridization results in three bonds per carbon atom, distributed evenly (120°) in the *xy* plane, with a weak $\pi$ bond along the *z* axis. The C–C bond length is 1.42 Å, and the $sp^2$ set creates the honeycomb (hexagonal) lattice typical of a single sheet of graphite. The $\pi$ (van der Waals) bond is responsible for weak interactions between the layers, which are 3.35 Å apart.

For generations, diamond and graphite were the only known allotropes of carbon. However, in 1985 a new form of carbon, buckminsterfullerene ($C_{60}$) (Kroto *et al*. 1985), appeared on the scene.

$C_{60}$ is a soccer-ball-like cage composed of 60 carbon atoms with a diameter of 7.1 Å. The shape and symmetry of $C_{60}$ is that of a truncated icosahedron, consisting of 20 hexagons and 12 pentagons (Fig. 1). Curvature is due to the presence of the pentagons.

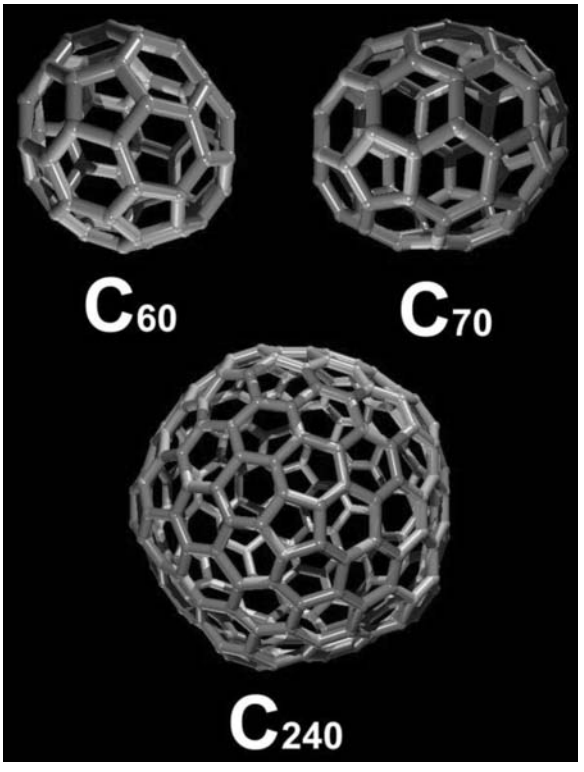

***Figure 1***
(a) Buckminsterfullerene ($C_{60}$), the third carbon allotrope, discovered in 1985. (b) $C_{70}$ with $D_{5h}$ symmetry. (c) $C_{240}$, an icosahedral giant fullerene.

The relationship between the vertices, faces, and edges of $C_{60}$ finds expression in Euler's law (see Sect. 3). $C_{60}$ is but one example of closed structures made up of any number of hexagons (except one) and 12 pentagons now styled fullerenes.

## *1. Discovery of $C_{60}$*

One part of this story starts in the 1970s, when the chemists Harry Kroto and David Walton at Sussex University were studying cyanopolyynes $H(C{\equiv}C)_nC{\equiv}N$ (chain-like molecules, in which carbon atoms are linked by alternating single and triple bonds, being end-capped with hydrogen and nitrogen). These compounds display characteristic microwave spectra commensurate with their linear dipole structure (Kroto 1992).

The two Sussex scientists together with Anthony Alexander (a BSc-by-thesis student) succeeded in preparing $HC_5N$ and, with Colin Kirby (a research student), $HC_7N$. Subsequently, with Canadian astronomers Takeshi Oka and co-workers, radio waves emitted from $HC_nN$ ($n = 5, 7, 9$) in the center of our galaxy were detected (Kroto 1992).

In 1984 Kroto visited Robert Curl at Rice University (Houston, Texas) and was introduced to Richard Smalley, who was generating clusters of atoms by laser-vaporizing solids. Kroto was interested in subjecting graphite to this treatment in order to simulate the conditions thought to prevail in red giant stars.

In late August 1985 Kroto traveled to Houston in order to participate in the graphite experiment, which involved evaporating carbon from the surface of a rotating graphite disk in the presence of a high density helium flow. The resulting carbon clusters were allowed to expand though a nozzle and were detected by a time-of-flight mass spectrometer (Kroto *et al*. 1985).

The mass-spectral profile for carbon, obtained in these experiments, had in fact already been observed by Rohlfing *et al*. (1984) and consisted of two main groups of clusters: (a) those with low mass ($<30$ carbon atoms) consisting of odd numbers of carbon atoms and (b) high-mass clusters ($>36$ atoms) containing only even numbers of carbon atoms (Fig. 2). Rohlfing *et al*. (1984) proposed that clusters with less than nine carbon atoms were linear chains, and that the odd masses between 11 and 23 were due to rings. No comment was made regarding the structure of higher clusters other than that they were exceptional and possibly carbyne-like (consisting of linear carbon chains with alternating single and triple bonds, i.e., polyynes).

In the experiments carried out at Rice University, the dominant role played by the cluster of 60 carbon atoms was noted and its stability was ascribed to the unique nature of the truncated icosahedral cage (see above) without "dangling" bonds (Fig. 1). $C_{60}$ was named buckminsterfullerene by the Sussex/Rice

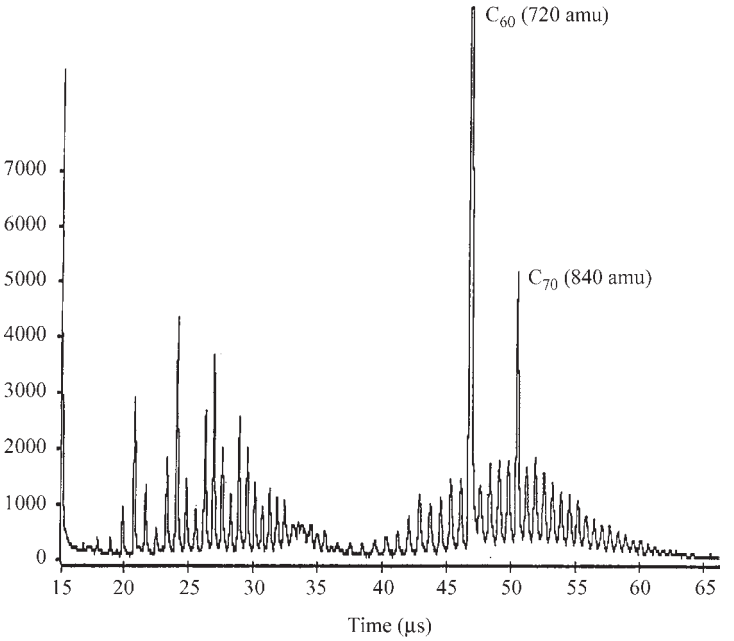

***Figure 2***
Mass-spectral profile obtained by the Sussex/Rice team, showing $C_{60}$ and $C_{70}$ as the most intense peaks. Additionally, they observed two groups of clusters: those with lower mass (<30 carbon atoms) consisting of odd numbers of carbon atoms and high-mass clusters (>36 atoms) exhibiting only even numbers of carbon atoms (courtesy of H. W. Kroto).

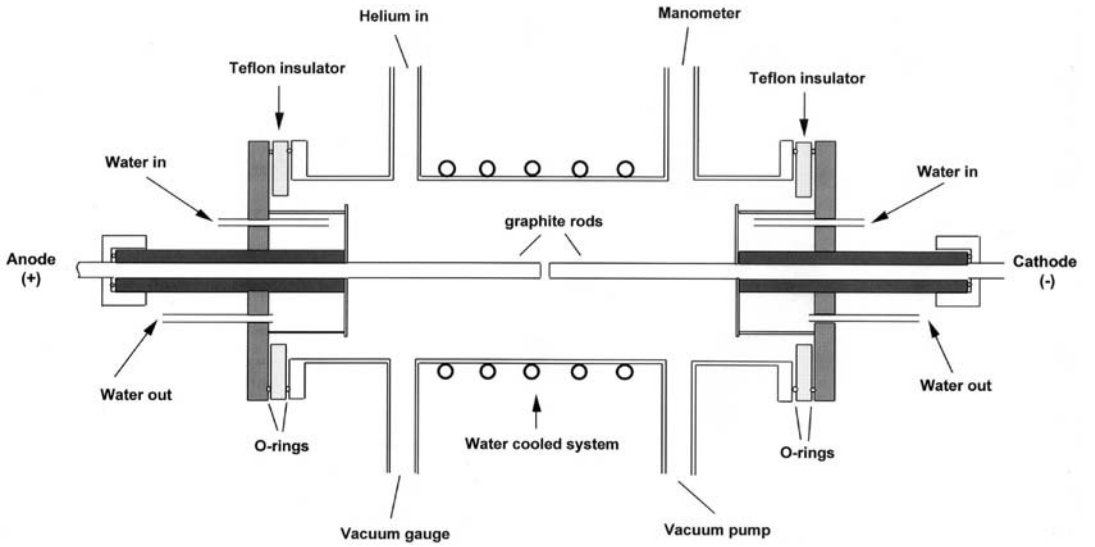

***Figure 3***

team, in recognition of the US architect R. Buckminster Fuller, who designed geodesic domes with similar topologies.

In order to verify the structure of $C_{60}$, bulk quantities were needed. However, at the time only picogram amounts were available.

## 2. *Bulk Production and Characterization of $C_{60}$*

In 1990 Krätschmer and Huffman succeeded in preparing milligram quantities of $C_{60}$, accompanied by smaller amounts of higher fullerenes (e.g., $C_{70}$, $C_{76}$, etc.) by extracting soluble material from soot deposits formed in an arc discharge between graphite electrodes in a helium atmosphere (Fig. 3). Subsequently, $C_{60}$ and $C_{70}$ were separated and characterized by the Sussex team using conventional chromatography and NMR techniques. Fullerenes have also been obtained by combustion and by pyrolysis of hydrocarbons such as naphthalene.

In the solid state, $C_{60}$ crystallizes as a cubic structure with a lattice constant of 14.17 Å, a nearest-neighbor $C_{60}$–$C_{60}$ distance of 10.02 Å, and a density of 1.72 g cm$^{-3}$ (Fig. 4(a)). At room temperature, $C_{60}$ clusters rotate rapidly in an f.c.c. structure about their lattice positions (Tables 1 and 2). However, a transition to a simple cubic phase ($a = 14.17$ Å consisting of four $C_{60}$ clusters per unit cell) occurs below 261 K (Tanigaki and Prassides 1995).

The first fullerene isolated other than $C_{60}$, was $C_{70}$ (isolated by Taylor *et al.*), which consists of two $C_{60}$ hemispheres connected by a ring of 10 carbons (resembling a rugby ball; Fig. 1). Crystalline $C_{70}$ has different crystallographic arrangements depending on the temperature: the most stable phases are the f.c.c. structure with a lattice constant of 15.01 Å and the hexagonal phase with $a = b = 10.56$ Å and $c = 17.18$ Å. Higher fullerenes such as $C_{76}$, $C_{78}$, $C_{82}$, $C_{84}$, were subsequently isolated and characterized.

## 3. *Geometry of Fullerenes*

Fullerenes are closed polyhedrons made of carbon, and understanding their geometry may eventually shed light on the way they are constructed. As mentioned above, Euler's law expresses the proportions of polygon types (pentagons and hexagons) needed to form $C_{60}$. For any polyhedron $F - E + V = \chi$, where $F$ is the number of faces, $E$ is the number of edges, $V$ is the number of vertices, and $\chi$ is the Euler characteristic, which is a geometric invariant that describes structures with the same shape or topology. For all closed polyhedrons $\chi = 2$. For example, in $C_{60}$, $F = 32$ (12 pentagons and 20 hexagons), $E = 90$, $V = 60$, and $\chi = 2$; for $C_{70}$, $F = 37$ (12 isolated pentagons, 25 hexagons, and $D_{5h}$ symmetry), $E = 105$, $V = 70$, and $\chi = 2$. All closed polyhedrons have the same topology as the sphere, which means that any polyhedron can be transformed into a sphere by bending and stretching without cutting or tearing. In addition, no fullerene can be formed from an odd number of atoms.

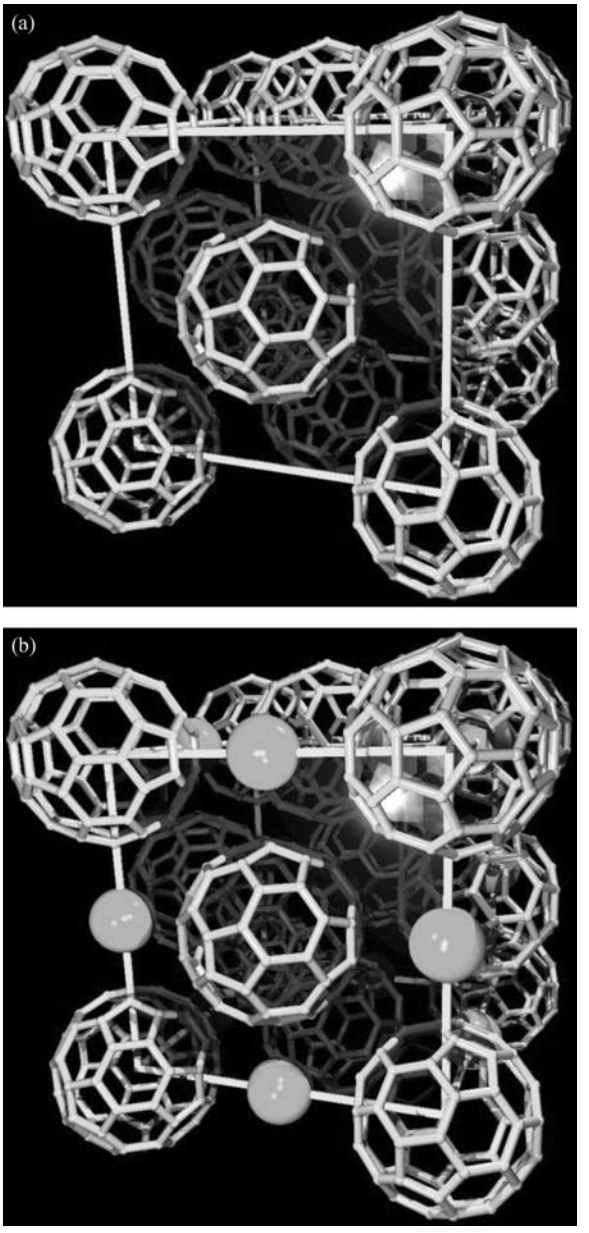

***Figure 4***

of carbon, Euler's law can be written:

$$N_5 - N_7 - 2N_8 = 6\chi = 12 \qquad (1)$$

where $N_n$ is the number of polygons with $n$ (5, 7, and 8) sides. As Eqn. (1) shows, $N_5$, $N_7$, and $N_8$ are defects in a "graphitic" structure which contribute to the curvature and topology of the arrangement (Terrones and Mackay 1992). $N_6$ is absent since hexagons do *not* contribute to curvature of the structure. In addition, Eqn. (1) demonstrates that it is possible to introduce heptagons and octagons in a closed graphitic cage if their proportion is maintained. Therefore, if pentagons are present in $C_{60}$, one cannot rule out the presence of higher-membered rings (e.g., heptagons) in larger fullerenes.

It turns out that there are 1812 possible ways of arranging 12 pentagons and 20 hexagons in $C_{60}$, so what is special in buckminsterfullerene? It is the smallest cage in which each pentagon is surrounded by five hexagons, thus leading to icosahedral ($I_h$) symmetry (the highest symmetry than can be obtained by a polyhedron). This suggests that curved graphite follows an isolated pentagon rule to form fullerenes, and explains why smaller fullerenes (less than 60 atoms) are difficult to produce.

## 4. *Fullerene Growth*

Although the precise growth mechanism leading to $C_{60}$ and other fullerenes is not well understood, it is worth reviewing ways in which they might be formed. First, the mass spectrometry data obtained by laser vaporization and arc discharge experiments indicate that there are three main groups of structures, depending upon the size: chains, rings, and fullerenes. In other words, for a small number of atoms ($<10$) carbon chains are the most stable (one dimension); subsequently rings start to appear ($>10$ atoms), thus avoiding dangling bonds at the ends (two dimensions); and finally fullerenes emerge in order to avoid dangling bonds in larger, three-dimensional structures.

According to Euler's law, the smallest fullerene that can possibly exist is the dodecahedron with 20 atoms or 12 pentagons ($C_{20}$; Fig. 5). Although this structure is quite regular (one of the five Platonic solids), with icosahedral symmetry, building it from sp$^2$ carbons introduces considerable strain. This is because the internal angle in a regular pentagon is 108°, which differs substantially from the internal (hexagon) 120° angles in graphite. Therefore, in order to relieve this strain, hexagons are required to stabilize larger fullerenes. At the same time, with 20 atoms, it is also possible to obtain a ring (cyclic polyyne) or a

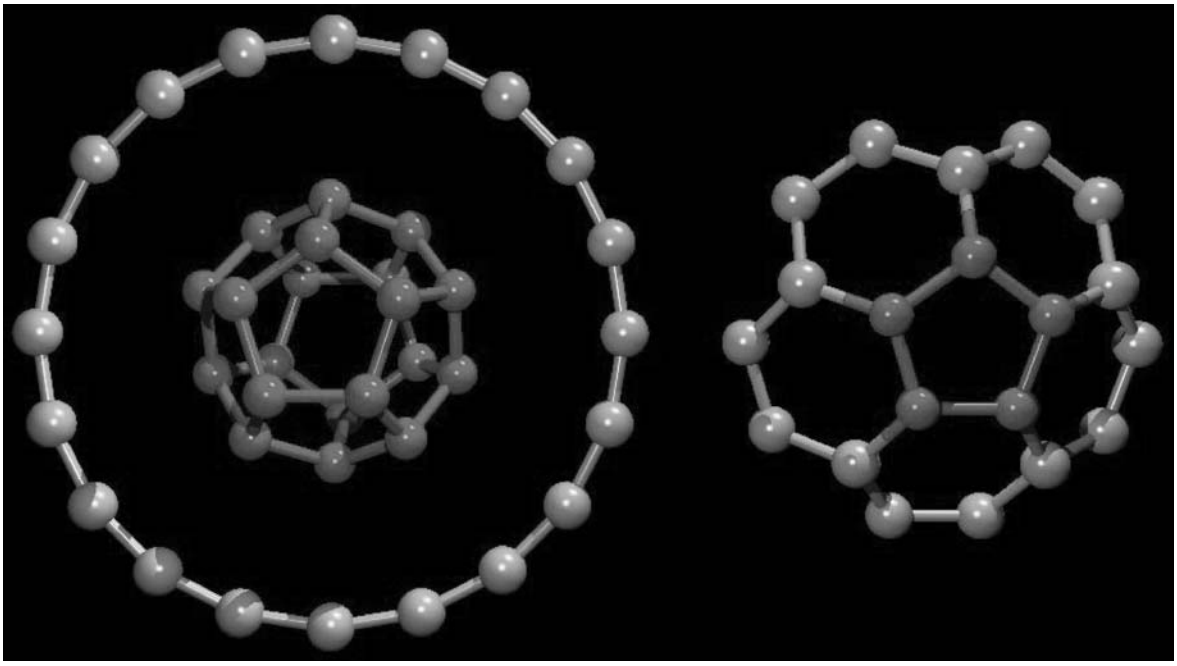

***Figure 5***
Possible isomers of $C_{20}$: (a) ring, (b) cage, and (c) bowl (corannulene-like molecule).

corannulene-like molecule (a bowl-shaped structure composed of one pentagon surrounded by five hexagons; Fig. 5). Various theoretical simulations have been carried out in order to ascertain which is the most stable structure composed of 20 atoms. The results show that, depending upon the computational method used, the ring, the corannulene-like molecule, and the dodecahedron are stable and feasible. However, for fullerene formation (under nonequilibrium conditions), corannulene and the dodecahedron might be relevant due to the presence of pentagons in their structures. Nevertheless, neither of them has ever been observed as a stable product.

It is worth noting that fullerenes are formed in a plasma at 3500 °C and under these conditions a wide variety of carbon clusters are present, e.g., dimers, trimers, rings, and small clusters. Thus, structures of the corannulene type or the dodecahedral $C_{20}$ may play a crucial role in the formation of $C_{60}$ since $C_2$ or bigger units can become attached to the pentagons, thus stimulating growth.

Two main mechanisms have been proposed to account for fullerene formation (Dresselhaus *et al*. 1995). They are based upon: (a) absorption of $C_2$ units and (b) Stone–Wales (S–W) transformations. The absorption of a $C_2$ cluster creates an extra hexagon within the structure; therefore, the addition of several $C_2$ units into a fullerene would generate a larger cage. An S–W transformation involves rotating a $C_2$ unit by 90°, thus changing the symmetry but maintaining connectivity. A combination of these two mechanisms is necessary in order to attain a stable "graphitic" cage. Nevertheless, the amount of energy involved in an S–W transformation is large ($\sim$7 eV). In this context, it has been shown that autocatalytic effects might overcome the potential barrier involved in this type of transformation (Eggen *et al*. 1996). It is also worth noting that fullerenes smaller than $C_{60}$ have been detected only in mass spectrometers, with one exception being the $D_{6h}$ isomer of $C_{36}$, isolation of which has been claimed (Piskoti *et al*. 1998).

## *5. Endohedral Complexes, Intercalated Compounds and Superconductivity*

Kroto *et al*. (1985) suggested that it should be possible to encapsulate atoms within the $C_{60}$ cage. Shortly afterwards a Rice University student, Jim Heath, succeeded in trapping lanthanum in $C_{60}$ by laser vaporizing a graphite disk impregnated with $LaCl_3$ (Heath *et al*. 1985). Following the bulk production of $C_{60}$, fullerenes containing encapsulated elements, denoted $M@C_n$, have been described, e.g., $Ar@C_{60}$, $He@C_{60}$, $Hf@C_{28}$, $Ti@C_{28}$, $U@C_{28}$, $U_2@C_{28}$, $Zr@C_{28}$, $U@C_{36}$, $Co@C_{60}$, $Sc@C_{74}$, $Er@C_{82}$, $La@C_{82}$, $La_2@C_{82}$, $Sc@C_{82}$, $Sc_2@C_{82}$, $Sc_3@C_{82}$, $La@C_{84}$, $La_2@C_{84}$, etc. (Dresselhaus *et al*. 1995). The separation and isolation of these endohedrals is difficult because the amounts available are minute,

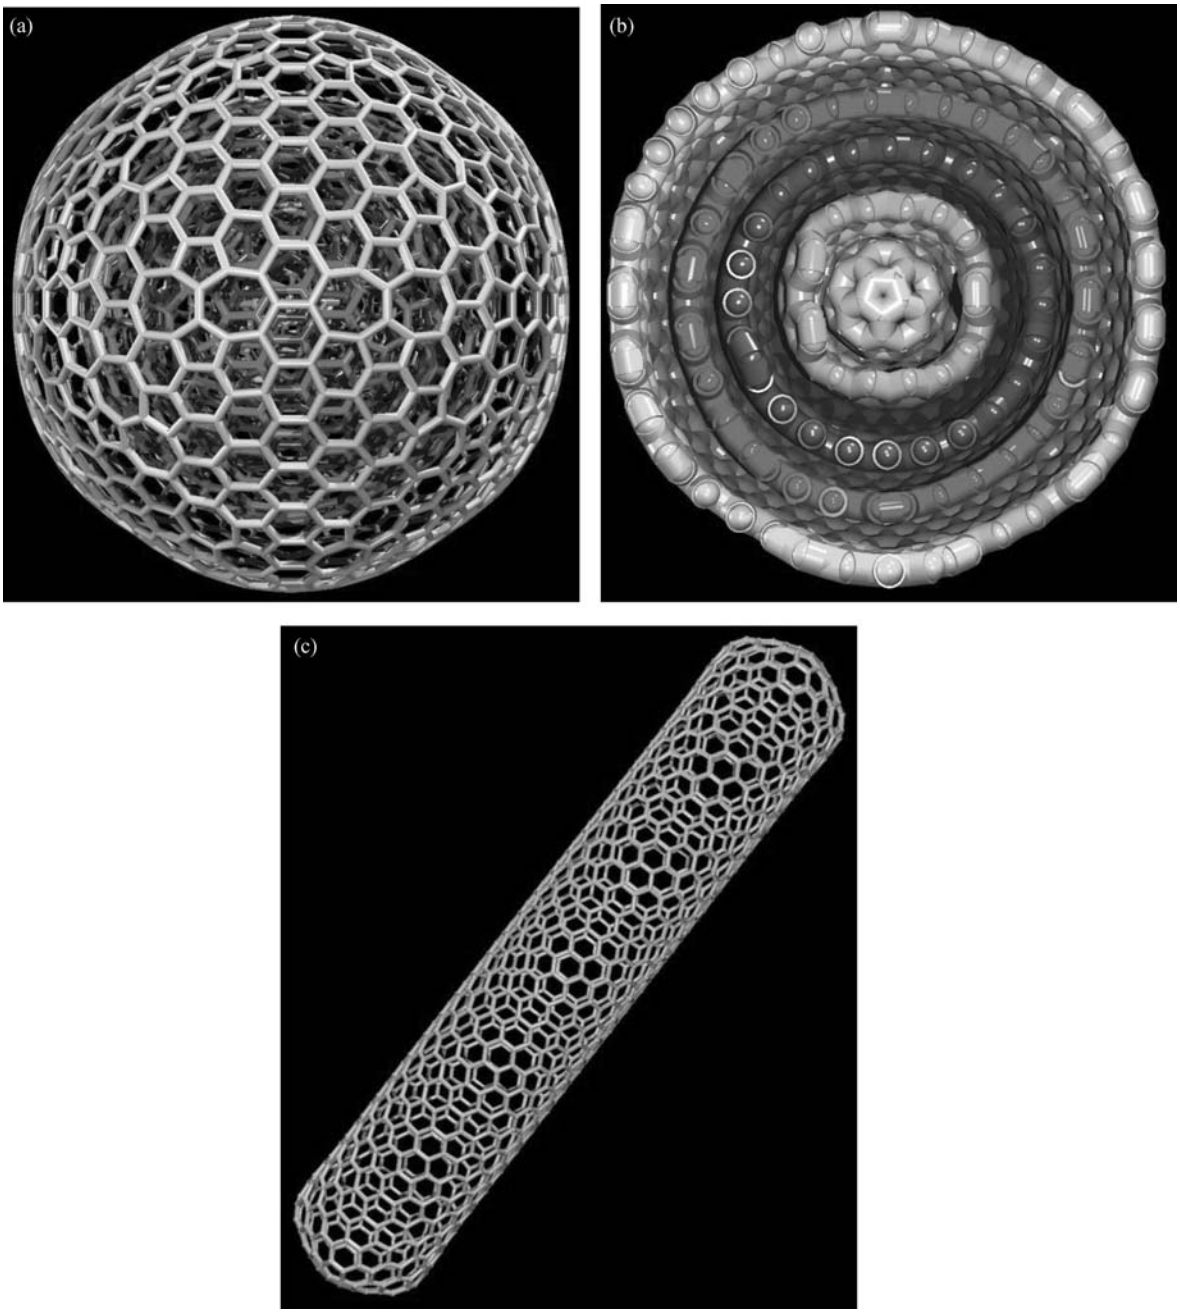

***Figure 6***
(a) Graphitic onion-like structures: concentric giant fullerenes with heptagons and additional pentagons. (b) Cross-section of the structure shown in (a) exhibiting concentric shells. (c) Elongated fullerene: a carbon nanotube.

there are solubility problems, and the products may be oxygen sensitive.

In 1991 Haddon and co-workers succeeded in intercalating alkali metals with $C_{60}$ in order to produce materials of stoichiometry $M_3C_{60}$ ($M = K$, Rb, Cs). These products displayed a relatively high, superconducting, value of $T_c$ (18–33 K) (Tanigaki and Prassides 1995). Other stable phases of intercalated $C_{60}$ were

prepared (e.g., $M_1C_{60}$, $M_3C_{60}$, and $M_6C_{60}$; Fig. 4(b)). All possess lattice constants greater than that of $C_{60}$ ($a = 14.24$ Å) due to the introduction of the metal ion into the crystal phase (Fig. 4(b)). It is important to note that superconductivity only arises when the tetrahedral and octahedral sites of $C_{60}$ are fully occupied by alkali atoms, thus creating a $M_3C_{60}$ structure. Other stable phases and crystal structures with one, two, four, and six alkali ions per unit cell have been also described.

## 6. Giant Fullerenes

In 1992 Daniel Ugarte discovered that carbon soot (generated in plasma arcs), under high-energy electron irradiation, produced what were effectively nested giant fullerenes, termed "graphitic onions" (Figs. 6(a) and 6(b)). It is interesting to note that in 1980 Iijima observed similar round structures in amorphous carbon films prepared by vacuum deposition (the morphology was proposed by Kroto and McKay in 1988). These closed polyhedrons possess millions of carbon atoms. It has been shown theoretically (Terrones *et al*. 1995) that the high sphericity of the onions is due to the presence of heptagons and octagons (Figs. 6(a) and 6(b); Eqn. (1)).

## 7. Uses of Fullerenes

Current fullerene research is developing rapidly and due to their exceptional properties (Tables 1 and 2), various applications can be envisaged. In particular, the optical properties have facilitated the fabrication of photodiodes and photovoltaic and photorefractive devices, etc. Fullerenes, in conjunction with conducting polymers, could give rise to $C_{60}$-based transistors and rectifying diodes. However, it should be pointed out that most of these $C_{60}$ devices are unstable in air due to the diffusion and photodiffusion of dioxygen into the large interball sites present in the solid.

From the catalysis point of view, fullerenes can be useful in the hydrocarbon refining industry, where an active catalyst is needed to enhance the efficiency with which hydrogen is used. Fullerenes can be used as a source of pure carbon in order to generate high-purity carbon allotropes such as diamond or nanotubes (see Sect. 8). In the nanotechnology area, $C_{60}$ and other "graphitic" particles may prove useful as scanning tunneling microscopy (STM) tips, lubricants, sensors, and other nanoscale devices.

Finally, $C_{60}$ has proved to be useful as an efficient inhibitor of HIV enzymes and research related to cancer treatments is underway. Therefore, this exciting area of research is likely to give birth to a new technology in the twenty-first century.

## 8. Elongated Fullerenes (Nanotubes)

The fullerenes reviewed above consist of closed, *round* cages. However, it is possible to generate elongated fullerenes, known as nanotubes (Fig. 6(c)). Iijima (1991) reported the existence of these structures, consisting of concentric graphite tubes, produced in the Krätschmer–Huffman fullerene reactor (operating at low direct current). A few months after Iijima's paper appeared, the first report on the bulk synthesis of nanotubes, by Ebbesen and Ajayan, was published. These authors collected the material from the inner deposit generated by arcing graphite electrodes in inert atmospheres (a similar procedure to that used for fullerenes).

Nanotubes can be produced by several methods (e.g., arc discharge, pyrolysis of hydrocarbons over catalysts, laser vaporization, electrolysis, etc.), with the products exhibiting various morphologies (e.g., straight, curled, hemitoroidal, branched, spiral, helical, etc.).

It has been predicted that carbon nanotubes may behave as metallic, semiconducting, or insulating nanowires depending upon their helicity and diameter. Conductivity measurements on bulk nanotubes, individual multilayered tubes, and ropes of single-walled tubules have revealed that their conducting properties depend strongly on the degree of graphitization, helicity, and diameter. Young's modulus measurements also show that multilayered nanotubes are mechanically much stronger than conventional carbon fibers (Terrones *et al*. 1999).

The advances typified by fullerenes and related structures herald a new age in nanoscale materials engineering. However, this may be only the "tip of the iceberg" since other layered structures (e.g., $MoS_2$, $WS_2$, $VS_2$, etc.) are also capable of creating closed cages.

## Fulleride Superconductors

The electronic and crystal structures of $C_{60}$ lead to a diverse chemistry based on the intercalation of electropositive elements into the interstitial sites within the solid and concomitant transfer of electrons to the fullerene. This produces solids with partially filled bands and results in a variety of phenomena including superconductivity (Hebard *et al.* 1991) at the highest temperatures yet seen for molecular solids.

### *1. Crystal and Electronic Structures of Solid $C_{60}$*

For a detailed description of fullerene solids (see *Fullerene Formation*). Face-centered cubic solid $C_{60}$ ($a = 14.17$ Å, $r(C_{60}–C_{60}) = 10$ Å) can to a first approximation be considered as the cubic close packing of 5 Å radius hard spheres. Simple radius ratio considerations then allow the calculation of the sizes of two tetrahedral (T, 1.1 Å) and one octahedral (O, 2.06 Å) interstitial site per $C_{60}$. The extensive intercalation chemistry of f.c.c. $C_{60}$ derives from the weak inter-$C_{60}$ forces and the size match between the octahedral and tetrahedral interstitial sites in the f.c.c. $C_{60}$ array and those of the cations of the electropositive elements.

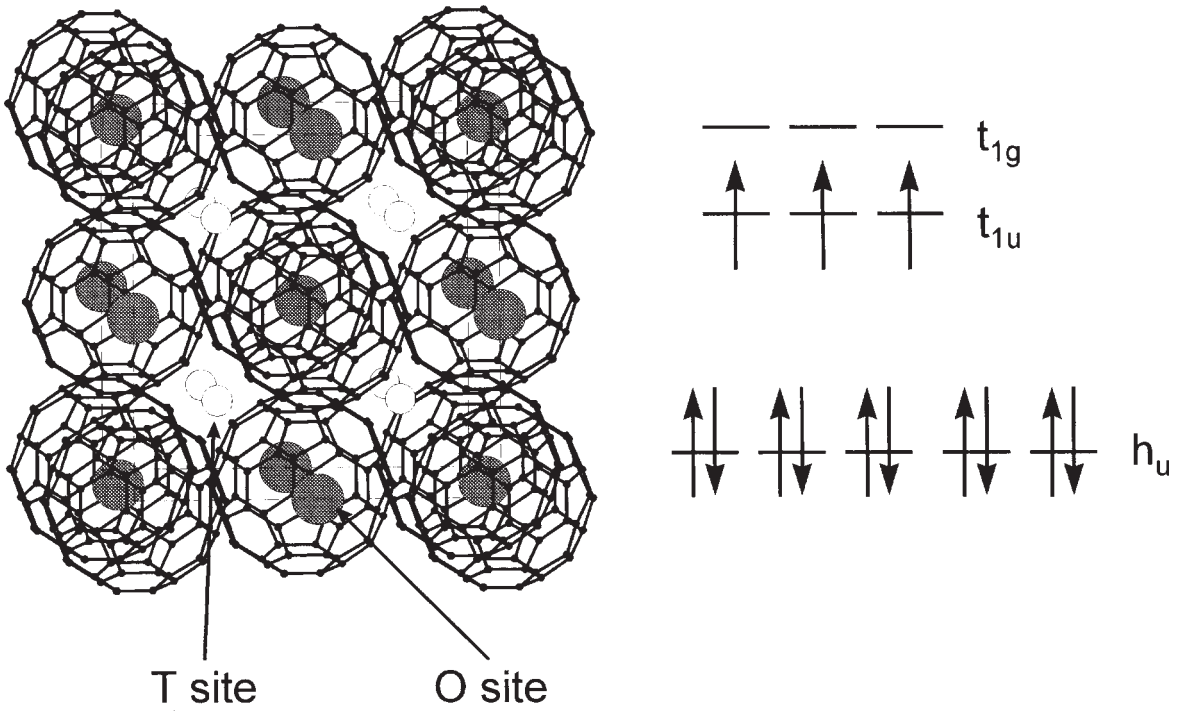

*Figure 1*
The ordered Fm3 structure of $A_3C_{60}$ (most phases, e.g., $K_3C_{60}$, have two-fold merohedral disorder of the $C_{60}^{3-}$ in space group Fm3m). Large gray spheres occupy the octahedral (O) site, and small unshaded spheres represent cations on the tetrahedral (T) sites. $Rb_2^TCs^OC_{60}$ is a site-ordered $A_3C_{60}$ phase. $A_1C_{60}$ phases, with only the O sites occupied, are known with both f.c.c. and polymer structures. $Na_2C_{60}$ results from occupancy of the T sites. $Na_{4+x}$ groups are found on the O sites in $Na_{6+x}C_{60}$. The frontier orbitals of the $C_{60}^{3-}$ anion are shown: the $(t_{1u})^3$ configuration produces a half-filled band and metallic behavior in $K_3C_{60}$.

The electronic structure of the molecule is important in determining the properties of the intercalates. The LUMO of $C_{60}$ is almost nonbonding in nature, accounting for the electronegative character of the molecule, and is triply degenerate with $t_{1u}$ symmetry. The $t_{1g}$"LUMO + 1" level is also chemically accessible, with possible anion charges of up to minus 12 (Fig. 1).

## 2. *Intercalate Structures*

### *2.1 Spherical Counterions*

Well-defined structural information exists for sodium, potassium, rubidium, caesium, calcium, strontium, barium, europium, samarium, and ytterbium intercalates (Rosseinsky 1998). An $A_1C_{60}$ rock-salt phase with the cation occupying the O site alone is formed for A = K, Rb, and Cs and may polymerize by [2 + 2] cycloaddition on cooling to form a unique air-stable linear-chain polymer if suitable cooling procedures are followed. A Pa 3 symmetry $Cs_1C_{60}$ phase is afforded by a particular cooling sequence. $Na_2C_{60}$ with sodium cations solely occupying the T sites forms due to the good size match: there is no analogue of this phase yet known for the other alkali metals.

The $A_3C_{60}$ phases are formed by complete occupancy of the O and T sites in the f.c.c. structure (Fig. 1). Cation ordering is observed when size differences are sufficiently pronounced (e.g., $Rb_2^TCs^OC_{60}$, $Na_2^TRb^OC_{60}$). Anion orientational order is controlled by cation size, with the structures of $K_3C_{60}$ (Fm3m) and $Na_2CsC_{60}$ (Pa3) being related by a 22° rotation of the anions around the [111] direction. Low-temperature polymerization is observed in slow-cooled Pa3 $Na_2RbC_{60}$, with the interfulleride bonding differing from the $A_1C_{60}$ polymers. $Yb_{2.75}C_{60}$ has a complex defect structure based on the $A_3C_{60}$ f.c.c. model, with vacancy ordering on the O site producing an eight-fold enlargement of the cell (Ozdas *et al.* 1995).

$Ba_3C_{60}$ is an $A_3C_{60}$ phase with b.c.c. packing, adopting the A15 structure of $Nb_3Sn$, with the caesium cations ordered over half of the interstitial sites in the $K_6C_{60}$ structure (Fig. 2(c)). This structure is also reported for $Cs_3C_{60}$, where the large $Cs^+$ cation forces a b.c.c. packing on the $C_{60}^{3-}$ anions due a size mismatch with the tetrahedral site in the f.c.c. structure.

$Li_3CsC_{60}$ adopts f.c.c anion packing with an $Li_2Cs$ unit on the octahedral site, but most $A_4C_{60}$ phases adopt the b.c.c. structure of $K_4C_{60}$. $Cs_4C_{60}$, $Ba_4C_{60}$, and $Sr_4C_{60}$ adopt an orthorhombic distortion of this structure due to anion orientational ordering (Fig. 2(b)). Like $Ba_3C_{60}$, these are also cation vacancy ordered derivatives of the $K_6C_{60}$ structure. $Na_4C_{60}$ adopts a unique two-dimensional polymerized structure.

$A_6C_{60}$ phases adopt the b.c.c. packing of $K_6C_{60}$ (Fig. 2(a)) with the cations in distorted tetrahedral sites. Alkali metal $A_6C_{60}$ salts are electrical insulators as the $(t_{1u})^6$ configuration produces a filled band. The small sodium cation can retain f.c.c. packing in $Na_6C_{60}$ with $Na_4$tetrahedral units on the octahedral site. This f.c.c. structure is retained up to $Na_{11}C_{60}$, with b.c.c. units on the octahedral site. $Ca_5C_{60}$ is f.c.c. but with an as-yet undefined superstructure, thought to be a defect $Na_6C_{60}$ type with similar $Ca_{4-x}$ units on the octahedral site.

### *2.2 Nonspherical Counterions*

The above structures are based on packing of near-spherical objects and all have close analogies in metal

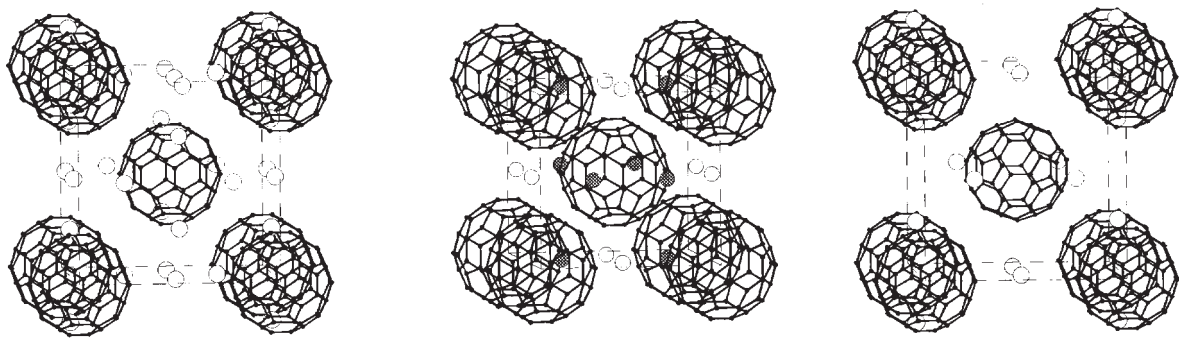

***Figure 2***
Body-centered fulleride arrays. (a) The Im3 $K_6C_{60}$ structure. The $K^+$ cations are in distorted tetrahedral sites. (b) The $A_4C_{60}$ structure, generated by ordered removal of one-third of the cations from (a). $Cs_4C_{60}$ and the $Sr_4C_{60}$ and $Ba_4C_{60}$ superconductors adopt an orthorhombic Immm structure with orientationally ordered anions, while $K_4C_{60}$ and $Rb_4C_{60}$ are tetragonal with disordered anions. (c) Ordered occupancy of half of the cation sites in (a) leads to the Pm3n $Ba_3C_{60}$ structure, in which the fulleride anions at the cell origin and body center adopt orientations related by 90° rotation about the cell vectors.

and alloy structures. Coordination of a ligand such as ammonia to the metal ion results in a complex ion whose size and symmetry are controllable and generally nonspherical. This results in new structure types (such as the expanded close-packed $(NH_3)_8Na_2C_{60}$ structure), new metal combinations (the $Cs_2NaC_{60}$ composition is multiphase, but a pure f.c.c. $Cs_2Na(NH_3)C_{60}$ phase is accessible with the linear Na–$NH_3$unit oriented in a disordered manner along with the [111] directions (Iwasa *et al.* 1997)), and opportunities to control the electronic properties of $C_{60}^{3-}$ phases in new ways (Rosseinsky 1998). The reaction of f.c.c. $K_3C_{60}$ with ammonia affords $(NH_3)K_3C_{60}^{3-}$ with the $NH_3$–K unit on the octahedral site. This lowers the symmetry to orthorhombic, resulting in the suppression of superconductivity and a metal–insulator transition at 40 K. Ion-exchange techniques allow access to transition metal substituted fullerides such as $Ni(NH_3)_6C_{60} \cdot 6NH_3$.

## 3. *Superconductivity in Fullerides*

The interest in fullerene intercalation chemistry stems from the discovery of superconductivity at a critical temperature ($T_c$) of 19 K in $K_3C_{60}$—this transition temperature was the highest found for a molecular solid. The interfulleride separation may be tuned by varying the size of the cations intercalated on the octahedral and tetrahedral sites, resulting in a monotonic increase in $T_c$ with lattice parameter (Fig. 3(a)). This is consistent with $T_c$ depending on $N(E_f)$, the density of states at the Fermi level, in a Bardeen–Cooper–Schrieffer (BCS)-like manner, as the increased interfulleride separation narrows the width of the $t_{1u}$ band. The same qualitative dependence of $T_c$ on interfulleride separation is apparent from studies of the pressure dependence of $T_c$ of $K_3C_{60}$ and $Rb_3C_{60}$, although the quantitative dependence differs slightly.

A range of experiments has clarified the empirical requirements for fulleride superconductivity. The observation of superconductivity in orthorhombic $Sr_4C_{60}$, $Ba_4C_{60}$, and $Yb_{2.75}C_{60}$ demonstrate that neither cubic symmetry nor a minus 3 fulleride charge is a prerequisite (Brown *et al.* 1999). However, $T_c$ does appear optimized at an anion charge of minus 3 in the $K_{3-x}Ba_xC_{60}$ and $Li_{2+x}CsC_{60}$ series. The relative orientations of the fulleride anions have a drastic effect on the $T_c(a)$ relationship—a 22° anion rotation about the [111] direction converts the Fm3m $K_3C_{60}$ structure into the Pa3 $Na_2CsC_{60}$ structure, resulting in a much more pronounced $T_c(a)$ slope. The highest reported transition temperature in an f.c.c. phase is 33 K in $Cs_2RbC_{60}$, while 40 K under 15 kbar pressure is reported for $Cs_3C_{60}$, which adopts a body-centered structure.

The fullerides present a challenge to theory (Gunnarsson 1997). The sharp peak in $T_c$ at a minus 3 charge (Fischer 1997) (Fig. 3(b)) has been explained using the density of states of an orientationally

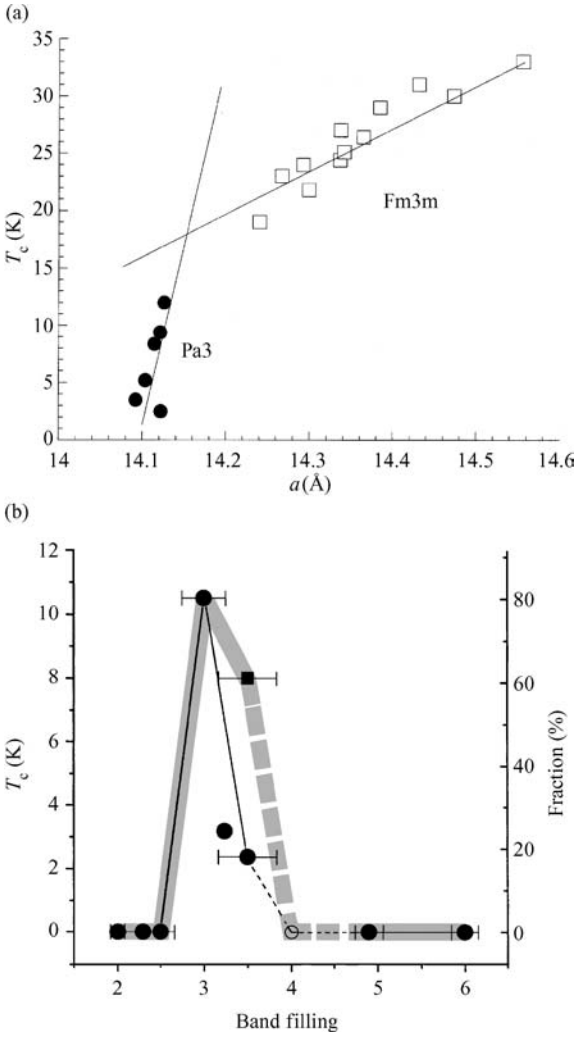

***Figure 3***
(a) Variation of $T_c$ with lattice parameter in $A_3C_{60}$ phases. Note the much steeper variation of $T_c$ with $a$ in the Pa3 family. (b) Variation of $T_c$ with charge per $C_{60}^{n-}$ anion in the $Li_xCsC_{60}$ series. The open circle is $KBaCsC_{60}$ (reproduced by permission of the American Physical Society from *Phys. Rev. B*, 1999, **59**, R6628–30).

disordered f.c.c. $A_3C_{60}$ calculated incorporating both orbital polarization and interelectron repulsion. This is a BCS-type explanation involving pairing of the $t_{1u}$ electrons by phonons. The $^{13}C$ isotope effect and the strong shifting and broadening of the $H_{(g)}$symmetry vibrational modes in metallic $A_3C_{60}$ compared with insulating $C_{60}$ and $A_6C_{60}$ support this view. Alternative models point to the inapplicability of a classical BCS model when the electronic bandwidth (approximately 0.5 eV in $A_3C_{60}$) is comparable to intramolecular

phonon frequencies and on-site electron repulsion energies, and are based on interelectron repulsion between the $t_{1u}$ electrons. These models can reproduce the isotope effect and the sharp peak in $T_c$ at the $(t_{1u})^3$ configuration. Important experimental evidence for the significance of interelectron repulsion in determining the electronic ground states of fullerides has come from the observation of magnetic ordering at the 40 K metal–insulator transition of $(NH_3)K_3C_{60}$. This phase has the same volume per $C_{60}^{3-}$ but adopts a lower symmetry structure (2.1.2). Application of pressure suppresses the magnetic ordering and associated metal–insulator transition, and restores superconductivity ($T_c = 28$ K, pressure = 15 kbar).

The high superconducting transition temperatures of the $A_3C_{60}$ phases are not understood, and considerable further experimental and theoretical detail is required to allow reconciliation between the observed $T_c$ and the parameters describing the normal-state electronic structure deduced from experiment.

## Giant Magnetoresistance

The resistance of a ferromagnetic metal changes when one applies a magnetic field. This change is related to the dependence of the resistance on the angle between the magnetization of the ferromagnet and the electrical current direction, and is called anisotropic magnetoresistance (AMR) (see *Magnetoresistance, Anisotropic*). Although AMR in ferromagnets does not exceed a few percent at room temperature, it is used in a number of devices, mainly because the magnetization of a soft ferromagnetic material can be easily manipulated in a low magnetic field. Giant magnetoresistance (GMR) is another type of magnetoresistance (MR) which is observed in magnetic multilayers and is much larger than the AMR of the ferromagnetic metals. It was discovered in 1988 (Baibich *et al.* 1988, Binash *et al.* 1989) on Fe/Cr multilayers (stack of Fe and Cr layers) and Fe/Cr/Fe trilayers. In these structures and at zero magnetic field, the magnetizations of adjacent Fe layers are oriented in opposite directions by antiferromagnetic coupling across Cr (Grünberg *et al.* 1986); when an applied field aligns these magnetizations in parallel, the resistance of the multilayer decreases dramatically and this effect has been called giant magnetoresistance (GMR). The GMR of multilayers is thus associated with a change of the relative orientation of the magnetization in consecutive magnetic layers. Since this pioneering work on exchange coupled multilayers, GMR has been observed in a number of magnetic nanostructures, including uncoupled multilayers, spin valve structures, multilayered nanowires, and granular systems (for an extensive review see Barthélémy *et al.* 1999). In multilayers, GMR has been observed either for current in plane (CIP) or with current perpendicular to the plane of the layers (CPP geometry). CPP GMR has revealed interesting spin accumulation effects which form the basis for further developments.

From the point of view of applications, GMR is already used in various types of devices such as sensors, read-heads, and magnetic memories (MRAM). Reading information from a hard disk, for example, is done in many computers by detecting the resistance change induced by the small field (about $10^{-3}$ T) generated by the disk. This was achieved with AMR at the beginning of the 1990s and subsequently with GMR. While comparable fields can activate both AMR and GMR devices, the amplitude of GMR is larger, which permits a reduction of the size of the information bits and an increase of the density of stored information to 10–20 gigabitsin$^{-2}$ (1.6–3.1 gigabitscm$^{-2}$).

This article gives an experimental review of GMR. First, we describe the effects observed in multilayers (Sect. 1) or spin valve structures (Sect. 2) when the current flows parallel to the layers. In Sect. 3 the case where the current flows perpendicular to the layers is discussed. In Sect. 4 we give a brief phenomenological overview of the physics of GMR. The theoretical models for the CIP and CPP geometries are summarized in Sect. 5. Finally, inverse GMR and GMR of granular structures are presented in Sects. 6 and 7.

### 1. CIP GMR in Magnetic Multilayers

GMR was first observed in Fe/Cr superlattices (Baibich *et al.* 1988) and in Fe/Cr/Fe trilayers (Binash *et al.* 1989), in both cases for samples grown by molecular beam epitaxy (MBE). Figure 1 shows the variation of resistance as a function of magnetic field for Fe/Cr superlattices at 4.2 K. As the magnetic field increases, the magnetic configuration of neighboring iron layers goes from antiparallel to parallel. A field $H_s$ is needed to overcome the antiferromagnetic coupling and saturate the magnetization. Between zero field and $H_s$, the resistance drops significantly as a result of GMR. The MR ratio is defined as the ratio of the resistivity change to the resistivity in the parallel configuration. It reaches 79% at 4.2 K for the sample in Fig. 1 with 9 Å thick chromium layers (and is still 20% at room temperature). For the Fe/Cr system, the GMR ratio can reach 220%

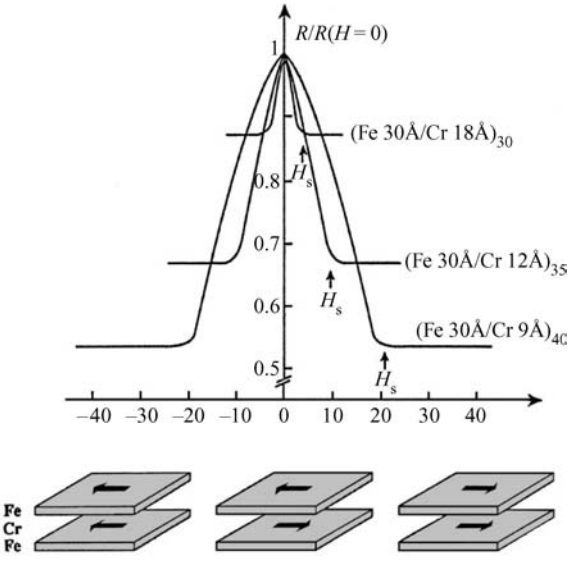

***Figure 1***
MR of Fe/Cr multilayers at 4.2 K (after Baibich *et al.* 1988).

(Schad *et al*. 1994), which is well above the AMR ratio observed in ferromagnetic films (a few %).

Parkin *et al*. (1990) succeeded in reproducing similar GMR effects in Fe/Cr, Co/Ru, and Co/Cr multilayers deposited by sputtering, i.e., with polycrystalline samples. Regarding applications, this is of definite interest as sputtering is a simpler and faster deposition technique than MBE. In addition, Parkin *et al*. (1990) explored details of the dependence of GMR on spacer layer thickness and found the oscillatory behavior which reflects the oscillations of the interlayer exchange coupling. Subsequently, oscillations of GMR with the spacer layer thickness have been found in many systems, as illustrated in Fig. 2 for the case of Fe/Cr multilayers. As shown in Fig. 2, the variation of the MR ratio as a function of chromium thickness presents four well-defined maxima associated with four ranges of antiferromagnetic (AF) coupling. In the ranges corresponding to ferromagnetic (F) coupling GMR vanishes. The height of the maximums is a decreasing function of the chromium thickness. GMR oscillations have been found in a large number of systems, but the typical variation illustrated in Fig. 2 is not always observed. It frequently occurs that, for low spacer layer thicknesses, the AF exchange coupling is reduced by F coupling arising from pinholes in the spacer layer. Indeed, avoiding pinholes is one of the key challenges in the synthesis of such multilayers. However, in some cases, the GMR can be restored by growing discontinuous magnetic layers which, when broken into small islands, reduce the deleterious effect of F coupling by pinholes (Duvail *et al*. 1995).

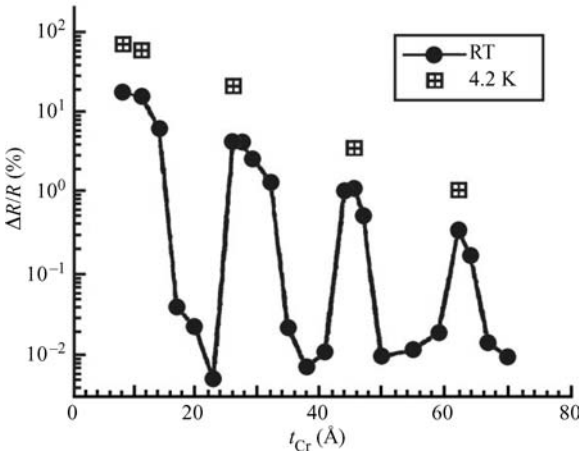

***Figure 2***
MR ratio of Fe/Cr multilayers as a function of chromium layer thickness, $t_{Cr}$, at 4.2 K and 300 K (after Fullerton *et al*. 1993).

Not all imperfections are as harmful for GMR as pinholes through the nonmagnetic layers. Other types of imperfection, by introducing spin-dependent scattering potentials, can act in the opposite direction and enhance GMR. For example, introducing cobalt or iron impurities in nickel layers or dusting permalloy/Cu interfaces with cobalt can enhance GMR. It has also been found that, in some cases, GMR can be enhanced by an increase of the roughness of the interfaces. An example of such an influence of the roughness of Fe/Cr multilayers on GMR is shown in Fig. 3.

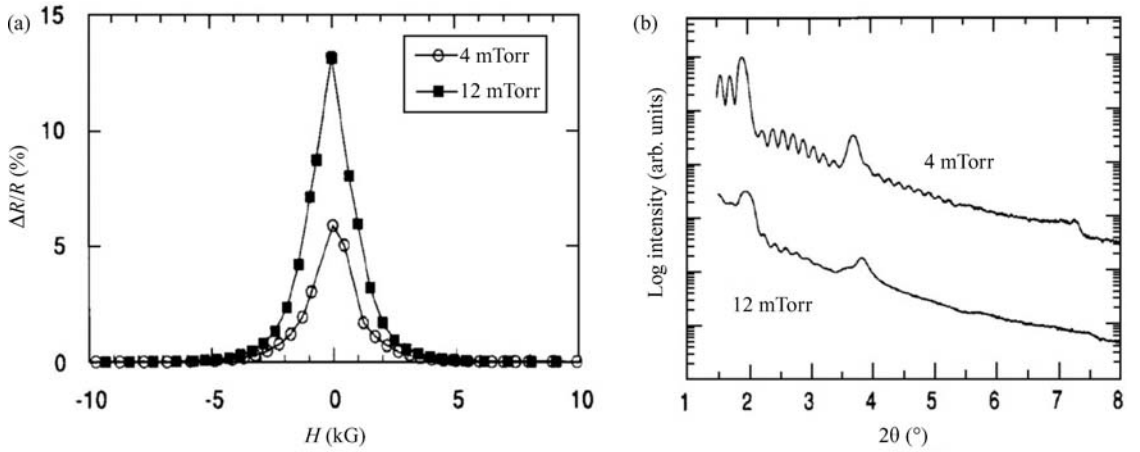

***Figure 3***
(a) GMR curves at 4 K for two Fe/Cr superlattices sputtered at different argon pressures. (b) Low-angle x-ray diffraction spectra of the same samples. The results show that GMR is enhanced by the presence of roughness (after Fullerton *et al*. 1992).

## 2. Hard/Soft and Exchange Biased Spin Valve Structures

GMR requires that an antiparallel configuration of the magnetizations can be switched into parallel by applying a magnetic field. AF interlayer exchange is not the only way to obtain an antiparallel configuration. GMR effects can also be obtained with tri- or multilayers combining hard and soft magnetic layers (Shinjo and Yamamoto 1990). As the switching of the magnetizations of the hard and soft magnetic layers occurs at different fields, there is a field range in which they are antiparallel and the resistance is higher. Such structures are often referred as hard/soft spin valves. The best-known structure in which interlayer exchange is not used to obtain GMR is the exchange biased spin valve structure, introduced by Diény *et al.* (1991). As shown in Fig. 4, two soft magnetic layers are separated by a nonmagnetic (NM) layer, one of the magnetic layers having its magnetization pinned by an exchange biasing interaction with an AF pinning layer. The operation of the exchange biased spin valve can be understood from the magnetization and MR curves in Fig. 5. One of the permalloy layers has its magnetization pinned by the AF FeMn layer in the negative direction. When the magnetic field is swept from negative to positive values, the magnetization of the free layer reverses at very small field, whereas the magnetization of the pinned layer remains fixed in the negative direction. This gives rise to a steep increase of resistance. A large positive field is needed to overcome the exchange biasing interaction and to reverse the magnetization of the pinned layer, which results in a drop of the resistance back to its initial value. The strong and almost reversible resistance variation in a low-field range makes this structure attractive for applications such as sensors or read-heads. Since the mid-1990s, many refinements have been developed to optimize the performances of exchange biased spin valve structures.

## 3. CPP GMR

The discussion of the preceding section concerns measurements performed with the electrical current parallel to the plane of the layers (CIP geometry). We now concentrate on GMR effects obtained for CPP geometry (for an extensive review see Bass and Pratt 1999).

The first measurement in CPP geometry was performed by sandwiching the multilayers between two superconducting niobium electrodes in a cross-strip geometry. A comparison between the amplitudes of CIP GMR and CPP GMR for a series of Co/Cu multilayers is shown in Fig. 6. It turns out that the CPP GMR is definitely larger and that the decay as a function of the spacer layer thickness is weaker in the CPP geometry.

Several alternative methods without superconducting contacts have been developed for measurements of CPP GMR at higher temperatures. Some of these methods are based on lithography and microfabrication techniques. Multilayers have been patterned into pillars using lithography by Gijs *et al.* (1993). Although a high-resolution lithography technique was used in these experiments, the aspect ratios were not high enough to ensure a pure CPP geometry without superconducting contacts. Nevertheless, the first temperature dependence of CPP GMR was obtained with these experiments.

CPP GMR has also been obtained by depositing multilayers onto grooved InP substrates. An oblique deposition technique is used, which results in multilayers deposited on one face of the groove. Thus, CPP measurement are achieved when the current flows perpendicular to the grooves, while, in the same sample, CIP GMR can be measured by flowing the current parallel to the grooves (Gijs *et al.* 1995).

Finally, CPP GMR has also been studied in multilayered nanowires electrodeposited into the pores of nuclear track-etched polycarbonate membranes (for an extensive review see Fert and Piraux 1999). As illustrated in Fig. 7(a), the aspect ratio of the nanowires is very high (of the order of 1000), which guarantees that the current is perpendicular to the layers. However, the number of nanowires connected in parallel is generally unknown, which restricts the investigations to the measurements of MR ratios. The Co/Cu and NiFe/Cu multilayer systems have been extensively studied in the nanowire geometry. An example of experimental CPP GMR result is shown in Fig. 7(b).

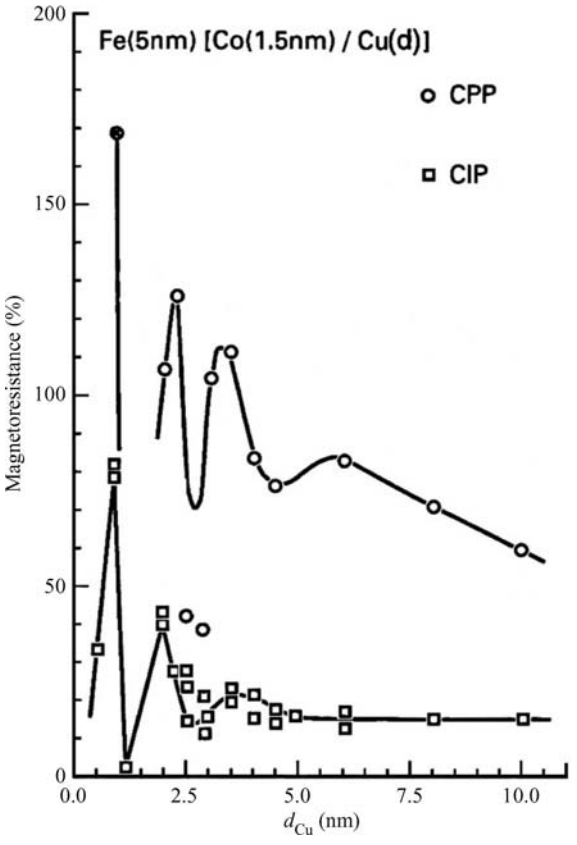

*Figure 6*

## *4. Brief Phenomenological Overview of the Physics of GMR*

GMR is related to the spin dependence of the conduction in ferromagnetic metals and alloys (Campbell and Fert 1982). At low temperature, when the spin flip scattering of the electrons by magnons is frozen out, there is conduction in independent parallel channels by the spin ↑ (majority) and spin ↓ (minority) electrons. The resistivity of the ferromagnet is then expressed as:

$$\rho = \frac{\rho_\uparrow \rho_\downarrow}{\rho_\uparrow + \rho_\downarrow} \tag{1}$$

where $\rho_\uparrow$ and $\rho_\downarrow$ are the resistivities of the spin ↑ and ↓ channels, respectively. The asymmetry between the two channels can be characterized by the spin asymmetry coefficient:

$$\beta = \frac{(\rho_\downarrow - \rho_\uparrow)}{(\rho_\downarrow + \rho_\uparrow)} \tag{2}$$

There are several origins of the difference between $\rho_\uparrow$ and $\rho_\downarrow$. First, there is an intrinsic origin, which is related to the spin dependence of the number, the effective mass, and the density of states at the Fermi level of the electrons. There are also extrinsic origins, which are related to the spin dependence of the impurity and defect potentials. In addition, away from the low-temperature limit, it is necessary to take into account the transfer of momentum between the two conduction channels by spin-flip electron–magnon scattering.

Figure 8 shows schematically the mechanism of GMR, in the situation where the mean free path (MFP), $\lambda$, of electrons is much larger than the period of the multilayer. Throughout this article, our notation is + and − for the spin directions corresponding to $s_Z = +\frac{1}{2}$ and $s_Z = -\frac{1}{2}$, $z$ being an absolute axis for the whole multilayer, and ↑ and ↓ for the majority and minority spin directions in a given ferromagnetic layer. In the parallel configuration, the electrons of the spin + and spin − channels are, respectively, majority and minority electrons in all the magnetic layers, and this gives different resistances, $r_+$ and $r_-$ for the two channels. The final resistance is:

$$r_P = \frac{r_+ r_-}{r_+ + r_-} \tag{3}$$

If, for example, $r_+$ is much smaller than $r_-$, the current is shorted by the spin + channel of fast electrons and $r_P \approx r_+$. In the antiparallel configuration, electrons of both channels are alternatively majority and minority spin electrons and the shorting by one of the channels disappears. The resistance is $(r_+ + r_-)/2$ for both channels and the final resistance is:

$$r_{AP} = \frac{r_+ + r_-}{4} > r_P \tag{4}$$

If $r_+$ is much smaller than $r_-$ then $r_{AP} \approx r_-/4$ is much larger than $r_P \approx r_+$. The general expression for the GMR ratio is:

$$\mathrm{GMR} = \frac{r_{AP} - r_P}{r_P} = \frac{(r_- - r_+)^2}{4 r_+ r_-} \tag{5}$$

The above simple picture no longer holds when the thickness of the layers becomes larger than the electron MFP (typically 10 nm in nonmagnetic layers, a few nanometers in ferromagnetic layers), at least for CIP. For example, when the thickness of the nonmagnetic layers, $t_N$, becomes larger than the MFP in these layers, $\lambda_N$, there is no overlap between the respective effects of two consecutive magnetic layers on the electron distribution function, and the GMR decreases as $\exp(-t_N/\lambda_N)$. This is discussed in Sect. 5.1. In CPP geometry, owing to spin accumulation effects, the scaling length becomes the spin diffusion length (SDL), $l_{sf}$, as discussed in Sect. 5.2. The SDL is related to spin flip scattering and can be much larger than the MFP which explains that the GMR can be observed for much thicker layers in the CPP geometry. It is only when the thickness, $t_N$, of the nonmagnetic layers exceeds the SDL, $l_{sf}^N$, in nonmagnetic materials that CPP GMR decreases as $\exp(-t_N/l_{sf}^N)$.

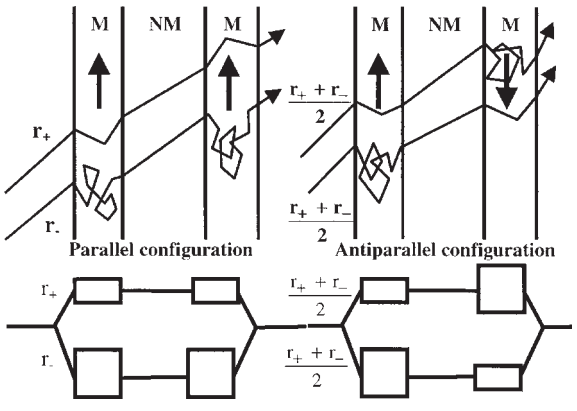

***Figure 8***
Schematic representation of the GMR mechanism. The scheme holds for both CIP and CPP geometries.

## *5. Models of GMR*

The theoretical models of GMR are based on the spin-dependent conduction described in the preceding section. However, predicting the GMR of a multilayer is difficult because there are various possible origins of the spin dependence in a given system. This is illustrated in Fig. 9, which shows the spin-dependent potential landscape seen by conduction electrons. One first sees the intrinsic potential of the multilayers

depicted by a periodic arrangement of steps. These steps reflect the band mismatch between the magnetic and nonmagnetic layers or, in simplified language, the different levels of the conduction band in different metals. The steps have different heights for the two spin directions, which expresses the exchange splitting of the majority and minority spins in a ferromagnetic metal. In Fig. 9 one also sees spin-dependent spikes which represent random scattering potentials generated by impurities, defects, or interface roughness. The spin dependence of the scattering by impurities or defects is well known in bulk magnetic materials (Campbell and Fert 1982) and it is also obvious that the modulation of the spin-dependent interface steps by roughness produces spin-dependent scattering potentials. The distribution of both the intrinsic and scattering (or extrinsic) potentials is different in the parallel and antiparallel magnetic configurations of the multilayers, as illustrated in Fig. 9 by the alternation of high and low steps or spikes only in the antiparallel configuration. This dependence of the intrinsic and extrinsic potential distribution on the magnetic configuration gives rise to the GMR effect and forms the basis of a number of theoretical models.

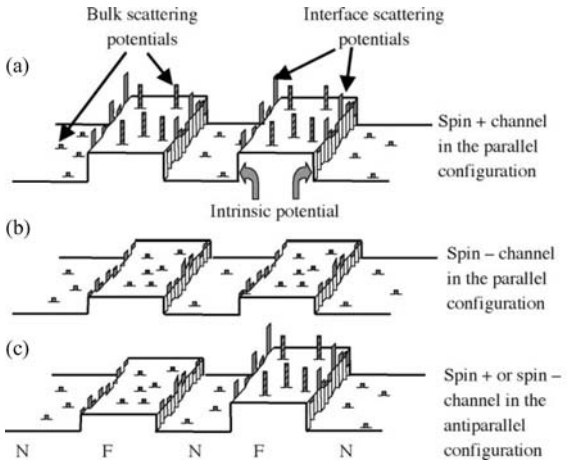

***Figure 9***
Potential landscape seen by spin + and spin − conduction electrons in the parallel and antiparallel configurations. The intrinsic potential is represented by a periodic array of steps (Kronig–Penney-like potential); the bulk and interface scattering potentials are represented by spikes.

### *5.1 Models of CIP GMR and Analysis of Experimental Data*

The first model of GMR was the semiclassical model of Camley and Barnas (1989). This model is based on the picture of free electrons scattered by a distribution of spin-dependent scattering potentials that

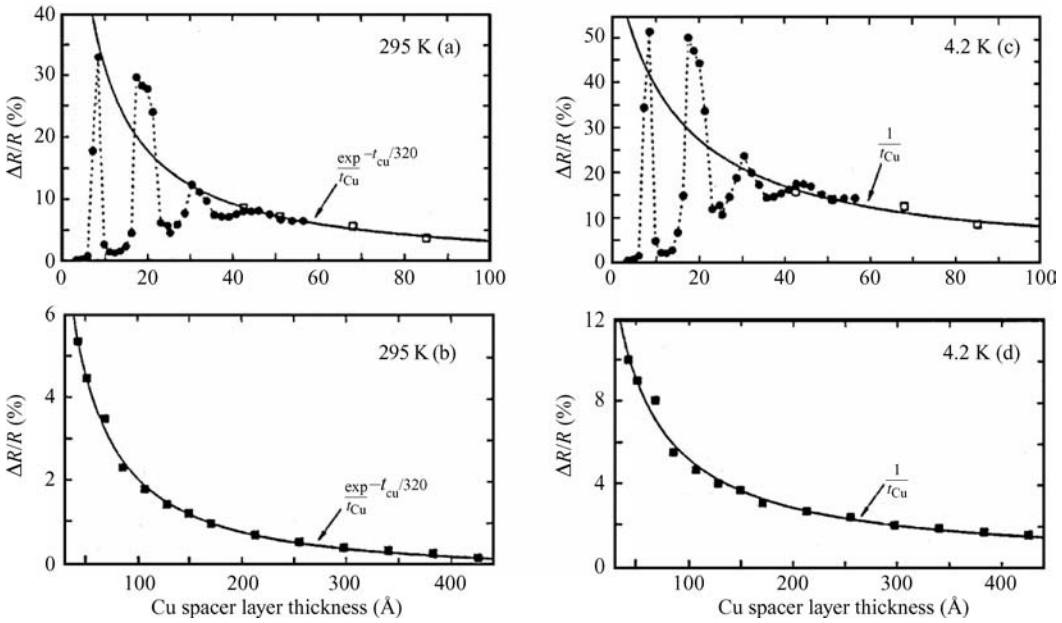

***Figure 10***
Saturation MR vs. copper spacer layer thickness for several series of (Co (11 Å)/Cu ($t_{Cu}$))$_N$ multilayers. The number of Co/Cu periods, $N$, is 20 (filled circles) and 6 (open and filled squares). Data are shown for temperatures of (a) and (b) 295 K, and (c) and (d) 4.2 K. The $N = 6$ data (in (a) and (c)) have been scaled by an empirical factor of 1.6 to make the comparison with $N = 20$ (after Parkin *et al.* 1993).

depends on the magnetic configuration of the multilayer, and uses a Boltzmann equation formalism (see *Boltzmann Equation and Scattering Mechanisms*). Bulk scattering is taken into account by introducing spin-dependent (spin-independent) relaxation times in the magnetic (nonmagnetic) layers. Interface scattering is described by introducing boundary conditions at the interfaces, i.e., by assuming that a proportion, $T_\sigma$, of the spin $\sigma$ electrons are transmitted without scattering, while a proportion $(1-T_\sigma)$ is diffusely scattered (a probability of specular reflection can also be introduced). The major success of this model is that it predicts the thickness dependence of GMR. It shows that the influence of the spin-dependent scattering on the electron distribution function does not extend further than about the MFP inside the nonmagnetic layers, so that the resistance becomes independent of the relative orientation of consecutive magnetic layers when they are apart by more than the MFP.

Analytical expressions of GMR in the Camley–Barnas model have been derived by Barthélémy and Fert (1991) in the simple case where only interface scattering is spin dependent. It is found that, in the limit of thick layers, the MR ratio depends on the nonmagnetic layer thickness, $t_N$, as $\exp(-t_N/\lambda_N)$, where $\lambda_N$ is the MFP in this layer. The variation as $t_F^{-1}$ at large values of the thickness, $t_F$, of the magnetic layers reflects the progressive dilution of the spin-dependent interface scattering.

Figure 10 shows an example of experimental data at 295 K for Co/Cu multilayers where the variation as $\exp(-t_{Cu}/\lambda_{Cu})$ is observed at large thicknesses of copper. At 4.2 K the exponential variation is not observed and it is supposed that, with a larger $\lambda_{Cu}$ at low temperature, the exponential behavior is repelled above the experimental thickness range.

The first quantum mechanical model of GMR, based on the Kubo formalism of transport, was proposed by Levy *et al.* (1990). As in the model of Camley and Barnas, it neglects the influence of the intrinsic potential of the multilayer and describes the scattering of free electrons by spin-dependent extrinsic potentials. Figure 11 shows an example of the application of the model to experimental data. After 1993 the influence of the intrinsic potential of the multilayer was progressively introduced into the theoretical models and *ab initio* models were also developed. For a general review of the models see Barthélémy *et al.* (1999).

A general result is that the theory of CIP GMR is far from being predictive. This comes from the combination of the intrinsic and extrinsic contributions. *Ab initio* calculations can predict correctly the influence of the intrinsic potential but the nature and distribution of imperfections are generally too poorly known to be introduced realistically into the calculations.

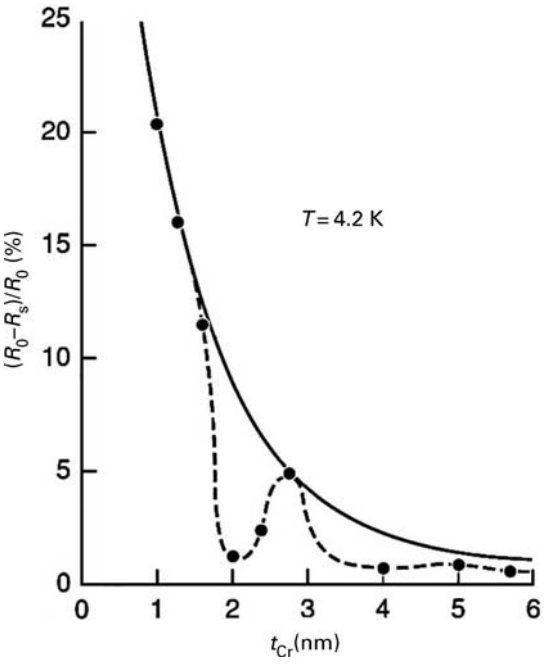

***Figure 11***
GMR ratio for Fe 30 Å/Cr multilayers vs. chromium thickness. The experimental data (dots) are obtained at 4.2 K. The solid line is calculated within the quantum model of (Levy *et al.* 1990) (after Gijs and Okada 1992).

### *5.2 Models of CPP GMR and Analysis of Experimental Data*

The advantage of CPP geometry for theory is that, in the usual diffuse limit, the contribution from the intrinsic potential (steps in Fig. 9) can be expressed by introducing spin-dependent interface resistances, $r_{\uparrow(\downarrow)} = 2r_b^*[1-(+)\gamma]$, for the spin $\uparrow$ and spin $\downarrow$ channels. Boltzmann equation models have been developed to express CPP GMR as a function of the interface parameters $r_b^*$ and $\gamma$, and the parameters describing the resistivity within the layers $\rho^F_{\uparrow(\downarrow)} = 2\rho^*_F[1-(+)\beta]$ and $\rho^*_N$ for the magnetic and nonmagnetic layers, respectively. An important point is the treatment of the spin accumulation occurring when the current is perpendicular to the interfaces. Valet and Fert (1993) have shown that, owing to spin accumulation, the SDLs $l^F_{sf}$ and $l^N_{sf}$ in the magnetic and nonmagnetic layers, respectively, become the scaling lengths of the thickness dependence instead of the MFP as in CIP geometry. As the SDL is much larger than the MFP, this explains why CPP GMR decreases more slowly as a function of the layer thickness than CIP GMR.

Valet and Fert (VF) have derived general expressions for CPP GMR as a function of the parameters

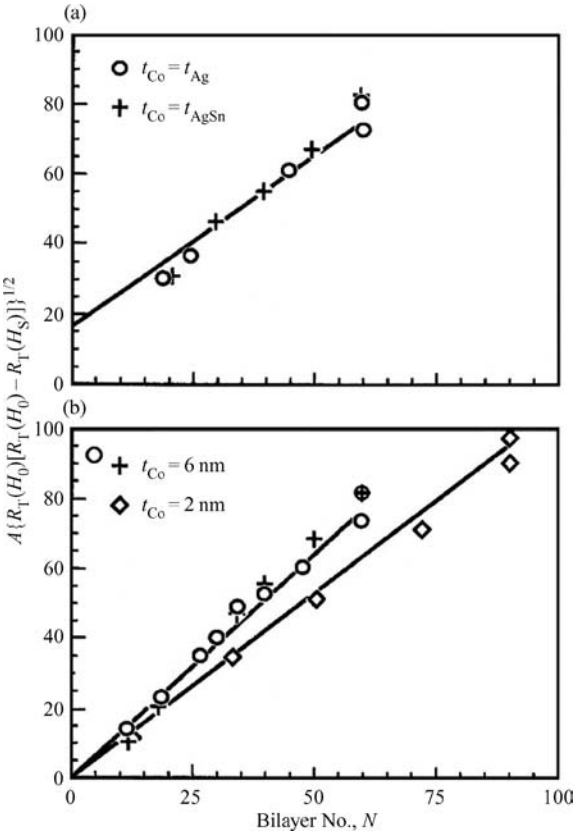

***Figure 12***
$A\{R_T(H_0)[R_T(H_0)–R_T(H_S)]\}^{1/2}$, where $A$ is the sample area, $R_T(H_0)$ the resistance in the virgin state (AP state), and $R_T(H_S)$ the resistance at saturation (P state), against $N$ for Ag/Co and AgSn/Co multilayers with a fixed total thickness $L = 0.72\,\mu$m: (a) $t_{Co} = t_{Ag} = t_{AgSn}$ and (b) $t_{Co} = 6$ nm and 2 nm with $t_{Ag}$ varying. The resistivities of the Ag and AgSn layers are 1 μΩ cm and 18 μΩ cm, respectively (after Pratt *et al.* 1993).

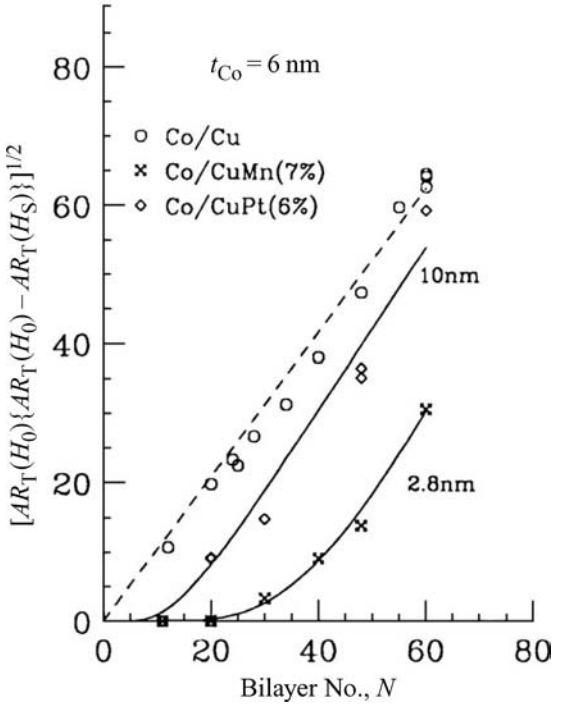

***Figure 13***
$\{AR_T(H_0)[AR_T(H_0)–AR_T(H_S)]\}^{1/2}$ vs. the number of bilayers, $N$, for Co/Cu, Co/CuMn (7%), and Co/CuPt (6%), where $A$ is the sample area and $R_T(H_0)$ and $R_T(H_S)$ the resistances at zero field and saturation field, respectively (after Yang *et al.* 1994). The dashed line corresponds to the linear variation expected when the SDL is much longer than the layer thicknesses. The solid lines are fits with the VF model with $l_{sf}^N = 10$ nm and 2.8 nm in CuPt and CuMn, respectively.

$r_b^*$, $\gamma$, $\rho_F^*$, $\beta$, $\rho_N^*$, $l_{sf}^F$, and $l_{sf}^N$. In most experiments the layer thicknesses are smaller than the SDL and, in this so-called long SDL limit, the simple expressions of a resistor series model (see Bass and Pratt 1999) can be derived from the general expressions of the VF model. For example, one obtains:

$$[(R^{AP} - R^P)R^{AP}]^{1/2} = \beta\frac{t_F L}{t_F + t_N}\rho_F^* + 2N\gamma r_b^* \qquad (6)$$

where $t_F$ and $t_N$ are the thicknesses of the magnetic and nonmagnetic layers, $N$ the number of period, and $L = N(t_F + t_N)$ is the total thickness. In multilayers with $t_F = t_N$ and a given total thickness $L$, this gives the linear variation of $[(R^{AP}–R^P)R^{AP}]^{1/2}$ as a function of $N$, as illustrated in Fig. 12(a). Once $r_b^*$, $\rho_F^*$, and $\rho_N^*$ have been determined from the thickness dependence of the resistance, the spin asymmetry coefficients, $\beta$ and $\gamma$, can be derived from, respectively, the slope and the intercept with the vertical axis of the straight line in Fig. 12(a). In the same way, for a given value of $L$ and $t_F$, one obtains the linear variations as a function of $N$ with different slopes for different values of $t_N$, as illustrated in Fig. 12(b).

Measurements on extensive series of samples have been analyzed in the above way to determine the parameters $r_b^*$, $\gamma$, $\rho_F^*$, $\beta$, and $\rho_N^*$ for silver, copper, cobalt, and NiFe layers, and Ag/Co, Cu/Co, Ag/NiFe and Cu/NiFe interfaces (Bass and Pratt 1999). Once these parameters have been determined, it turns out that GMR can be predicted for any multilayer composed of the same materials.

Simple expressions for CPP GMR can also be found in the opposite limit, i.e., when the thickness is much larger than the SDL.

For $t_N \gg l_{sf}^N$ with $t_F \ll l_{sf}^F$, the VF model predicts a reduction of GMR by a factor $\exp(-t_N/l_{sf}^N)$. This

behavior is observed in Fig. 13 for multilayers in which the SDL of the copper layers has been shortened by doping with manganese or platinum impurities. The fit with the VF expression (solid lines) leads to the values of the SDL indicated in Fig. 13. For pure nonmagnetic metals, the SDL is much larger and can be determined only by measurements on multilayered nanowires with very thick nonmagnetic layers (Fert and Piraux 1999). For copper layers, one obtains $l_{sf}^{Cu} = 140$ nm at low temperature.

In the limit $t_F \gg l_{sf}^F$ with $t_N \ll l_{sf}^N$, the VF model predicts:

$$\frac{(R^{AP} - R^P)}{R^P} = \frac{2p\beta^2 l_{sf}^F}{(1-\beta^2)t_F} \tag{7}$$

where $p$ is the proportion of antiparallel configuration between consecutive magnetic layers. Experimental results on the linear variation of the inverse of GMR as a function of $t_F$ are shown in Fig. 14 and a fit with Eqn. (7) gives $l_{sf}^{Co} = 59 \pm 18$ nm for cobalt at low temperature (45 nm at room temperature). The SDL turns out to be even shorter in permalloy, around 5 nm (Bass and Pratt 1999, Fert and Piraux 1999).

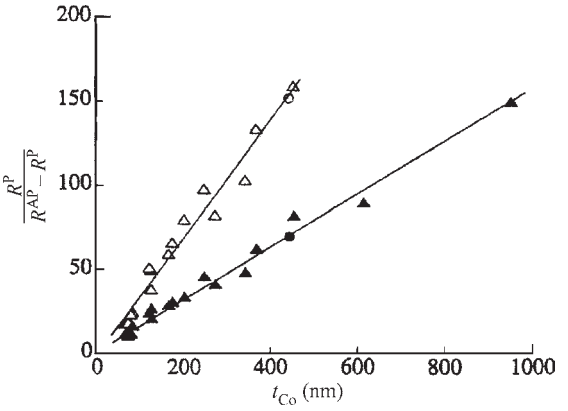

*Figure 14*
Linear variation of the inverse of the MR vs. cobalt thickness for Co ($t_{Co}$)/Cu (8 nm) multilayered nanowires at $T = 77$ K (filled symbols) and $T = 300$ K (open symbols). The circle refers to data obtained on a Co (435 nm)/Cu (15 nm) sample (after Fert and Piraux 1999).

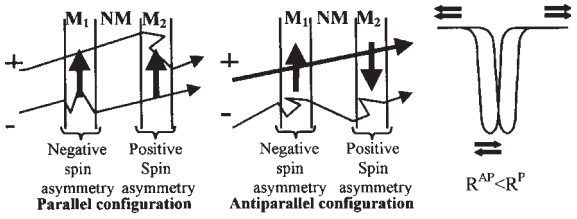

*Figure 15*
Schematic representation of the inverse GMR effect. The signs + and − are for spins $s_z = +\frac{1}{2}$ and $-\frac{1}{2}$, respectively. The arrows represent the majority spin direction in the magnetic layers. The electron trajectories between two scatterings are represented by straight lines and the scattering by abrupt changes in direction. When $M_1$ and $M_2$ are made of two different magnetic materials having opposite spin asymmetries, one of the spin directions (e.g., the spin + direction) is weakly scattered everywhere in the antiparallel configuration. This gives rise to a short circuit effect and a smaller resistance in this antiparallel configuration, and consequently to an inverse GMR effect.

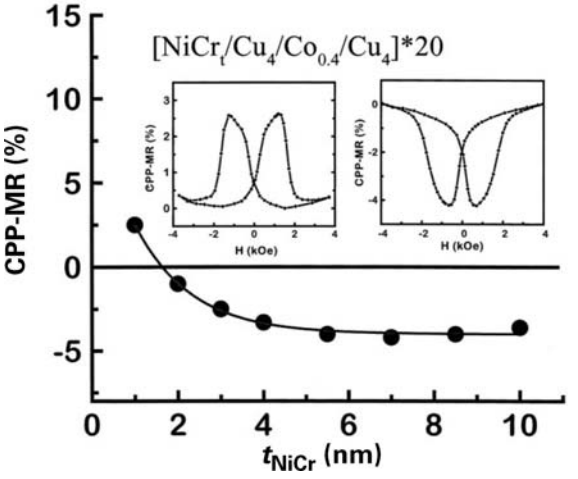

*Figure 16*
Variation of CPP GMR as a function of the thickness of $Ni_{0.95}Cr_{0.05}$ layers in NiCr/Cu/Co/Cu multilayers. The competition between the bulk scattering (characterized by $\beta_{NiCr} < 0$) and interface scattering (with $\gamma_{NiCr/Cu} > 0$) gives rise to a compensation thickness $t^*_{NiCr}$ at which they cancel each other ($t^*_{NiCr}$ is determined in the long SDL limit by $\beta_{NiCr}\rho^*_{NiCr}t^* + 2\gamma_{NiCr/Cu}r^*_{NiCr/Cu} = 0$). Below this compensation thickness the interface scattering is predominant, the global spin asymmetry of the NiCr layer is positive as is that of the cobalt layer (characterized by $\beta_{Co} > 0$ and $\gamma_{Co/Cu} > 0$), and the effect is normal (insert (a)). Above $t^*_{NiCr}$, the bulk scattering in NiCr becomes predominant, so that the global asymmetry of the NiCr layers is negative. Consequently, with alternating spin asymmetries for the NiCr and cobalt layers, the effect is the inverse (insert (b)) (after Barthélémy *et al.* 1999).

## 6. Inverse GMR

Normal GMR, i.e., a smaller resistance in the parallel configuration, is obtained when the spin asymmetry has the same sign in consecutive magnetic layers. This is always the case for multilayers of the type $(F/N)_n$. But it is also possible to fabricate multilayers of the type $(F_1/N/F_2/N)_n$ in which the ferromagnetic layers $F_1$ and $F_2$ have opposite asymmetries, e.g., $F_1$ slowing down more strongly the majority spin electrons and $F_2$ the minority spin electrons. In these cases, it is in the antiparallel configuration that one of the spin directions propagates easily everywhere and shorts the current (see Fig. 15).

An example of experimental results is shown in Fig. 16 for (NiCr/Cu/Co/Cu) multilayers in CPP geometry. The spin asymmetry coefficients $\beta_{Co}$, $\gamma_{Co/Cr}$, and $\gamma_{NiCr/Cu}$ are positive while $\beta_{NiCr}$ is negative. GMR becomes inverse for $t_{NiCr} > 2$ nm when the contribution from the bulk scattering (related to $B_{NiCr}$) exceeds the contribution from the interface scattering (related to $\gamma_{Co/Cr}$) in the NiCr layers. Figure 16 shows the variation of GMR as a function of the thickness with a crossover from positive to negative at about 2 nm. An example of an inverse GMR curve can be seen in inset (b). Such experiments on extensive series of $(F_1/N/F_2/N)_n$ multilayers have been performed to determine not only the magnitude but also the sign of the spin asymmetry coefficients of a number of magnetic materials and interfaces (Barthélémy *et al*. 1999).

## 7. GMR in Granular Systems

GMR effects have also been observed in granular systems, i.e., magnetic clusters embedded in a nonmagnetic matrix (Xiao *et al*. 1992, Berkowitz *et al*. 1992). Figure 17 shows an example of a GMR curve obtained in such systems. The resistivity drops when the magnetic moments of the clusters are aligned by an applied magnetic field. The advantage of granular materials is that they are not very sensitive to the effect of pinholes. The drawbacks are the large magnetic field needed to overcome the anisotropy energy of nonspherical clusters and to saturate the GMR (Fig. 17), and the crossover to superparamagnetic behavior (Fig. 17(b)) above a blocking temperature, which is generally below room temperature.

With the aim of avoiding the propagation of pinhole effects and obtaining a large GMR effect in low field, some attempts have been made to prepare intermediate systems between multilayers and clusters. Interesting results have been obtained starting from multilayers and annealing them to create discontinuous layers of pancake-shaped clusters with low anisotropy energy. Another way to obtain intermediate structures is to grow multilayers with very thin magnetic layers. Hybrid structures combining continuous and discontinuous clustered magnetic layers have also been grown. These kinds of structures lead to large GMR ratios in very low fields (34% in 10 Oe (796 $Am^{-1}$)) (Duvail *et al*. 1995).

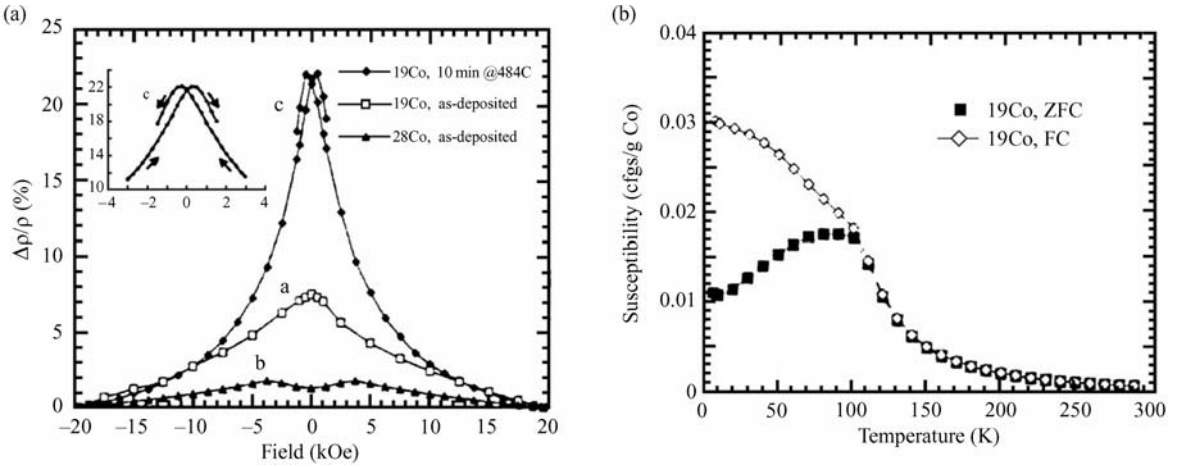

*Figure 17*
(a) GMR curve obtained in granular alloys by codeposition of immiscible elements such as cobalt and silver. The Co concentration is indicated on the curves. For concentrations above 28% cobalt, the clusters reach their percolation threshold and the whole sample becomes ferromagnetic leading to the disappearance of the GMR effect. (b) Field-cooled and zero field-cooled curves measured in a $Co_{19}Cu_{81}$ granular system. Above a blocking temperature around 100 K, the cobalt clusters are in a superparamagnetic state and a very large magnetic field is needed to obtain the GMR effect (after Berkowitz *et al*. 1992).

## Giant Magnetoresistance: Metamagnetic Transitions in Metallic Antiferromagnets

In intermetallic compounds with antiferromagnetic (AF) ordering, a large change in the resistivity (magnetoresistance: MR) occurs within a magnetic field, associated with a metamagnetic transition (MT). The mechanisms responsible are discussed here in relation to several examples.

The MR ratio is defined as:

$$\frac{\Delta\rho(B)}{\rho(0)} = \frac{\rho(B) - \rho(0)}{\rho(0)} \qquad (1)$$

where $\rho(B)$ is the resistivity under a magnetic field $H$ ($B = \mu_0 H$).

The term "giant magnetoresistance" (GMR) was first used for the large resistance decrease in magnetic multilayers (MML) associated with the field-induced

change of interlayer coupling from AF to ferromagnetic (F) (Baibich *et al.* 1988). The spin-dependent scattering, namely the difference in the relaxation times between the up- and down-spin electrons, is now recognized to be the origin.

### *1. GMR in Layered Antiferromagnets*

UNiGa (hexagonal ZrNiAl-type structure) was the first intermetallic compound discussed in relation with the GMR in MML (Sechovsky *et al.* 1991). The ground state AF structure in UNiGa is characterized by the *c*-axis stacking of U-moments $\uparrow\uparrow\downarrow\uparrow\downarrow\downarrow$ and oriented along the *c*-axis ferromagnetically ordered within the basal plane sheet. The magnetic field applied along *c* induces a MT at $B_c \sim 0.8$T (at 4.2K) leading to F stacking, and accompanied by a negative GMR. Figure 1 compares the field dependencies of MR and magnetization measured on the same crystal. The GMR is largely anisotropic: $\Delta\rho/\rho_0 = 90\%$ for $B \| i$ and 56% for $B \perp i$. Besides the anisotropy, the geometrical resemblance to the MLL initially led to the conclusion that the GMR in UNiGa has the same origin as MML: the spin-dependent scattering (Sechovsky *et al.* 1993). However, the inherent assumptions for the GMR in MML, the dominance of conduction electron scattering at interlayer boundaries, and the spin-split density of states for each U-monolayer, are not appropriate for UNiGa.

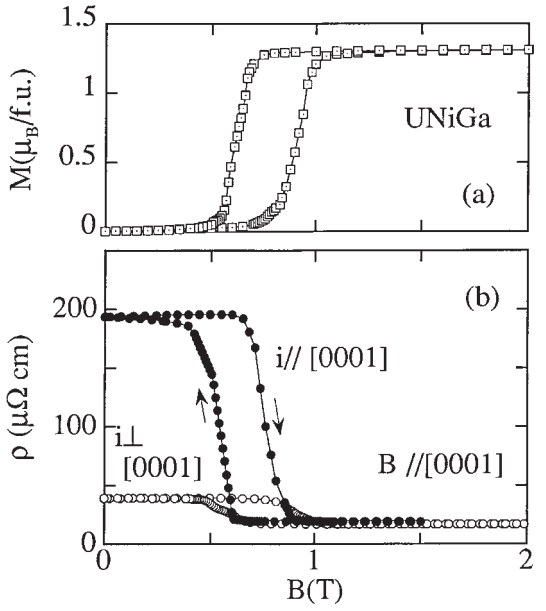

***Figure 1***
Field dependence of (a) magnetization and (b) magnetoresistance in UNiGa.

### *2. Mechanisms of GMR–Fermi Surface Reconstruction*

The GMR in UNiGa might be more naturally ascribed to a Fermi surface (FS) reconstruction connected with the disappearance of the superzone gap across the MT. Figure 2 shows a simplified model for MT, across which the unit cell size along *c* changes from 2*c* to *c*. As a result, the superzone gap at $\pm\pi/2c$ disappears in the wave vector (**k**-) space. Even from such a simple model, one can infer the reduction of resistance across the MT. The electrical conductivity tensor $\sigma_{ii}$ along the *i*-axis is given as an integral over FS as (Dugdale 1977)

$$\sigma_{ii} = \frac{e^2}{4\pi^3\hbar} \int \tau(\boldsymbol{k}) v_i(\boldsymbol{k}) \frac{\mathrm{d}S_\mathrm{F}}{|v|} \qquad (2)$$

where $\tau(\mathbf{k})$ and $v_i(\mathbf{k})$ are the relaxation time and the *i*-component of velocity, respectively, for a conduction electron with a wave vector **k**. The change in conduction electron scattering is reflected in $\tau(\mathbf{k})$, while those in FS appear both in the FS area through $\int \mathrm{d}S_\mathrm{F}$ and in the velocity $v(\mathbf{k})$.

Generally, the AF superzone gap reduces the FS area (Elliott and Wedgwood 1963), leading to an isotropic reduction of resistance, as expected from Eqn. (2). In addition, the AF superzone gap reduces the velocity component normal to the Brillouin zone boundary as shown in Fig. 2. Thus, the velocity factor reduces the conductivity along the *c*-axis selectively across the MT, which explains the anisotropic MR in Fig. 1. Antonov *et al.* (1996) have succeeded in ascribing the GMR in UNiGa to the FS reconstruction semiquantitatively by first-principle calculations based on the density-functional band structure. This scenario has been experimentally confirmed both by the specific heat and the Hall effect measurements (Aoki *et al.* 1997, Kobayashi *et al.* 1996).

$SmMn_2Ge_2$ (van Dover *et al.* 1993) and FeRh (Schinkel *et al.* 1974), which also posses the AF stacked two-dimensional ferromagnetic planes, exhibit a negative MR accompanying the MT as well.

### *3. GMR in Nonlayered Antiferromagnets*

The AF stacking of two-dimensional ferromagnetic planes is not a necessary condition for the GMR. For more general AF structures, numerous intermetallic compounds have been reported to exhibit a large MR correlated with the MT. $NdGa_2$ ($T_\mathrm{N} = 9.5$K) with the $AlB_2$ type hexagonal structure and $PrFe_4P_{12}$ ($T_\mathrm{N} = 6.2$K) with the cubic filled Skutterudide structure may serve as examples.

Figure 3 shows the transverse MR and magnetization measured on a $NdGa_2$ single crystal at 4.2K below $T_\mathrm{t}$ where the magnetic structure is close to the antiphase type. The magnetization exhibits a multistep

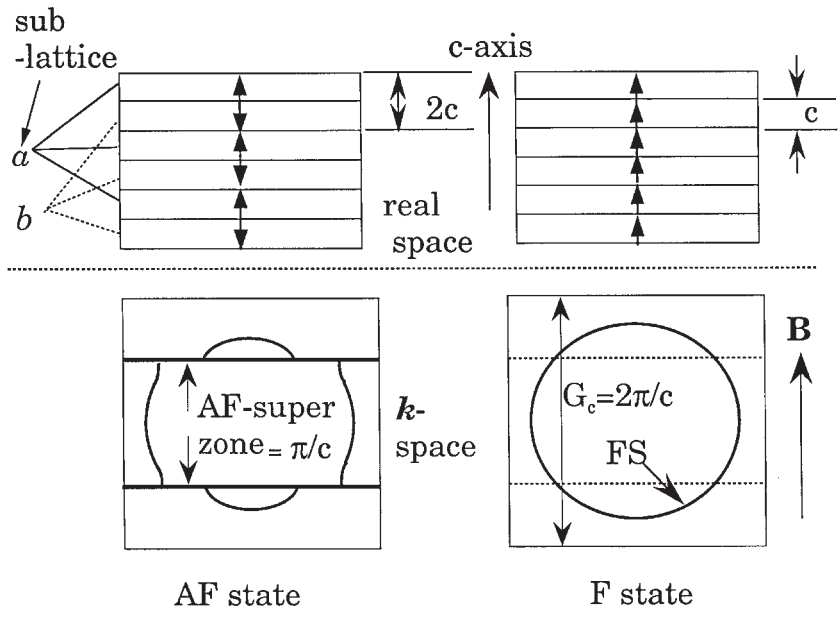

***Figure 2***
Simplest model for the MT. Top and bottom figures correspond to the real and **k**-space geometry. In zero field (left), two-dimensional ferromagnetic sheets form AF structure made of parallel (a) and antiparallel (b) sublattices. The superzone gap formed in AF state disappears across the MT.

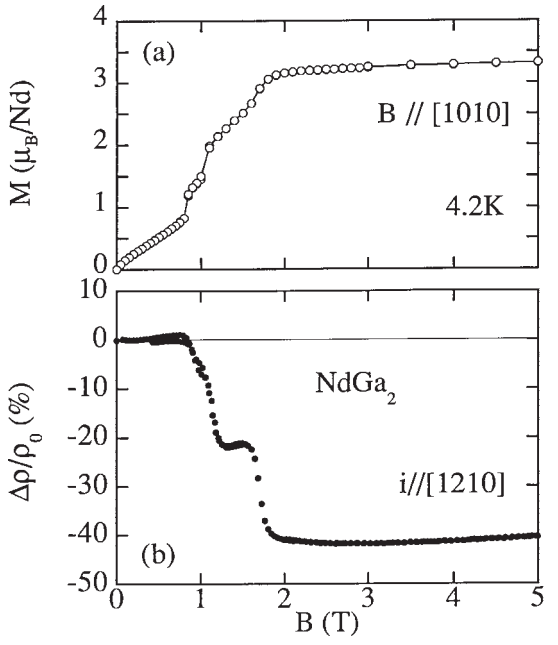

***Figure 3***
Field dependence of (a) magnetization and (b) MR ratio in $NdGa_2$.

metamagnetic behavior, which is well reflected in the MR curve. Even in the intermediate magnetic configuration, the MR is always negative, which suggests the existence of conduction electron scattering in zero field state resulting from the low energy excitation, as was inferred from the specific heat measurement (Aoki *et al.* 1997).

Figure 4 shows the field dependence of the MR in $PrFe_4P_{12}$ along with the magnetization above and below the Néel temperature ($T_N$) of 6.5K. For this material, the FS reconstruction at $T_N$ can be clearly seen as a jump in the temperature dependence of the resistivity in zero field. This was also manifested in the temperature dependence of the Hall coefficient (Sato *et al.* 2000). A notable feature in Fig. 4 is the initial increase of resistivity in fields below $B_M$. Yamada and Takada (1973) have explained such an effect by the critically enhanced conduction electron scattering on magnons. They calculated the MR due to electron-spin scattering in a simplest uniaxial AF metal considering the *s–d* interaction. For the field parallel to the easy axis, they found a positive MR below $B_M$, which results from the increase in the total number of excited magnons. More intuitively, the enhancement of spin fluctuations in the antiparallel sublattice *b* in Fig. 2 overcomes the suppression of spin fluctuations in the parallel sublattice *a*. On the

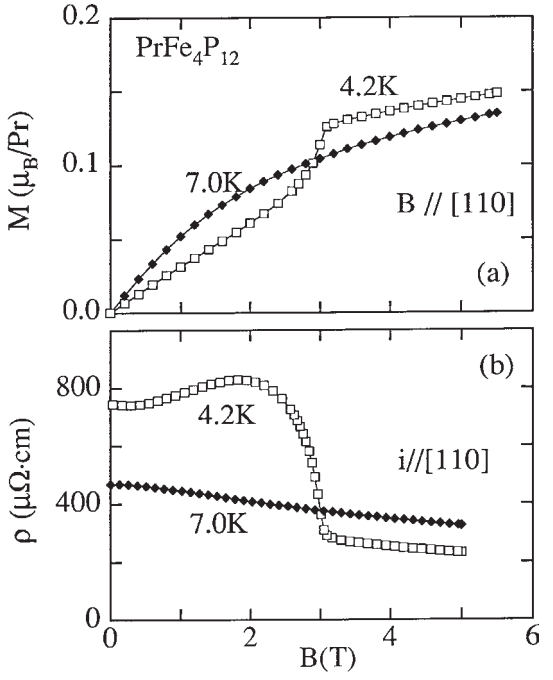

***Figure 4***
Field dependence of (a) magnetization and (b) MR in $PrFe_4P_{12}$.

other hand, Baranov *et al*. (1993) ascribed the anomalous increase of the resistivity to the conduction electron scattering at interface boundaries separating the phases with different magnetic structures.

To summarize, in the process of the MT from an AF state, the GMR has been observed in variety of intermetallic compounds and ordered alloys. The disappearance of the AF superzone gap across the MT plays the main role in the GMR in many cases. Additional mechanisms, such as the spin fluctuation scattering, the domain wall scattering, etc., should also be taken into account in order to explain the overall behavior including the temperature variation of the MR. Especially for itinerant magnetic electron systems such as UNiGa, the splitting of the up- and down-spin sub-bands might lead to a further change of FS in the high-field ferromagnetic state.

## Giant Magnetostrictive Materials

The magnetostrictive materials exhibit a strain caused by the orientation of the magnetic moment when exposed to a magnetic field (see *Magnetostrictive Materials*). A new class of magnetostrictive materials discovered by Ullakko and co-workers (1995, 1996) is

called magnetic shape memory (MSM) alloys or ferromagnetic shape memory alloy (FSMA) materials. The thermoelastic martensitic phase transformation in MSM materials produces a low-symmetry phase with a large magnetocrystalline anisotropy and highly mobile twin boundaries between the variants. MSM materials exhibit giant magnetic-field-induced strain (MFIS) based on the rearrangement of the crystallographic domains (twin variants). In the magnetic field, those martensite variants having the easy axis of magnetization along the field, start to grow due to twin boundary motion and become dominant. This process lowers the magnetization energy. The MFIS of MSM materials is unique since it produces a large strain with rather high frequencies without a change in the external temperature. Consequently, MSM materials are potentially important for actuator and sensor applications (Tellinen *et al*. 2002).

The currently best working MSM materials are the near stoichiometric $Ni_2MnGa$ Heusler alloys. Their structural, magnetic, and mechanical properties are highly sensitive to the chemical composition and temperature. These have been studied in detail by researchers in several countries (Vasil'ev *et al*. 2003, Söderberg *et al*. 2004). Depending on the martensite crystal structure (5 M or 7 M), one can obtain 6% or 10% strain response in a magnetic field less than 800 kA m$^{-1}$ (Murray *et al*. 2000, Sozinov *et al*. 2003), with the optimum frequencies up to 300–500 Hz (O'Handley and Allen 2001) in the temperature range 150–333 K (Heczko and Straka 2003) and at ambient temperature the MSM fatigue life can be more than $50 \times 10^6$ shape change cycles.

The schematic behavior of an MSM material is shown in Fig. 1. In the Ni–Mn–Ga 5 M and 7 M martensitic structures, the *c*-axis is the shortest crystallographic axis and, simultaneously, the easy axis of magnetization. When the material is exposed to a magnetic field, the variants having *c*-axis along the field become dominant and, consequently, the material contracts in the direction of the applied field. Since this MFIS remains after removing the magnetic field (Fig. 1 (1)), the actuation movement is only obtained by turning the magnetic field perpendicular to its original orientation (e.g., applying a rotating magnetic field, Fig. 1 (2)) or with an external spring-back load (Fig. 1 (3)). Consequently, with this way, it is possible to change one single-variant structure to another and to obtain cycling of the giant MFIS.

Figure 2 represents the behavior of the MSM material under compressive stress in a constant transversal magnetic field ($H$). The opposite stress induced by the magnetic field ($\Delta\sigma_{mag}$) is growing with increasing $H$ and it saturates at $\Delta\sigma_{mag} = (1-c/a)^{-1}K_U$, where $K_U$ is the magnetocrystalline anisotropy energy density of martensite (see insert in Fig. 2). Consequently, the giant MFIS is limited to the materials with rather low twinning stress ($\sigma_{tw}$) as the requirement for MFIS is $\Delta\sigma_{mag} > \sigma_{tw}$ (Likhachev *et al*. 2001).

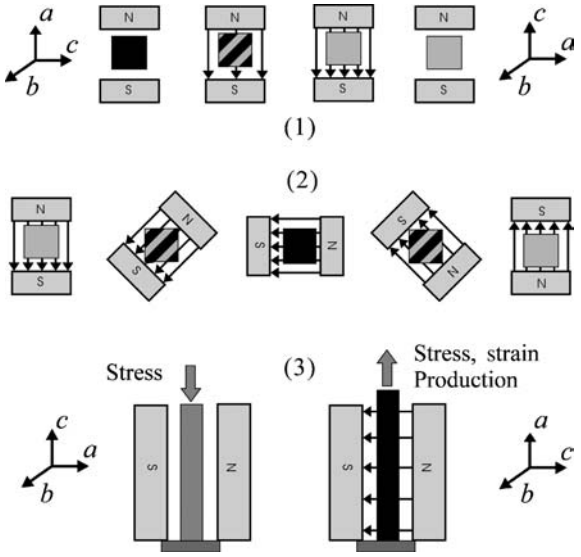

***Figure 1***
MSM element in (1) unidirectional, (2) rotating magnetic field, and (3) in the actuator. $a$, $b$ and $c$ are crystallographic axes of martensite ($c < a, b$), $c$-axis is easy axis of magnetization.

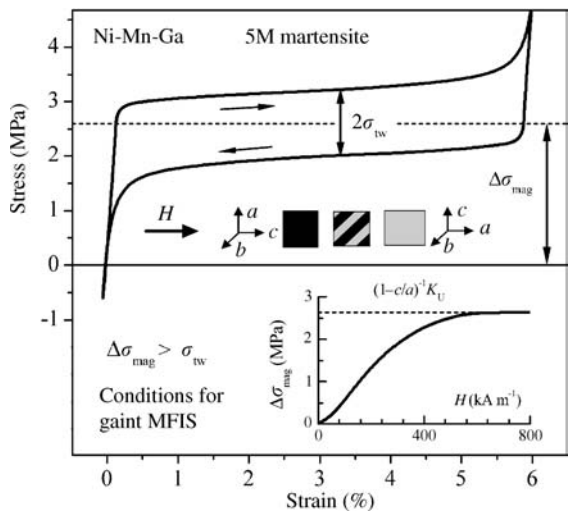

***Figure 2***
Compression of MSM element in constant transversal magnetic field $H = 800$ kA m$^{-1}$. $\sigma_{tw}$ is twinning stress and $\Delta\sigma_{mag}$ the magnetic stress. Inset shows influence of magnetic field on $\Delta\sigma_{mag}$.

The mechanical behavior of an MSM element in a constant transversal magnetic field (in Fig. 2) resembles the conventional superelastic (SE) behavior of the austenitic alloys: the large strain related to the

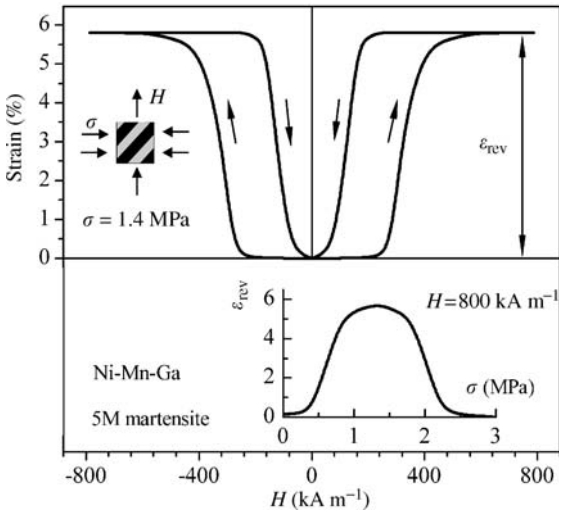

*Figure 3*
MFIS at constant blocking stress. $\varepsilon_{rev}$ is the reversible strain. Inset shows influence of blocking stress on $\varepsilon_{rev}$ at constant magnetic field $H = 800\,\mathrm{kA\,m^{-1}}$.

stress-induced phase transformation recovers totally when applied stress is removed. However, as in the conventional case SE behavior is obtained only in a rather narrow temperature region, the magnetically assisted superelasticity of the martensitic MSM alloys can be realized in a broad temperature range.

The behavior of MSM alloys at a variable magnetic field and under constant transversal stress is presented in Fig. 3. This behavior is applied in actuators (Fig. 1 (3)). The reversible strain ($\varepsilon_{rev}$) observed under these conditions (see insert at Fig. 3) has the maximum at a certain optimal value of blocking stress (O'Handley and Allen 2001, Likhachev *et al.* 2001). With this optimum blocking stress, the MSM element is brought back to the initial state when the magnetic field is removed (Fig. 3). In case the stress is below the optimum, it cannot move the twin boundaries back totally and, therefore, the cycling shape change is only partial. Furthermore, if the optimum value is considerably exceeded, this disables the MFIS.

Many other alloy systems (Vasil'ev *et al.* 2003, Söderberg *et al.* 2004) (e.g., Fe–Pd, Fe–Pt, Ni–Mn–Al, Co–Ni, Co–Ni–Al, Co–Ni–Ga and Ni–Fe–Ga) having magnetic and martensitic transformations are at present under intensive investigation as promising candidates for MSM applications.

## Growth and Magnetic Properties of YIG Films

Yttrium iron garnet (YIG), $Y_3Fe_5O_{12}$, is a typical ferrimagnetic material. In this article, "YIG" is used to refer not only to $Y_3Fe_5O_{12}$, but also to any other magnetic garnet crystal, including $Fe^{3+}$ ions, such as $Y_{3-y}R_yFe_{5-x}A_xO_{12}$ and $Bi_{3-y}R_yFe_{5-x}A_xO_{12}$, where R denotes a rare-earth element and A denotes a non-magnetic element. The use of YIG has been studied for a long time. In the 1970s, YIG crystals were used in bubble memory devices for computers.

A bubble memory is created when the magnetic domains in a YIG crystal film are placed under an external static magnetic field. Later, YIG was used in optical isolators, a key device in optical communication systems. The optical isolator is based on the Faraday effect, which is a magneto-optic property of YIG. For these applications, YIG film crystals have been used. On the other hand, spherical YIG crystals have been used in microwave isolators and resonators. These devices are based on spin waves and magnetostatic waves (MSW), which are high-frequency microwaves that propagate through YIG when an external static magnetic field is applied.

Recently, there has been active research on MSW propagating through YIG film. MSW are a mode of electromagnetic wave generated in ferrite crystals (see *Ferrite Ceramics at Microwave Frequencies*) when microwaves are coupled with electron spins in the material. An MSW is characterized by a frequency that changes as the external static magnetic field is varied. In this article, we shall consider the properties of YIG crystals, growth techniques with regard to MSW applications, and an MSW device called an *S/N-enhancer*. The S/N-enhancer is a noise-reduction device that improves the reception of direct-broadcasting satellite receivers.

## 1. YIG Crystals

The lattice constant of a YIG crystal is 1.2373 nm. The growth techniques for YIG crystals have been developed for applications in bubble memories, microwave devices, and optical devices. A garnet crystal (space group: *Ia3d*) is formed from eight $C_3A_2D_3O_{12}$ sub-units. In a YIG crystal, 24 C-sites with $Y^{3+}$ are each at the center of a dodecahedron whose apexes are occupied by oxygen atoms. Similarly, 16 A-sites with $Fe^{3+}$ and 24 D-sites with $Fe^{3+}$ are each at the center of a tetrahedron and an octahedron, respectively, whose apexes are occupied by oxygen atoms. A YIG crystal can be designed for applications in specific devices, because the composition of a solid solution of YIG can be easily controlled by doping cations.

A fraction of the D-site cations can be replaced with non-magnetic cations, such as $Ga^{3+}$ or $Al^{3+}$, to decrease the saturated magnetization (*Ms*). On the other hand, a fraction of the A-site cations can be replaced with non-magnetic cations, such as $In^{3+}$, to increase the *Ms*. In addition, a fraction of the C-site cations can be replaced with $Bi^{3+}$ or rare-earth atoms, such as $La^{3+}$, to modify the lattice parameter of the YIG and adjust it to that of the garnet substrate for epitaxial growth. For example, the lattice constant of $Gd_3Ga_5O_{12}$ (gadolinium gallium garnet, or GGG), which is usually used as the substrate crystal for YIG epitaxal films, is 1.2383 nm.

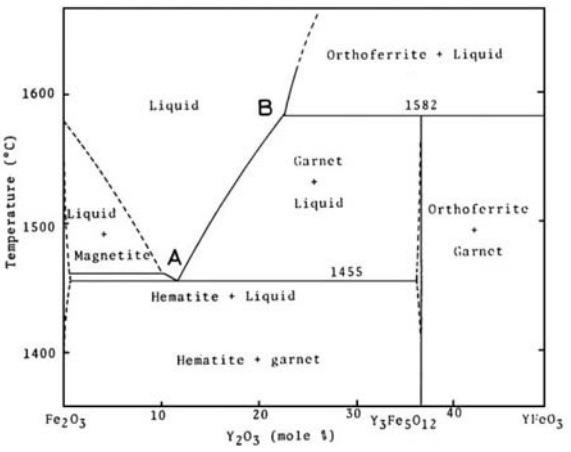

***Figure 1***
Phase diagram for the $Fe_2O_3$-$YFeO_3$ system.

Figure 1 shows the phase diagram of the $Fe_2O_3$–$YFeO_3$ system obtained by Van Hook (1962). As the phase diagram shows, YIG crystals cannot be obtained from a stoichiometric melt, because YIG decomposes into $YFeO_3$ and $Fe_2O_3$ at around 1580 °C. Therefore, YIG films are grown by liquid-phase epitaxy (LPE). LPE uses flux, and growth is done under a thermo-equilibrium condition, so the YIG films obtained should have good crystallinity. A solvent mixture of PbO and $B_2O_3$ is usually used as the flux, and the films are grown on a crystalline substrate with a garnet structure. Although YIG crystals are grown by LPE for both optical and MSW devices, there are great differences between the epitaxial films required for each application. In optical applications, such as optical isolators, the film thickness is at least several hundred micrometers, and the film surface must be polished to prevent optical scattering. In MSW applications, the film thickness is less than a hundred micrometers, and in order to reduce cost, the as-grown films have no surface treatment.

## 2. Growth of YIG Films

In LPE, the solute for the crystal and the solvent are put into a crucible, and the crucible is kept at a constant temperature under constitutional supercooling condition of the solution. The crystal substrate is then dipped into the solution in the crucible, and the crystal film grows epitaxally on the substrate. There are two important things to note concerning the temperature in the crucible. First, the temperature profile must be kept uniform; and second, temperature fluctuations must be minimized. That is the reason why the crystal grows under quasi-equilibrium conditions.

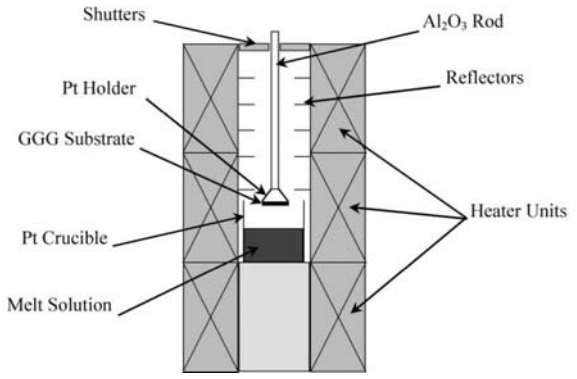

***Figure 2***
Schematic cross section of an LPE growth furnace.

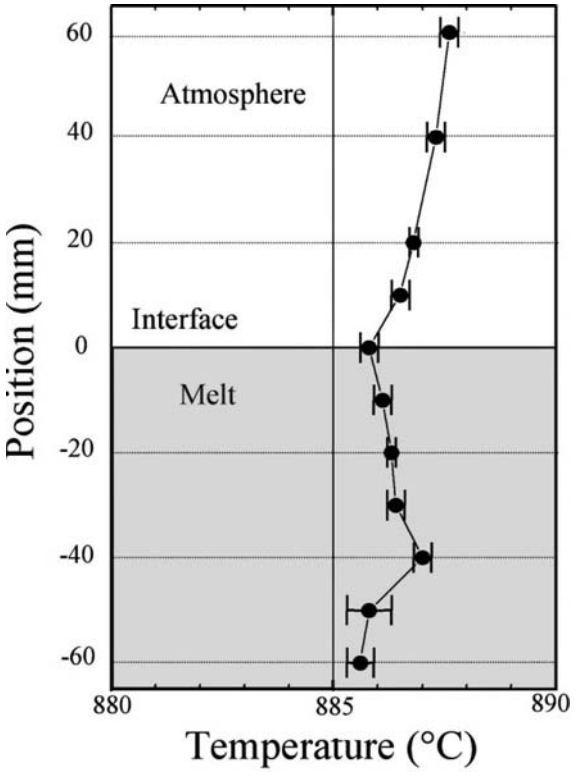

***Figure 3***
Temperature profile in the growth furnace. The origin of the vertical axis is the gas-melt interface.

Figure 2 shows a typical growth furnace for LPE. The furnace includes three heater units, which can be controlled independently. The platinum crucible is at the center of the furnace. Five donut-shaped platinum reflectors are positioned above the crucible to reflect thermal radiation and control airflow. The temperature distribution in the crucible under optimum furnace conditions is shown in Fig. 3, where the gas-solution interface is set as the origin, and temperature fluctuations are shown by error bars. The temperature gradient in the solution was as small as 0.03 °C mm$^{-1}$ at −40 mm, where the LPE growth temperature had a fluctuation of less than 0.5 °C. If there had been much temperature difference between the regions above and below the gas–solution interface, or much temperature fluctuation in the solution, YIG crystals could have easily nucleated and clung to the substrate when it was dipped.

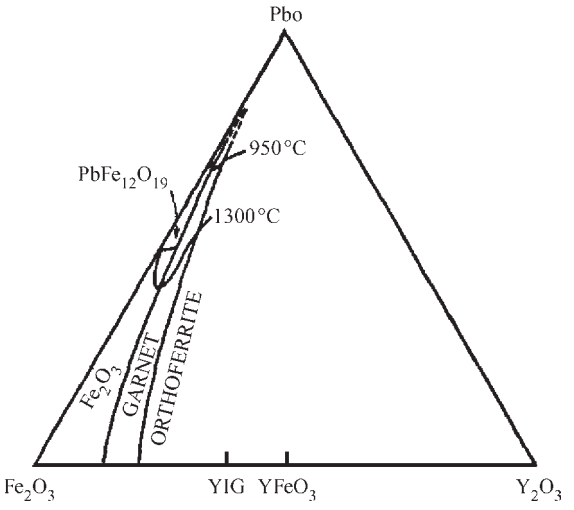

***Figure 4***
Phase diagram for the PbO-$Fe_2O_3$-$Y_2O_3$ system.

Next, the YIG growth example is described. In this case, the YIG films were designed for application in an S/N-enhancer, for which the target composition was $La_{0.07}Y_{2.93}Ga_{0.45}Fe_{4.55}O_{12}$ (LaGa:YIG) with an operating frequency range of 1.03 to 1.35 GHz. The starting materials with a total weight of about 10 kg were $Fe_2O_3$ (4N), $Y_2O_3$ (4N), $Ga_2O_3$ (4N), and $La_2O_3$ (4N) as the crystal constituents; and PbO (4N) and $B_2O_3$ (4N) as the flux. Figure 4 shows the phase diagram for the PbO–$Fe_2O_3$–$Y_2O_3$ system. $Fe_2O_3$ and $Y_2O_3$ are the solutes, and PbO is the main constituent of the solvent. The garnet structure can be obtained in a definite region. The $B_2O_3$ controls the viscosity of the solvent and deters YIG nucleation. The typical compositions of the starting materials are described in Table 1 using Blank's *R*-parameter.

As shown in Fig. 2, the starting materials were mixed and placed in the platinum crucible, 150 mm in diameter and 150 mm in height. Each (111)-oriented GGG substrate of 76 mm in diameter was held horizontally by the platinum holder and dipped into the melt solution during growth. The substrates were

***Table 1***
Blank's *R*-parameters. $R_i$ shows the molar ratio.

| *R*-parameter | Molar ratio |
|---|---|
| $R_1 \equiv \dfrac{[Fe_2O_3]}{[Y_2O_3] + [La_2O_3]}$ | 20.0–25.0 |
| $R_2 \equiv \dfrac{[Fe_2O_3]}{[Ga_2O_3]}$ | 20.0–25.0 |
| $R_3 \equiv \dfrac{[PbO]}{[B_2O_3]}$ | 14.0–16.0 |
| $R_4 \equiv \dfrac{[Fe_2O_3] + [Y_2O_3] + [La_2O_3] + [Ga_2O_3]}{[PbO] + [B_2O_3] + [Fe_2O_3] + [Y_2O_3] + [La_2O_3] + [Ga_2O_3]}$ | 0.10–0.11 |
| $R_5 \equiv \dfrac{[Y_2O_3]}{[La_2O_3]}$ | 5.00–7.00 |

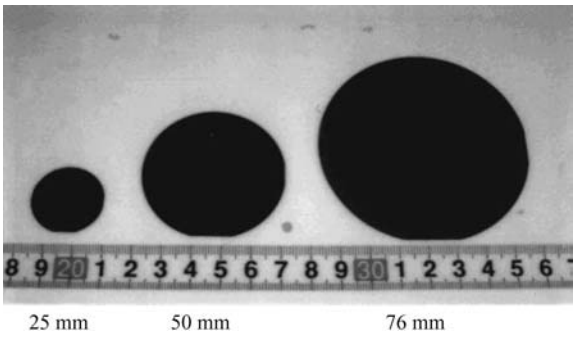

***Figure 5***
As-grown YIG wafers of 25 mm, 50 mm, and 76 mm in diameter.

rotated horizontally by rotating the holder, and the rotation direction of the substrate was changed at regular intervals. Typical growth temperature was 860 to 920 °C. The rotation rate was 100 rpm, and the intervals between changing the direction were 15 s.

As-grown (111)-oriented YIG wafers of 25 mm, 50 mm, and 76 mm in diameter are shown in Fig. 5. All epitaxial YIG wafers were grown on both sides of the GGG substrate. The thickness distribution, which was measured using an optical-interference thickness-measuring system, was $10.0 \pm 0.5$ μm for the as-grown YIG films on the 76-mm substrate.

## *3. Magnetic Properties*

For MSW applications, the important magnetic properties of YIG films are the *Ms* and the half-line width of the ferromagnetic resonance (FMR), or $\Delta H$. To examine these properties, FMR spectra were measured using the electric spin resonance (ESR) method with X-band microwaves (9.2 GHz). Square samples $2.0 \times 2.0\,mm^2$ in size were cut from the as-grown YIG wafers, and the YIG film on one side of each sample was removed. After measurement, the $\Delta H$ was calculated from peak to peak by Lorenz-type resonance in the FMR spectra. The *Ms*-*Ha*, where *Ha* is the anisotropic magnetic field, was calculated by using Kittel's resonance equation with the results from applying two resonant external magnetic fields, one parallel to the film and one perpendicular.

For the S/N-enhancer application, the *Ms* must be kept within $120.0 \pm 5.0$ mT, and the $\Delta H$ must be less than $80\,A\,m^{-1}$. For the YIG films above mentioned, both the $\Delta H$ and *Ms* (the *Ha* was estimated at 3.0 mT by using other measurements) met the requirements for the S/N-enhancer.

To satisfy the requirement for magnetic properties, there are some important conditions for YIG growth. First, a suitable growth furnace must be used to control the temperature profile. Second, the impurity concentrations of the starting materials must be carefully controlled. For example, nine elements (silicon, titanium, chromium, cobalt, hafnium, tin, germanium, magnesium, and tantalum) degraded the FMR properties, at concentrations ranging from 10 to 50 ppm by weight in the starting materials.

Finally, a periodic layer structure (PLS) in a YIG film is effective in improving the FMR properties. Figure 6 shows an x-ray rocking curve measurement using a monochrometer consisting of four crystals. The main peak corresponds to the YIG (888) reflection, and the second peak corresponds to the GGG (888) reflection. A pair of reflections is found, symmetrical around the main YIG peak. These satellite reflections, indicated by the two arrows, indicate the existence of a PLS, like a superlattice of compound semiconductor

materials. The PLS was estimated to be around 150 nm long, based on the angular difference between the main and satellite peaks. This indicates that the length of the PLS can be controlled by changing the LPE growth conditions, such as the growth temperature or the interval of changing the rotation direction. Figure 7 shows the FMR spectra with and without a PLS. At a film thickness of 20 μm, both FMR spectra were excellent. However, at 5 μm, only that with a PLS was excellent. This explains why the magnetic direction is ordered above the film-substrate interface for the YIG film with the PLS.

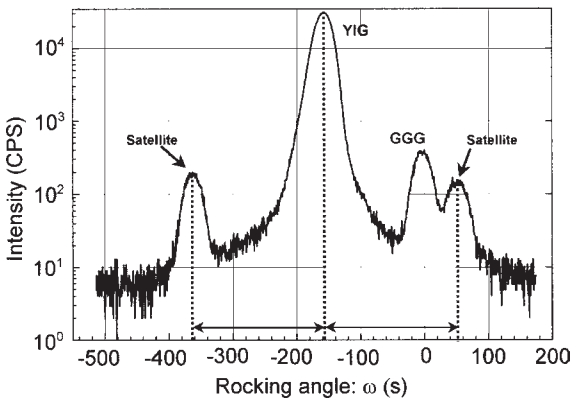

***Figure 6***
Measured x-ray rocking curve using Cu-K$\alpha_1$. The main peak shows the YIG (888) reflection.

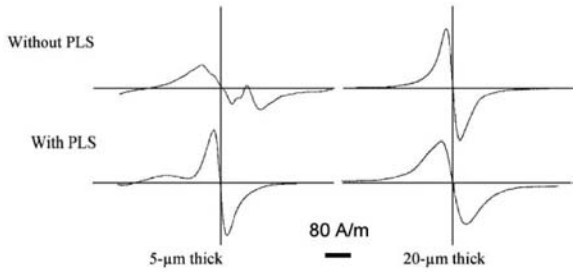

***Figure 7***
Effect of a PLS on FMR spectra.

## *4. S/N-enhancer*

An S/N-enhancer is an MSW device that cancels noise and emphasizes the signal in direct-broadcasting satellite receivers. It utilizes the nonlinear characteristics of MSW propagation through YIG films, so that the MSW output power finally saturates with increasing input power, as shown in Fig. 8(a). The device operates as shown in Fig. 8(b). The input microwave is divided, and each part passes a separate YIG film. In path (1), the signal amplitude decreases while the noise level does not change, because the signal amplitude is above the saturation level and the noise amplitude is below it. After propagating through the YIG film, the microwave amplitude decreases further at the attenuator (Att-1).

In path (2), both the signal and noise amplitudes decrease at the attenuator (Att-2), but they do not change in the YIG film because they have already decreased below the saturation level. Furthermore, the phase shifter creates a 180° phase difference between paths (1) and (2). The noise amplitude is then reduced after the two microwaves are added, because the noise amplitude through path (1) is almost similar to that through path (2). As a result, the ratio of the signal and noise amplitudes (S/N) is emphasized. Thus, the performance of the two YIG films in the S/N enhancer

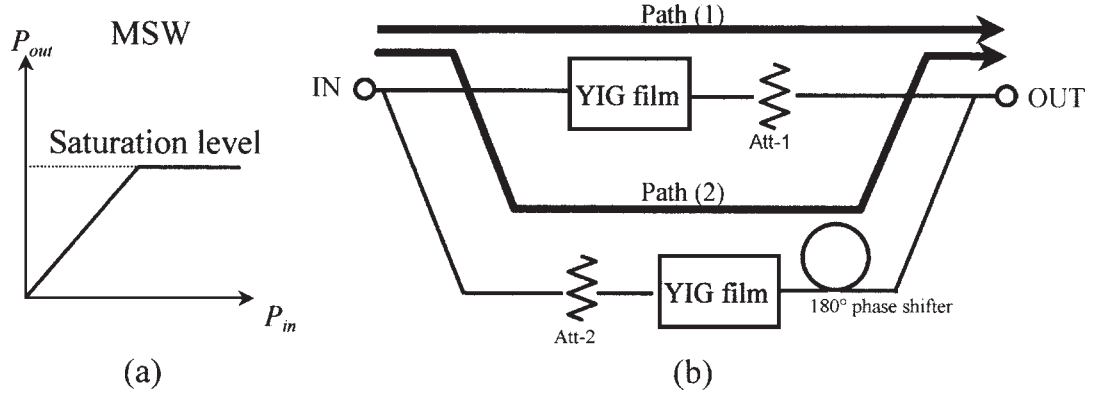

***Figure 8***
Relationship between input power ($P_{in}$) and output power ($P_{out}$) for propagation through a YIG film. $P_{out}$ saturated at a high $P_{in}$ level. (b) Operating principle of a S/N enhancer with two YIG films.

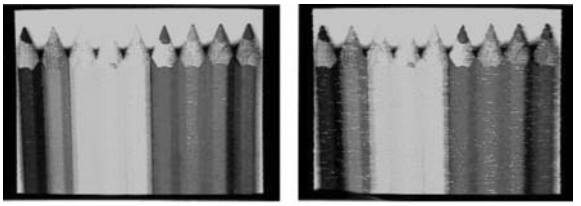

***Figure 9***
Photographs showing the effect of a S/N enhancer on TV pictures: (a) picture output with S/N enhance; (b) original picture.

must be uniform. As shown in Fig. 9, the S/N enhancer improves the quality of TV pictures.

## Half-metallic Magnetism

The electronic structure of a magnetic solid can be described by two independent band structures for the two spin directions in the absence of spin–orbit interactions. A half-metal is defined as a solid with metallic properties for one of the spin directions only. As a consequence, the electrical conduction takes place for one spin direction exclusively. Also the magnetic moment of a half-metal is integral. This follows from the integer number of electrons for the nonconducting spin direction as well as the integral total number of electrons. Historically, the possibility of unusual physics in magnetic systems with integral magnetic moments was recognized as early as 1950 (Pickett and Moodera 2001), however, the first discussion on half-metallicity and its origin appeared in 1983 (De Groot *et al.* 1983).

### *1. Physical Origin of Half-metallicity*

A remarkable feature of a half-metal is the occurrence of a bandgap for one spin direction. Bandgaps occur for distinct physical and chemical reasons, leading to distinct behavior as function of pressure, disorder, surface sensitivity, etc. Because of this, the origin of the bandgap is a useful criterion for the classification of half-metals (Fang *et al.* 2002). Three categories exist.

#### *1.1 Systems with Covalent Bandgaps Such As in III–V Semiconductors*

Although the origin of the bandgap in this category is the least straightforward, the materials, in which half-metallicity was first described (NiMnSb), fall into this category. NiMnSb crystallizes in the Heusler $C1_b$ structure. This structure consists of a face-centered cubic Bravais lattice with Ni in the origin, Mn at $\frac{1}{4},\frac{1}{4},\frac{1}{4}$ and Sb at $\frac{3}{4},\frac{3}{4},\frac{3}{4}$. So this structure is quite similar as the zinc-blende structure. Both the Mn and the Sb have the fourfold tetrahedral coordination characteristic for the zinc-blende structure. The band structure and chemical bonding for the minority spin direction is very similar as in the III–V semiconductors. The extra atom, Ni, mediates the interactions, while the role of the *p*-electron of the metal in the III–V semiconductor is played by an Mn $t_{2g}$-electron in NiMnSb. A bandgap results very similar as for the zinc-blende semiconductors. The metallic spin direction is characterized by four extra *d*-electrons 4 eV lower in energy due to the exchange splitting. Wide bands, without any bandgap, result for the majority spin direction like in an alloy (see Fig. 1). The role of the $t_{2g}$-electron in the band formation has two important consequences. First, it implies NiMnSb is a weak ferromagnet: strong magnetism and half-metallicity are mutually exclusive in this category. Second, the $t_{2g}d$-electron can play the role of a *p*-electron in the zinc-blende structure only as long as inversion symmetry is absent. Hence, no half-metallicity in this category exists in the Heuslers $L2_1$ structure, since it possesses inversion symmetry. Several other $C1_b$ Heusler alloys have been investigated.

Isoelectronic PtMnSb shows also half-metallicity (De Groot *et al.* 1984), but the spin–orbit interaction will cause the Fermi energy to cross the top of the valence band. PbMnSb shows a small overlap of the Fermi energy with the top of the valence band for the minority spin directions. In IrMnSb, RhMnSb, PtMnSn, and OsMnSb, the Fermi level overlaps with the top of the valence band (De Groot and Buschow 1986). CoMnSb (Kübler 1984) as well as FeMnSb (De Groot *et al.* 1986) are calculated to be half-metals; however, CoMnSb crystallizes in a superstructure and FeMnSb is always Fe-deficient when synthesized. Extrapolation of the measured moment

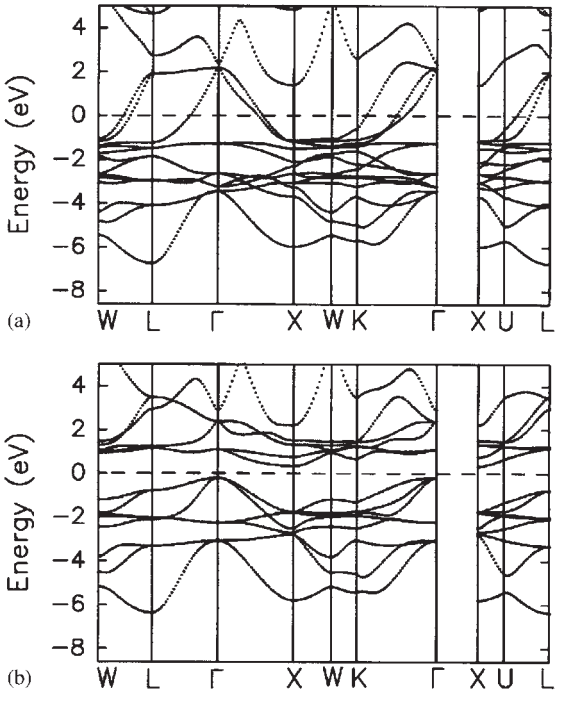

***Figure 1***

to the stoichiometric composition leads to the required integral moment $2\mu_\beta$, however. A more recent development is the growth of transition-metal pnictides and chalcogenides in the zinc-blende structure as a meta-stable phase on top of III–V semiconductors. Successful experiments on CrAs (Akinaga *et al.* 2000) as well as CrSb (Zhao *et al.* 2001) have been reported. The magnetic moment in these cases is $3\mu_\beta$.

### *1.2 Strongly Magnetic, Ionic Compounds*

Strong magnetic materials are defined as solids, where a hypothetical increase in exchange splitting does not lead to an increase in magnetic moment. This means, in practice, that for a transition metal the majority spin *d*-states are completely filled or the minority spin *d*-states are completely empty. The former is, for example, the case of Ni. However, there are still itinerant *s–p* electrons present, which show hardly any spin polarization and are responsible for normal metallic behavior. In an ionic compound, these mobile electrons are localized on some anion and half-metallic properties emerge. Up till now, the occurrence of half-metals in this category is confined to systems with an empty minority *d*-shell. The bandgap is of the charge transfer type, whereas the conduction band-minimum has primarily transition-metal *d*-character. Examples in this category are $CrO_2$ (Schwartz 1986) and the double-exchange perovskite materials (Pickett and Singh 1996).

### *1.3 Narrow Band Materials*

In systems, where bandwidths are smaller than interactions like crystal field and exchange splittings, several bandgaps will show up in a *d*-manifold. Usually, these systems will be Mott insulators. If, however, the bandwidths are not too small and show metallic behavior, the multitude of bandgaps makes the occurrence of half-metallicity likely. The most predominant example in this category is the mineral magnetite, $Fe_3O_4$ (Yanase and Siratori 1984), above the Verwey transition of 120 K. $CoS_2$ is nearly half-metallic and can be transferred into a half-metal by substituting part of the Co by Fe (Mazin 2000). Several other half-metals have been reported in this category such as Heusler $L2_1$ phases (Fujii *et al.* 1995, Weht and Pickett 1999) as well as several nitrides (Fang *et al.* 2002). The bandgap of the semiconducting spin direction is of the *d–d* type: both the top of the valence band as well as the bottom of the conduction band are primarily derived from transition-metal *d*-states. Hence, half-metals in this category should be classified as weak magnets.

## *2. Physical Properties of Half-metals*

Most of the early work on half-metallic magnetism was based on electronic structure calculations, presumable because, in spite of the profound influences of half-metallicity, there is no real simple "smoking gun experiment" to prove its existence in a specific compound. The requirement of an integer moment is a necessary but certainly not a sufficient condition. The test of the integral moment should be applied with care on partially substituted systems such as $Fe_{1-x}Co_xS_2$ since an integral moment per formula unit can be obtained with integral number of atoms in the formula unit only. In considering experiments, surface-sensitive ones should clearly be distinguished from bulk measurements. The most stringent one in the last category is without doubt spin-resolved positron annihilation. Positron annihilation measures the Fermi surface of a solid. Since positrons obtained from $\beta$-decay are spin polarized and the annihilation process of an electron–positron pair in a singlet state is easily discriminated from that of a triplet pair, the measurement of the Fermi surface can be realized spin dependent. In the case of NiMnSb, it was proven that only for one spin direction a Fermi surface exists (Hanssen *et al.* 1990). Unfortunately, measurements of this type on other half-metals are lacking.

Surface-sensitive measurements are less clear because of the occurrence of surface segregations, surface reconstructions (Ristoiu *et al.* 2000), or simply by the fact that even a perfect surface of a half-metal is not necessarily half-metallic itself. Spin-resolved photoemission showed $La_{1-x}Ca_xMnO_3$ to be half-metallic, although the interpretation of these measurements is not uncontroversial (Park *et al.* 1998). Andreev reflection on NiMnSb showed a spin polarization of the electrons at the Fermi energy of 58% only, whereas spin-polarized tunneling shows 28% polarization only (Tanaka *et al.* 1999). The highest degree of spin polarization of the conduction electrons measured by Andreev reflection is $CrO_2$: 90% (Soulen *et al.* 1998). Under some conditions, inverse photoemission shows close to 100% spin polarization in NiMnSb (Ristoiu *et al.* 2000).

There exists some confusion in the literature about the influence of disorder, specifically in the first category of half-metals. Since interchange of nickel and manganese in NiMnSb will sacrifice the tetrahedral coordination of the latter atom, it is very effective in destroying the half-metallic properties (Orgassa *et al.* 1999). This has fuelled some belief that the lack of spin polarization at its surface is an indication of such disorder at the surface or even in the bulk. While the latter is in disagreement of the spin-resolved positron-annihilation measurements, the introduction of the former is unnecessary: the presence of the surface itself breaks the tetrahedral symmetry already sufficiently to destroy the half-metallic properties locally (genuine half-metallic *interfaces* are possible, however (De Wijs and De Groot 2001)). Moreover, Ni–Mn interchange is energetically unfavorable. Although it was possible to prepare highly disordered $Ni_2MnSb$

by molecular beam epitaxy, recent NMR work on thin-film NiMnSb shows a very low amount of disorder and of a type (Mn–Sb interchange) that does not influence the half-metallic properties (Van Roy *et al*. 2003).

### 3. *Half-metallic Antiferromagnetism*

The *average* magnetic moment in half-metals in the Heusler structure is well described by a generalized Slater–Pauling curve (Kübler 2000). This calculated curve shows materials with an averaged moment of zero. Besides a nonmagnetic solution this can imply an unusual form of magnetism: half-metallic antiferromagnetism (Van Leuken and De Groot 1994). Half-metallic antiferromagnets differ from traditional antiferromagnets, because local moments on crystallographically different sites cancel. Theoretically, they are predicted to show an unusual form of magnetism (Rudd and Pickett 1998). Experimentally, they have not been realized yet (Pickett 1998).

## Hard Magnetic Materials, Basic Principles of

The progress in the field of permanent magnets has been dramatic since the 1960s. This would have been impossible without a fundamental understanding of the physical phenomena responsible for hard magnet properties, which led to the discovery of new families of permanent magnet materials based on rare earth(R)–transition metal (T) compounds (see *Rare Earth Magnets: Materials*). The search for new compounds with superior properties focuses on materials

with high values of Curie temperature ($T_C > 500$ K), high saturation magnetization $M_S$ ($\mu_0 M_S > 1$ T, with $\mu_0$ the permeability of free space ($4\pi \times 10^{-7}$ Tm $A^{-1}$)), and high magnetocrystalline anisotropy, $H_A$.

In this article, these intrinsic properties which depend on crystal structure and chemical composition will be described. In addition, it will be elucidated that a favorable combination of these values does not automatically lead to a good hard magnet material but can only be regarded as a prerequisite (for more detailed descriptions see Cullity 1972, Coey 1996, Chikazumi 1997 and Buschow 1997). The final suitability can only be assessed when the extrinsic properties such as coercive field $H_C$, remanent magnetization $B_r$, and maximum energy product $(BH)_{max}$, derived from the intrinsic properties by the preparation of appropriate microstructures, fulfill certain criteria.

Ferromagnetic materials are characterized by a parallel orientation of the participating magnetic moments below the Curie temperature, i.e., the magnetic ordering temperature. This is caused by an exchange interaction $H_{ex}$ that was described by Heisenberg in 1928 by:

$$H_{ex} = -2J_{ij}S_iS_j \qquad (1)$$

where $J_{ij}$ is the exchange integral, and $S_i$ and $S_j$ are the localized magnetic spin vectors of the ions $i$ and $j$. For a ferromagnetic interaction, the exchange integral is positive, whereas it is negative for an antiferromagnetic coupling between the two ions. The coupling is sensitive to the interatomic spacing $r_{ij}$ and the ferromagnetic interaction is strongest for cobalt, and significantly weaker for iron and nickel (Bethe–Slater curve).

The above description requires localized electrons and needs to be modified for transition metals (T–T interactions) where the electrons are itinerant: that means the 3*d* ions do not have an integral number of electrons. Nonetheless, the atomic moment $m$ of the transition metal element can be defined as

$$m = gS_T\mu_B \qquad (2)$$

where $g$ is the Landé factor (ratio of the magnetic moment to the angular moment), $S_T$ an effective spin and $\mu_B$ the Bohr magneton ($1\,\mu_B = 9.274 \times 10^{-24}$ J $T^{-1}$). In a weak ferromagnet both spin-up and spin-down bands are partially depleted, and in a strong ferromagnet the majority spin-up band is completely occupied (Fig. 1). Despite its relatively large moment iron is a weak ferromagnet (2.22 $\mu_B$ at $T = 0$ K) whereas cobalt (1.72 $\mu_B$) and nickel (0.61 $\mu_B$) are strong ferromagnets (Slater–Pauling curve, see Fig. 2). If iron were a strong ferromagnet its moment could be extrapolated to 2.7 $\mu_B$

In rare-earth–transition metal compounds three types of exchange interactions may occur: T–T, R–T, and R–R. In the case of $SmCo_5$ for example, where the transition metal carries a well-established magnetic moment, the T–T interactions dominate. The strongly ferromagnetic coupling is responsible for the magnetic order up to the very high Curie temperature. The R–R exchange coupling proceeds indirectly via 4*f*–5*d*–5*d*–4*f* and is generally very small compared to the R–T interaction. The latter also proceeds via an indirect mechanism (4*f*–5*d*–3*d*) in which the strong interatomic direct 5*d*–3*d* exchange is transmitted to the 4*f* electrons via the intra-atomic 4*f*–5*d* ferromagnetic interaction (Brooks and Johansson 1993). The 5*d*–3*d* exchange is antiferromagnetic when the 5*d* band is less than half full and the 3*d* band is more than half full, as is the case for compounds of rare-earth metals with ferromagnetic 3*d* metals.

Qualitatively it can be summarized that, as the transition metal spin $S_T$ couples antiparallel to the rare-earth spin $S_R$, the magnetizations of R and T sublattices couple parallel for the light rare-earth

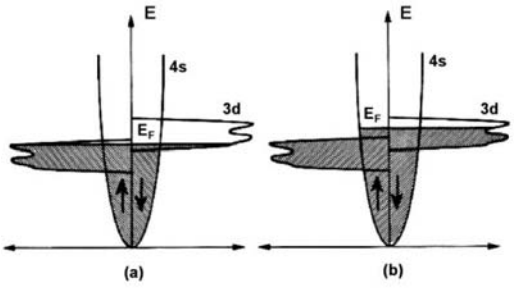

***Figure 1***

elements ($J = L - S$) and antiparallel for the heavy rare-earth elements ($J = L + S$). The orbital magnetic moments in rare-earth metals remain unquenched by crystalline fields because the magnetic moments are produced by 4*f* electrons well inside the atoms and protected from the surrounding atoms. If the total magnetization rotates together with the orbits in the crystal lattice, the electrostatic interaction between the orbits and the lattice favors certain directions of the magnetization. The result of this interaction is an enormous magnetocrystalline anisotropy (see *Magnetic Anisotropy*) as illustrated in Fig. 3 for hexagonal terbium. In that case the shape of the 4*f* orbit (pancake-like electron cloud) and the crystal symmetry (compressed along the *c*-axis) finally lead to easy and hard directions of magnetization.

The intrinsic properties are determined by magnetic moments and interactions on an atomic scale and are independent of the microstructure of the specific material. The disappearance of long-range magnetic order at the Curie temperature is a second-order thermodynamic phase transition, as can be seen from specific heat capacity measurements, where a significant magnetic contribution arises. Above this temperature the material becomes paramagnetic. The transition metals cobalt, iron, and nickel exhibit Curie temperatures of 1127 °C, 770 °C, and 358 °C respectively, whereas of the rare-earth metals only gadolinium ($T_C = 16$ °C) is ferromagnetic close to room temperature.

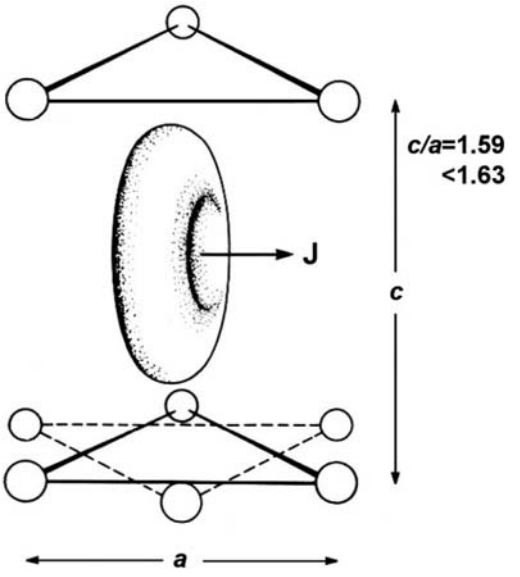

***Figure 3***
Electron cloud of the 4*f* electron of a terbium atom in a hexagonal lattice (Chikazumi 1997). The *c*-axis is the hard direction of magnetization. The ideal $c/a$ value for a closed-packed hexagonal lattice is 1.63.

The magnetization of a ferromagnetic material has its origin in the spin and orbital magnetic moments of the electrons. In a continuum description called *micromagnetism*, a local magnetization vector **M** can be defined by summing the elementary contributions per unit volume. In most materials the spatial distribution of the magnetization is dominated by magnetic domains (see *Magnets, Soft and Hard: Domains*). The direction of magnetization varies from domain to domain and normally lies along a crystallographic axis. However, within one domain the magnitude of $M$ is uniform, and it is called the *spontaneous magnetization* $M_S$. The magnetization over the entire volume of a polycrystalline sample would normally average out to zero, but a net magnetization can be retained when the ferromagnetic material can be prepared in a metastable state.

This remanent state can be achieved after saturation in a magnetic field which corresponds to a complete alignment of all the moments (see also Fig. 4) parallel to the field and which eliminates the domain walls in each crystallite. An easy-axis anisotropy is indispensable for maintaining the metastable domain configuration. The crystalline electric field mentioned above, together with the spin-orbit coupling, gives rise to the single-ion anisotropy on an atomic scale. The atomic moment has local easy directions that reflect the point symmetry of the site. The overall crystal symmetry is described macroscopically by the magnetocrystalline anisotropy that is obtained by summing all single-ion contributions.

In a material with uniaxial symmetry (e.g., hexagonal cobalt) the anisotropy energy of a crystal $E_A$ may be described by

$$E_A = K_1 \sin^2\theta + K_2 \sin^4\theta + K_3 \sin^6\theta + K_4 \sin^6\theta \cos 6\phi \quad (3)$$

where $K_1$, $K_2$, etc. are the anisotropy constants which vary with temperature and differ for different

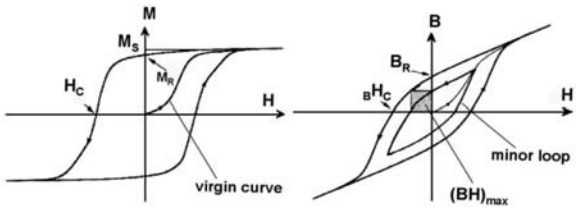

***Figure 4***
Hysteresis loops for a permanent magnet: (left) *M–H* loop and (right) *B–H* loop. The initial magnetization curve after thermal demagnetization starts at the origin; a minor loop arising after the application of fields insufficient for saturation is also shown. The energy product $(BH)_{max}$ is the shaded area in the second quadrant of the *B–H* loop.

materials; and where the direction of the spontaneous magnetization relative to the single uniaxial direction ($c$-axis) and the $a$-axis is given by the polar angles $\theta$ and $\phi$, respectively. With $K_1$ dominating and $K_1 > 0$, the easy direction of magnetization will be along the $c$-axis in hexagonal or tetragonal structures. (SI units of $E_A$ and $K_i$ are J m$^{-3}$.) The anisotropy field $H_A$ is the intersection of the magnetization curves when measured with the field parallel and perpendicular to the easy magnetization direction and, therefore, can be used as an estimate for $K_1$ (for materials where $K_2$ is negligible, this is the case when the magnetization measured with the field applied perpendicular is a straight line, e.g., tetragonal $Nd_2Fe_{14}B$ at room temperature).

$$H_A = (2K_1 + 4K_2)/\mu_0 M_S \tag{4}$$

The static magnetic properties are described by hysteresis loops as shown in Fig. 4 where either magnetization $M$ or magnetic flux density $B$ is plotted as a function of field $H$ ($M$–$H$ or $B$–$H$ curves). Provided that the applied field, corrected for the demagnetization effect (the demagnetization factor $N$ is a pure number between 0 and 1 and depends only on sample shape, e.g., 1/3 for spherical particles and the sum in the three orthogonal directions is unity), is sufficient to achieve saturation, one symmetric major loop is traced (the intrinsic property $M_S$ is delineated in the $M$–$H$ presentation); otherwise minor loops are obtained. In the SI system the relationship between $B$, $M$, and $H$ is given by:

$$B = \mu_0(H + M) \tag{5}$$

$M$–$H$ or $B$–$H$ loops have different contours, the former being more relevant for fundamental aspects, the latter of interest from an application point of view and being usually presented in the magnet data sheets.

For an ideal permanent magnet the second quadrant $B$–$H$ loop is a straight line, with slope $\mu_0$. The remanence $B_r$ or $\mu_0 M_r$ is the flux density or remanent magnetization that persists after removing the magnetizing field $H$. Another extrinsic property is given when the loop cuts the field axis; with $M = 0$ the coercivity $H_c$ is obtained (often referred to as *intrinsic coercivity*, which is rather unfortunate because the coercivity is not an intrinsic property but is very much microstructure-dependent). The maximum energy density $(BH)_{max}$, or also energy product, of rare-earth permanent magnets is a measure of the magnetostatic energy stored and, thus, describes the performance of the magnet (the shaded area in Fig. 4). It is the most widely spread figure of merit and is found where the product of $B$ and $H$ is maximized, which is equal to twice the potential energy of the magnetic field outside the magnet divided by its volume.

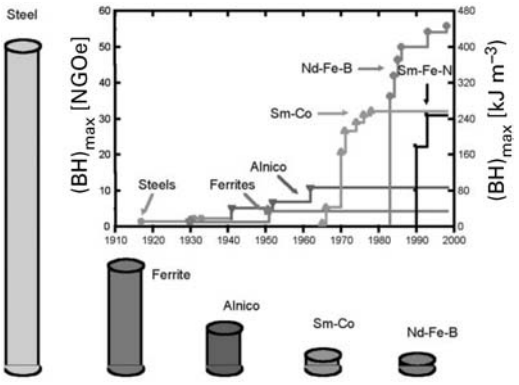

***Figure 5***
Development in the energy density $(BH)_{max}$ of hard magnetic materials in the twentieth century and presentation of different types of materials with comparable energy density.

$(BH)_{max}$ is limited by the remanence, provided the coercivity has at least half the value of the remanence:

$$(BH)_{max} \leqslant \mu_0 M_r^2/4 \tag{6}$$

where, for example, the remanent magnetization $M_r$ is half of the saturation magnetization $M_S$, as postulated by Stoner and Wohlfarth in 1948 for an assembly of isotropic noninteracting single-domain particles (or for an ideal permanent magnet: $M_r = M_s$). $(BH)_{max}$ doubled every 12 years during the twentieth century (see *Rare Earth Magnets: Materials*) and the spectacular development is illustrated in Fig. 5. The progress has been made due to the improvement in coercivity, $H_c$, and not in magnetization, $M_s$. The coercivity $H_c$ is usually approximated by (assuming $K_1 \gg K_2$):

$$H_c = 2(K_1/\mu_0 M_S)\alpha - N_{eff} M_S \tag{7}$$

where $\alpha$ and $N_{eff}$ are microstructural parameters, the former describing the reduction of the crystal field by defects as well as by misaligned grains and the latter taking into account internal stray fields (Adler and Hamann 1985, Durst and Kronmüller 1985).

The mechanism by which a hard magnet is locked in the metastable state described above is controlled by many factors (see *Coercivity Mechanisms*). Here it is only stated that reverse domain nucleation and domain wall propagation result in $H_c \ll H_A$ (the so-called *Brown's paradox*), which means that the anisotropy field represents an upper limit on the coercivity $H_c$, but typical coercivities in high-performance magnets do not exceed 20% of $H_A$. This reduction is principally attributed to microstructural effects and it is remarked that the type of coercivity

mechanism can be determined by analyzing the initial magnetization curves after thermal and d.c.-field demagnetization and the demagnetization curves in the respective hysteresis loops.

Larger grains of a ferromagnetic phase are not uniformly magnetized but consist of magnetic domains in order to reduce the magnetostatic energy. The domains are separated by Bloch walls and the wall width $\delta_w$ in hard magnets is comparable in size to the exchange length $l_{ex} = \sqrt{(A/K_1)}$ with $A$ being the exchange stiffness in J m$^{-1}$ (proportional to $T_C$), the latter describing the scale of the perturbed area when a spin is unfavorably aligned. These micromagnetic parameters are especially relevant for exchange-coupled magnets, which are characterized by an unusual coercivity mechanism when consisting of finely dispersed hard and soft magnetic phases (''exchange spring magnets,'' Kneller and Hawig 1991; see *Magnets: Remanence-enhanced*). The critical single-domain particle size $d_c \sim \mu_0\sqrt{(A/K_1)}/(\mu_0 M_S)^2$ describes the size of the largest possible crystallite in which the energy cost for the formation of a domain wall is higher than the gain in magnetostatic energy.

Typical values for iron-based rare-earth–transition metal permanent magnets are of the order of $d_c =$ 200–300 nm. There are two basic concepts (see *Coercivity Mechanisms*) for the prevention of nucleation and growth of reverse domains from the fully magnetized state (magnetization reversal): (i) for microcrystalline magnets (see *Magnets: Sintered*) and (ii) for single-domain grains found in nanostructured magnets (see *Magnets: Mechanically Alloyed*, *Magnets: HDDR Processed*). The former concept is realized first in the nucleation type, as found in sintered NdFeB-type magnets consisting of multidomain grains in the thermally demagnetized, equilibrium state. The wall motion within a grain is relatively easy but the spontaneous nucleation of reverse domains is hindered by smooth grain boundaries, which also decouple the individual crystallites and thus impede propagation. Second, in the pinning type as found in sintered $Sm_2(Co, Fe, Cu, Zr)_{17}$ magnets where the growth of reverse domains is prevented by pinning the existing domain walls at inclusions or defects. The nucleation- and pinning-types can be easily recognized from their respective initial magnetization curve, the former showing a large low-field susceptibility whereas the latter is characterized by a weak low-field susceptibility.

Stable coercivities and magnetizations at temperatures often exceeding 200 °C are required for applications as in motors, actuators, and electromagnetic machines. Both quantities naturally decline as the operating temperature approaches the Curie temperature. Reversible temperature coefficients of coercivity ($dH_C/dT$) and remanence ($dB_r/dT$) are used for magnet specifications in order to design a machine. Ideally, irreversible magnetic losses are avoided, i.e., they are only temporary on heating, and the original values are recovered when returning to room temperature.

## Heavy-fermion Systems

Heavy-fermion metals represent a class of archetypical strongly correlated electron systems (Stewart 1984, Grewe and Steglich 1991). Mostly, these materials are based upon intermetallics containing the *f* electron elements cerium, uranium, ytterbium, or neptunium, and this review will focus entirely on these ''classic'' heavy fermions. The heavy-fermion-like behavior of a number of compounds not containing these elements is beyond the scope of this work; there is still some controversy over whether the

underlying physical mechanisms here are truly analogous to those of the classic heavy-fermion materials.

Historically, the term heavy fermion (HF) refers to the observation of a largely enhanced electronic contribution to the specific heat $C_p$ at low temperatures $T$, compared to normal metals. The specific heat of a nonmagnetic metal at $T \ll \Theta_D$ ($\Theta_D$ = Debye temperature) evolves as $C_p = \gamma T + \beta T^3$. The term $\gamma T$ represents the electronic specific heat, $\beta T^3$ the phonon part. In free electron approximation the electronic specific heat coefficient is

$$\gamma = \frac{\pi^2 k_B^2 N(E_F)}{3} = \frac{k_B^2 k_F^2 m^*}{3\hbar^2} \qquad (1)$$

where $N(E_F)$ is the Fermi level density of states, $k_F$ is the Fermi wave vector, and $m^*$ is the effective electron mass. For simple metals such as sodium the value of $\gamma$ is of the order of $1\,\mathrm{mJK^{-2}\,mole^{-1}}$, which corresponds to an effective mass $m^*$ almost equal to the free electron mass. In contrast, in HF systems $\gamma$ values of 100–1000 $\mathrm{mJK^{-2}\,mole^{-1}}$ are found, reflecting an equally bigger effective electron mass—hence the label *heavy-fermion* or *heavy-electron materials*.

HF behavior is intimately connected to the suppression of magnetic order. In HF systems magnetism is unstable due to the competition between two processes involving the magnetic moment on the $f$ ion site and its hybridization $\Gamma$ with the surrounding conduction electrons: the indirect magnetic interaction between $f$ moments promotes long-range magnetic order, while a moment screening process, the Kondo effect, tends to suppress magnetic ordering. The strength of the hybridization $\Gamma$ controls the competition of these two processes, and by variation of $\Gamma$ a transition from a magnetic to a nonmagnetic ground state can be achieved.

Experimentally, the hybridization of a material can be tuned by applying chemical or hydrostatic pressure. Ideally, both similarly change the material properties, as is the case for $CeRu_2Ge_2$ (Fig. 1). Here, the crystallographic unit cell volume is reduced by 5% by the isoelectronic substitution of silicon by germanium ($x = 1$ in $CeRu_2(Ge_{1-x}Si_x)_2$) or applied pressure $p = 70$ kbar, leading to an increase of $\Gamma$ (Süllow *et al.* 1999). Physically, the ground state of the system is tuned from a local moment ferromagnet (FM) via two reduced moment antiferromagnetic (AFM) phases, through the magnetic instability with $T_N = 0$ into a nonmagnetic Fermi liquid (FL) below a characteristic temperature $T_{FL}$. The magnetic phase diagram, derived from alloying (shaded symbols, top scale) and pressure (open symbols, bottom scale) studies, is plotted in Fig. 1, with the FM phase I and the two AFM phases II and III. Included in the figure are $T_{FL}$ and the Kondo temperature $T_K$ (filled symbols). The HF regime for $CeRu_2(Ge_{1-x}Si_x)_2$, with large effective electron mass (i.e. $\gamma > 100\,\mathrm{mJK^{-2}\,mole^{-1}}$), consists of a narrow pressure range of less than 10 kbar on both sides of the magnetic instability, with the mass enhancement increasing on approaching the instability. At the instability, with $T_{FL} = T_N = 0$, non-Fermi liquid (NFL) behavior is observed (see *Non-Fermi Liquid Behavior: Quantum Phase Transitions*).

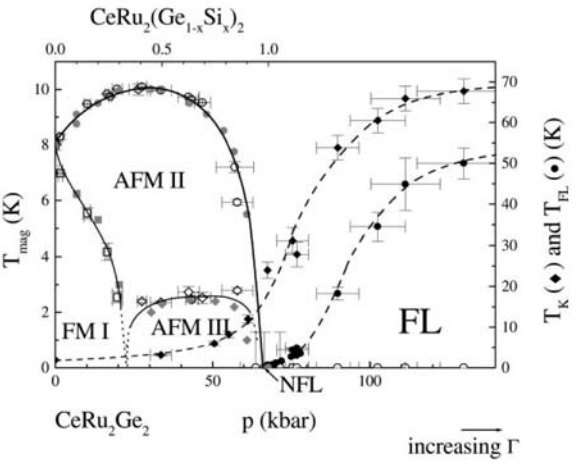

***Figure 1***
The pressure/chemical pressure phase diagram of $CeRu_2(Ge_{1-x}Si_x)_2$. Open symbols □, ○, and ◇ denote the ferromagnetic FM I, antiferromagnetic AFM II and AFM III transition temperatures determined in a pressure experiment on $CeRu_2Ge_2$, the corresponding shaded symbols those established from an alloying study on $CeRu_2(Ge_{1-x}Si_x)_2$. Further, the single-ion Kondo temperature $T_K$, derived from a combination of inelastic neutron scattering and pressure dependent resistivity measurements, and the Fermi liquid temperature $T_{FL}$, representing the temperature range of a resistivity $\rho = \rho_0 + AT^2$, are included in the figure (filled symbols). Note that an increasing pressure corresponds to an increasing hybridization $\Gamma$.

Microscopically, the large mass enhancement in the HF state reflects the appearance of a very large resonance peak, the Kondo resonance, in the enhanced electron density of states at the Fermi energy $E_F$. Based on inelastic magnetic neutron scattering and dilution studies on prototypical nonmagnetic HF compounds such as $CeCu_6$ or $CeRu_2Si_2$, this resonance at least in part can be traced back to the single-ion Kondo effect, which causes the screening of the local magnetic moments by conduction electrons below a characteristic temperature, the Kondo temperature $T_K$. On the other hand, the observation of a quasielastic magnetic response at certain distinct wave vectors in reciprocal space attests to the importance of intersite effects, which give rise to short-range and short-lived antiferromagnetic fluctuations. As the intersite interactions compared to the onsite

Kondo interactions gain importance, an antiferromagnetically ordered state will eventually be entered which, sufficiently close to the magnetic instability, is carried by even more strongly mass-enhanced electrons.

While the fundamental properties of HF materials derive from the single-ion Kondo model, they do not fully correspond to it. In particular, as manifestation of single-ion Kondo behavior the resistivity saturates far below $T_K$ with $\rho \propto 1-(T/T_K)^2$, while in HF compounds below $T_{FL}$ a *metallic* resistivity $\rho = \rho_0 + AT^2$ occurs ($\rho_0$ being the residual resistivity). This deviation from single-ion Kondo behavior is referred to as the transition into the coherent state. Phenomenologically, it is viewed as the realization of a "Bloch-wave state of Kondo scatterers," i.e., the coherent superposition of scattering amplitudes from Kondo ions with the periodicity of the crystallographic lattice. Because of this transition into a coherent state, HF materials are also called *Kondo lattice systems* (see *Kondo Systems and Heavy Fermions: Transport Phenomena*).

Closely linked to HF behavior, a rich variety of ground state properties and exotic physical phenomena is observed. There is the intricate relationship between the HF state and FL as well as NFL behavior. For a number of HF compounds, superconductivity—possibly unconventional—and unusual types of magnetic order are observed. Further, a gap can open in the enhanced electron density of states at $E_F$, causing a semiconducting strongly correlated behavior. These, as the most relevant anomalies of the HF state, are briefly discussed below.

## 1. Fermi Liquid Behavior

The principal feature of nonmagnetic HF compounds below $T_{FL}$, which is not zero, is that the materials behave as if they were free electron materials, but with largely enhanced electron mass $m^*$. This highlights the presence of a novel kind of electronic "quasiparticles" (the "heavy fermions"), whose contribution to the electronic specific heat evolves like $\gamma T$, and whose susceptibility behaves Pauli paramagnetic, saturating at a value $\chi_0$. In addition, the resistivity $\rho - \rho_0$ obeys $AT^2$, as expected for dominant quasiparticle–quasiparticle scattering. The coefficients $\gamma$, $\chi_0$, and $A$ reflect the mass enhanced state with $\gamma \propto \chi_0 \propto \sqrt{A} \propto m^*$. The heavy FL state, coherently formed out of conduction electrons and $f$ electrons, weakly delocalized due to their hybridization with the former, has been studied by de Haas–van Alphen and Shubnikov–de Haas measurements (see *Magnetic Systems: De Haas–van Alphen Studies of Fermi Surface*). The experimentally determined renormalized band structures of HF systems are reproduced by calculations, if the mass renormalization is taken into account as an empirically introduced parameter. Altogether, the physical properties are linked by a single parameter, the electron mass enhancement. The concept to describe such single-parameter scaling is the Landau theory of the Fermi liquid. Within this concept a one-to-one correspondence between the quasiparticles of the HF state and the electrons in a free electron gas is drawn via a renormalization of the effective mass. In this way, the Fermi liquid theory achieves a mapping of the HF state onto the well-known non-interacting free electron gas.

At the magnetic instability, for $T_N = T_{FL} = 0$, the description of the HF properties within the Landau FL theory appears to fail. Here, temperature dependencies of the physical properties are recorded which do not adhere to the FL predictions, and which are collectively referred to as NFL behavior.

## 2. Superconductivity and Magnetism

One of the most spectacular and elusive phenomena of HF materials is the appearance of superconductivity in a few compounds (Zwicknagl 1992, Heffner and Norman 1996). Presently, six materials are regarded as heavy-fermion superconductors (HFS): $CeCu_2Si_2$, $UBe_{13}$, $UPt_3$, $URu_2Si_2$, $UPd_2Al_3$, and $UNi_2Al_3$. Furthermore, $CeCu_2Ge_2$, $CeRh_2Si_2$, $CePd_2Si_2$, and $CeIn_3$ are probably HFS at high pressure. The unifying aspect of HFS is that superconductivity is carried by the heavy quasiparticles. Thus, superconductivity in HF systems is a property of the strongly correlated state and involves those electrons that also take part in the magnetic exchange, i.e., the $f$ electrons.

The electronic correlations manifest themselves in highly unusual superconducting properties, such as multiple superconducting phases, anomalous pinning behavior, or impurity effects. In analogy to the superfluidity of $^3$He, it is assumed that in HFS the symmetry of the superconducting order parameter is highly anisotropic and that they behave as unconventional superconductors, i.e., show an order parameter with a lower symmetry than that of the underlying crystal lattice. While for $CeCu_2Si_2$, $UBe_{13}$, and $UPd_2Al_3$ the order parameter most probably is of even parity, Knight-shift results suggest an odd-parity superconducting state in $UPt_3$ (Tou *et al.* 1996). Further candidates for this variant are $URu_2Si_2$ and $UNi_2Al_3$. An important question concerns the superconducting pairing mechanism. In contrast to the classical, phonon-mediated superconductors, in HFS the Cooper-pair formation may be, at least partly, mediated by electronic exchange mechanisms. So far, however, neither the unconventional superconducting order parameter nor the specific pairing processes have been established beyond doubt.

The main difficulty in determining the basic physical principles of HFS is the multitude of physical

phenomena observed in this class of compounds, in particular with respect to the interdependence, competition, and coexistence of superconductivity with other ground states. In the cerium-based systems, superconductivity is observed close to the magnetic instability, implying an intimate connection of HFS to the suppression of magnetic ordering. In contrast, in $UPt_3$, $URu_2Si_2$, $UPd_2Al_3$, and $UNi_2Al_3$, magnetism and superconductivity coexist on a microscopic scale. Yet, in these uranium systems the magnetically ordered ground states are vastly different. In $UPt_3$ a spin-density-wave (SDW) state of ultralow moments ($\mu_{ord} = 0.02\,\mu_B$) forms. Apparently similar to $UPt_3$, an ultralow-moment SDW state exists in $URu_2Si_2$. However, here magnetism probably does not constitute the primary order parameter; instead, quadrupolar ordering mechanisms are considered. $UPd_2Al_3$ and $UNi_2Al_3$ both exhibit a more common type of antiferromagnetic order, but the ordered moment in the palladium system ($\mu_{ord} = 0.85\,\mu_B$) is huge compared to the nickel compound ($\mu_{ord} = 0.24\,\mu_B$) and to all other HFS. Again in variance, no long-range magnetic order is observed in pure $UBe_{13}$, but alloying the system with a few percent thorium triggers ultralow-moment magnetism and leads to a complicated superconducting phase diagram.

Possibly the most remarkable anomaly of HFS is the multiple superconducting $B$–$T$ phase diagram of $UPt_3$ shown in Fig. 2. This phase diagram constitutes the strongest evidence for the unconventional superconductivity in HFS. Theoretical proposals to explain the multiple phase diagram started from the assumption of two different anisotropic superconducting states A and C, each with lower symmetry than the crystalline lattice and energetically almost degenerate. The corresponding phase boundaries cross at a tetracritical point. The phase B below

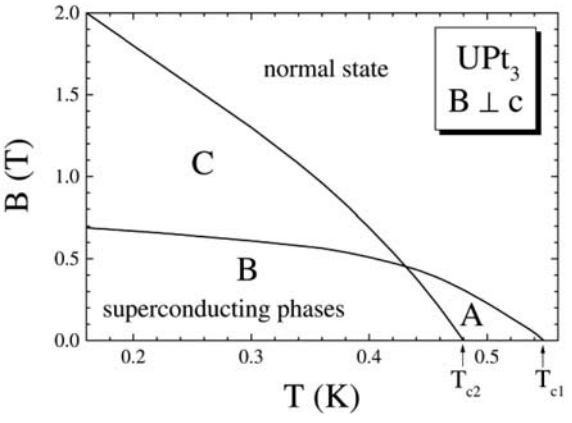

***Figure 2***
Schematic $B$–$T$ phase diagram of the three superconducting phases of $UPt_3$.

$T_{c2}$, as a combined state of the phases A and C, shows magnetic signatures that have been attributed to the nonunitary property of this state (Tou *et al.* 1998). However, a conclusive experimental verification of unconventional superconducting order parameters in $UPt_3$ or other HFS is still lacking. An even greater challenge remaining is the determination of the superconducting pairing mechanisms. While there is an abundance of theoretical studies on electronic pairing, only a few experiments have yet been presented in support of such pairing mechanisms in HFS. The nonuniversality of the superconducting phenomena has led to the proposal that more than one coupling mechanism may have to be considered for all HFS.

Aside from the superconducting properties of HF metals, their magnetic behavior is also remarkable (Amato 1997). Most important, low- and ultralow-moment magnetism is observed, i.e., the transition into antiferromagnetically ordered states with staggered magnetic moments as low as $0.001\,\mu_B$. To some extent, this behavior can be understood by proximity of the magnetic instability in HF materials. On approaching the instability within the magnetically ordered phase, the $f$ moment is increasingly screened by the Kondo effect, which thus can attain any arbitrary small value.

This mechanism for low-moment magnetism relates the size of the moment to the magnetic transition temperature, which both decrease in a corresponding way. For a number of HF systems, however, such a link does not exist; here additional effects come into play. First, a magnetic order sometimes realized in a SDW indicates that nesting of the renormalized Fermi surface plays a role. Second, in a few HF materials the magnetic ordering appears to be only a secondary, "spurious" effect, which masks the underlying order/disorder transition of the "true" order parameter, frequently being of quadrupolar nature. Finally, for some of the "ultralow-moment" systems, i.e., those with an ordered moment of $\sim 0.01\,\mu_B$, the distinction between "long-range magnetic ordered" and "slowly fluctuating" apparently gradually disappears. For all these materials the magnetic behavior remains very much a mystery to date.

## *3. Kondo Insulators*

These materials are HF or intermediate valence (IV) compounds with a small gap in their quasiparticle density of states (Aeppli and Fisk 1992, Degiorgi 1999). Accordingly, at temperatures $T \gg \Delta$ ($\Delta$ = width of the energy gap; typically $\cong 10$–$100$ K) the magnetic properties of Kondo insulators are those of paramagnetic HF metals, with a Curie–Weiss local $f$-moment susceptibility. But, as $T$ decreases, thermal depopulation controls the $T$ dependence of the susceptibility. Hence, $\chi$ goes through a maximum at

$T \approx \Delta$ and saturates at a value $\chi_0$, which is much smaller than in HF metals. Similarly, the transport properties at $T \gg \Delta$ resemble a dirty HF metal, but as $T$ is lowered below $\Delta$, semiconducting behavior develops. The effective carrier mass in the semiconducting state is as large as in HF or IV metals, reflecting a strongly enhanced density of states at the gap edges. And while the electronic specific heat coefficient is small ($\sim 1\,\mathrm{mJK^{-2}mole^{-1}}$), upon closing the gap of a Kondo insulator due to doping, semiconductivity is wiped out, and a large $\gamma$ value ($> 100\,\mathrm{mJK^{-2}mole^{-1}}$) is observed in the specific heat. In summary, Kondo insulators are nonmagnetic, mass-enhanced semiconductors at $T \ll \Delta$, while at $T \gg \Delta$ they are reminiscent of HF/IV metals.

The essential properties of Kondo insulators are captured in a simple model of a flat $f$-band hybridizing with a single broad conduction band, generating the gap $\Delta$. The total number of valence electrons is even, including $f$ electrons in the count. At $T = 0$ the electrons fill the lower hybridized band. Then, for fields $H$ smaller than the energy gap $\Delta$ the susceptibility is zero due to the equal number of spin up and spin down electrons. As $T$ increases, $\chi$ increases because of a thermally activated Pauli-like susceptibility, until at $T \gg \Delta$ Curie–Weiss paramagnetism develops. Similarly, the transport properties show a transition from semiconducting to metallic behavior as function of temperature. This model represents the realization of an Anderson lattice Hamiltonian, with two electronic states per $f$ site applied to a system containing one $f$- and one conduction band, and the $f$ onsite Coulomb repulsion $U$.

This simple picture qualitatively accounts for the fundamental properties of Kondo insulators, but it fails to fully explain the Kondo insulating state. For instance, it has not conclusively been resolved whether the opening of a gap in Kondo insulators is entirely a band structure effect. Surely, electronic correlations do play an important role. Further, four phenomena, which appear to be characteristic features of Kondo insulators, elude simple models: (i) In Kondo insulators the band structure is renormalized in a fashion similar to HF metals. It causes the piling up of states at the gap edges, and thus the mass enhancement. To understand this behavior, electronic interactions have to be taken into account. (ii) The energy gap is renormalized in temperature, i.e., its signatures already disappear well below $T = \Delta/k_B$. (iii) In contrast to magnetic semiconductors or HF metals, in which magnetic interactions play a fundamental role and eventually cause the formation of magnetically ordered ground states, for Kondo insulators the intersite magnetic interaction $J$ vanishes in the limit $\omega \to 0$. Thus, in spite of a dense array of magnetic ions in Kondo insulators the net magnetic exchange is zero. (iv) There are a number of problems related to the gap structure of Kondo insulators. Most important, it is not clear whether a gap or a pseudogap intrinsically opens up in the density of states.

## High-resolution Fourier Transform Spectroscopy: Application to Magnetic Insulators

Optical spectroscopy is used widely for studying magnetic insulators. Various aspects of these studies have been reviewed by Hüfner (1982), Eremenko *et al.* (1986), and Cone and Meltzer (1987). Typically, the spectral resolution of grating spectrometers used for these studies is 0.5–1 $\mathrm{cm^{-1}}$ in the visible range of the spectrum. For magnetic compounds containing rare earths (REs) the inhomogeneous width of some

spectral lines is less than $0.1\,\mathrm{cm}^{-1}$ (Popova 1998). The most intense optical transitions allowed for a free ion lie in the infrared and occupy broad spectral regions for the majority of $RE^{3+}$ ions. It is advantageous to register such spectra by a Fourier transform spectrometer (FTS) rather than by a classical one.

Substantial gain in sensitivity of a FTS compared with grating spectrometers permits the study of weak spectra of RE ions introduced in a small amount as a probe into a magnetic material, even if the latter is available in a polycrystalline form only. Far-infrared (FIR) study of magnetic compounds that undergo a magnetoelastic phase transition is another field where FTS can be successfully applied. High-resolution Fourier transform spectroscopy offers new possibilities for studying magnetic phase transitions, short-range order, and magnetic structures in magnetic insulators.

## 1. Fourier Transform Spectroscopy

The principal parts of a FTS are the Michelson interferometer with a moving mirror (see Fig. 1) and a computer that performs the Fourier transform of the interferogram and thus calculates the spectrum of an incident radiation $E(t)$. A detector registers the averaged intensity at the output of the Michelson interferometer

$$\begin{aligned}\Phi(t) &\sim \overline{[E(t)+E(t+\tau)]^2} \\ &= \overline{E^2(t)} + \overline{E^2(t+\tau)} + 2\overline{E(t)E(t+\tau)} \end{aligned} \quad (1)$$

Here $\tau = l/c$ is the time delay between the two interfering beams, $l$ being the path difference. Under certain conditions, that usually are fulfilled, the first two terms in Eqn. (1) are equal to the time-independent mean intensity while the third term represents the autocorrelation function

$$\psi(\tau) = \overline{E(t)\cdot E(t+\tau)} \quad (2)$$

which depends on the time delay $\tau$. The Fourier transformation of $\psi(\tau)$ yields the spectrum, namely,

$$B(\omega) = \frac{2}{\pi}\int_0^\infty \psi(\tau)\cos\omega\tau\mathrm{d}\tau \quad (3)$$

A real instrument delivers $\psi(\tau)$ for the interval $[0, L/c]$, where $L$ is the maximum path difference which depends on the maximum displacement of the moving mirror of the FTS.

The $L$-dependent instrumental function, that is the response of an instrument to a monochromatic incident light $E(t) = \cos\omega_0 t$, can be written as

$$f_L = \frac{1}{\pi}\frac{\sin(\omega-\omega_0)L/c}{(\omega-\omega_0)} \quad (4)$$

$f_L \to_{L\to\infty} \delta(\omega-\omega_0)$, where $\delta(\omega-\omega_0)$ is the delta-function; for a finite $L$, $f_L$ exhibits secondary maxima, and the distance between the first zeros of $f_L$, $\delta\omega = 2\pi c/L$, or, in wavenumbers ($\sigma = 1/\lambda = \omega/2\pi c$), $\delta\sigma = 1/L$, characterizes the spectral resolution. In high-resolution instruments $L$ may reach several meters which corresponds to the better than $0.01\,\mathrm{cm}^{-1}$ resolution.

The free spectral range $\Delta\sigma$ for the FTS depends on a number $N$ of points registered in the interferogram:

$$\Delta\sigma = N\delta\sigma \quad (5)$$

Typically, $N \sim 10^6$, and so even for high-resolution ($\delta\sigma \sim 10^{-3}\,\mathrm{cm}^{-1}$) instruments $\Delta\sigma \sim 10^3\,\mathrm{cm}^{-1}$, and thus broadband high-resolution spectroscopy is possible with FTS.

FTS analyzes all the spectral elements simultaneously which results in the so-called Fellgett or multiplex advantage of FTS over conventional instruments in signal-to-noise ratio. For the intensity-independent noise of a detector (infrared spectral region) the Fellgett advantage is maximum, namely, $\sqrt{M}$, where $M = \Delta\sigma/\delta\sigma$ is the number of registered spectral elements. Additional gain comes from the large throughput of a FTS in comparison with a slit spectrometer (Jacquinot advantage). In Fourier transform spectroscopy, the wave number scale is established relative to the frequency of a stabilized laser used for the measurement of the path difference and, as a result, is precise in the whole spectral region (Connes advantage). General advantages of the FTS over conventional instruments make them a useful tool for material research.

## 2. *Rare Earth Spectroscopic Probe in a Magnetic Compound*

A crystal field of any symmetry lower than cubic raises all but the Kramers degeneracy of the levels of a free $RE^{3+}$ ion with an odd number of electrons. Kramers doublets are further split by the magnetic interactions in a magnetically ordered state. These splittings are usually called exchange splittings. If the crystal unit cell contains $n$ equivalent RE ions, additional so-called Davydov or factor-group splittings of the excited levels into $n$ components occur, due to the interactions between these ions. Usually, Davydov splittings in the RE spectra are small ($\sim 0.1\,cm^{-1}$) and not observable and a single-ion crystal field model shown schematically in Fig. 2 is suitable even for concentrated materials. Each spectral line of a paramagnetic compound splits into a maximum of four components in a magnetically ordered state. Using the fact that the population of the upper component of the split ground Kramers doublet diminishes with decreasing temperature, it is possible to assign all the components of a split spectral line and to find the ground and excited state splittings from optical measurements. Figure 3 gives an example of the spectra of a Kramers ion in a magnetic compound and of the spectral line identification. It shows the absorption of $Er_2Cu_2O_5$ at different temperatures, both higher and lower than the Néel temperature $T_N = 28\,K$. A single-ion crystal field model is true for this concentrated material.

For magnetic compounds containing both RE and transition metal (TM) ions, the main contribution to the splitting comes from the electronic exchange interaction between the RE ion and neighboring TM ions. Usually, the electron clouds of intervening anions are involved, so the superexchange interaction is to be considered. In purely RE compounds, the magnetic dipole–dipole interaction makes comparable or even major contributions to magnetic splittings.

The magnetic dipole–dipole contributions to the splittings of the Kramers levels of a particular RE ion may be described by an action of an effective magnetic field $\mathbf{H}_{dip}$ created by all the magnetic ions of the lattice at the RE site and can be calculated accurately. As for the exchange interaction, a concept of an effective field fails to describe the splittings in this case. The effective exchange potential can be written as an expansion in products of spherical tensor operators for electrons at the two sites, with coefficients that are linear combinations of the two-electron exchange integrals. Only a small number of symmetry-dependent coefficients is required. These may be regarded as empirical parameters and may be found from a set of level splittings measured by optical spectroscopy, which is analogous to the case of crystal field parameters describing the single-ion energy levels of

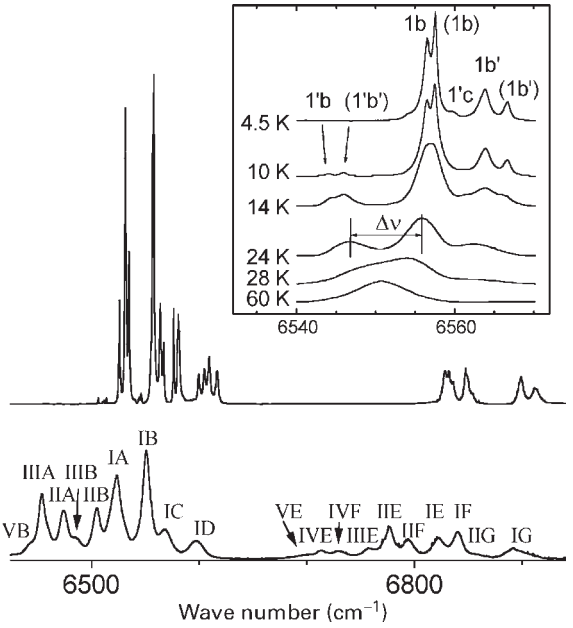

***Figure 3***
Absorption in the region of the $^4I_{15/2} \rightarrow {}^4I_{13/2}$ optical transition in $Er_2Cu_2O_5$ at $88\,K > T_N$ (lower trace) and $6.2\,K < T_N$ (upper trace). Identification is given according to the scheme of Fig. 2. Inset shows the temperature dependence of the line IB. The following values of the level splittings (in $cm^{-1}$) have been found from the spectra: $\Delta = 20.6$ (19.7); $\Delta_A = 3.3$ (5.7); $\Delta_B = 9.0$ (7.2). Values and notations in parentheses refer to the second crystallographic position for $Er^{3+}$ in $Er_2Cu_2O_5$ (after Popova 1998).

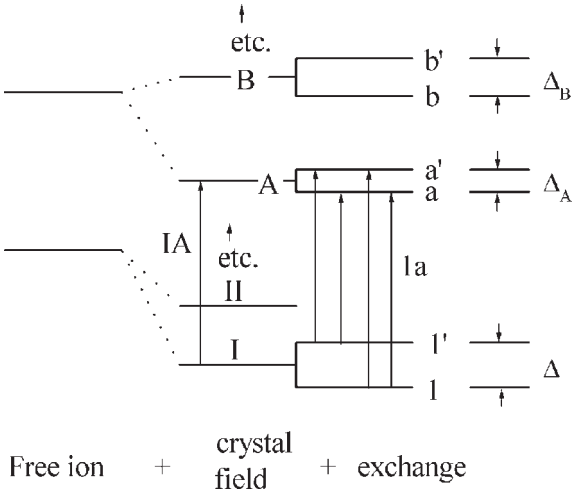

***Figure 2***
Levels of a Kramers ion in a magnetically ordered crystal.

RE ions in crystals. A review of the two-electron spherical operator method for the description of the interionic exchange interaction and of applications of the method to different RE magnetic compounds has been given by Cone and Meltzer (1987). They have shown in particular that (i) there is a unique set of parameters describing the splittings of both ground and a wide range of excited states; (ii) these parameters vary systematically through the RE series; and (iii) the contributions of anisotropic terms to the splittings are comparable or, in some cases, even appreciably larger than the contribution of the isotopic term.

### *2.1 Spectral Detection of Magnetic Phase Transitions*

High spectral resolution and absolute wavenumber precision in Fourier transform spectroscopy make it possible to measure small line splittings $\Delta\nu$ and also to register the width $\delta\nu$ and shape of spectral lines. The temperature of a magnetic ordering $T_c$ can be determined as the abscissa of the point of inflection in the experimentally measured $\Delta\nu(T)$ dependence (see, e.g., Popova 1996, 1998). As an example, Fig. 4 shows the $\Delta\nu(T)$ dependence for the absorption line IB of Fig. 3. The tail of line splittings at $T > T_c$ is due to the short-range order. Additional evidence of the ordering comes from the spectral line narrowing in the vicinity of $T_c$ (Fig. 4).

In many of the magnetic compounds containing both RE and TM ions (*f–d* compounds) anisotropic interactions lead to spin-reorientation transitions at lower temperatures $T_R < T_c$. Figure 5 illustrates the use of the high-resolution FTS to detect a spin-reorientation transition. It shows the $Er^{3+}$ probe spectrum in $Yb_2BaCuO_5$ which orders magnetically

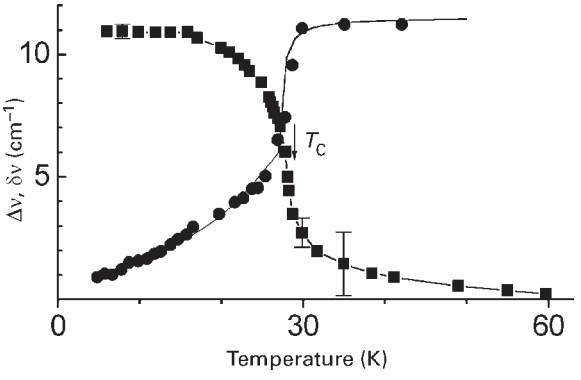

***Figure 4***
The temperature dependence of the splitting $\Delta\nu$ (squares) of the line IB (see Fig. 3) and of the half-width $\delta\nu$ of the component 1a (circles). The temperature $T_c = 28 \pm 0.5$ K follows from the point of inflection in the $\Delta\nu(T)$ dependence.

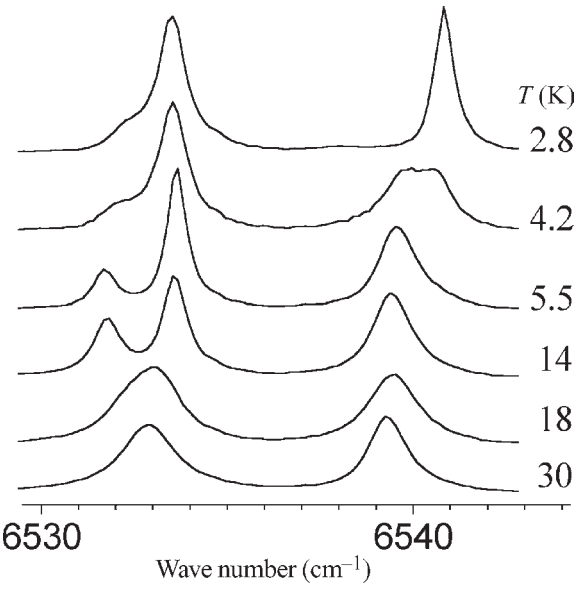

***Figure 5***
Two lines in the $^4I_{15/2} \rightarrow {}^4I_{13/2}$ optical transition of $Er^{3+}$ probe in $Yb_2BaCuO_5$ at different temperatures. $Yb_2BaCuO_5$ orders antiferromagnetically at $T_N = 16.5$ K and undergoes a spin-reorientation transition at $T_R = 4.0$ K.

at $T_c = 16.5 \pm 0.5$ K. In the temperature interval 5.5–3.5 K, the spectrum is a superposition of two different spectra with temperature-dependent relative intensities corresponding to two different magnetic phases which is typical for first-order spin-reorientation phase transition.

### *2.2 Magnetic Structure of the d Subsystem*

The level splittings of the RE ion in a magnetically ordered state of a crystal containing both RE (*f*) and TM (*d*) ions are due mainly to RE–TM exchange interactions which are, as a rule, highly anisotropic. Because of this, the spectra of a rare earth probe are extremely sensitive to the alignment of the magnetic moments of the TM ions in the nearest surroundings of the RE ion. On these grounds, it is possible to make a choice between several magnetic structures that fit neutron scattering data equally well (see, e.g., Popova 1996, 1998).

### *2.3 Low-dimensional Magnetic Correlations*

For $T > T_c$, the splittings of spectral lines do not vanish—a tail of residual splittings is observed due to short-range magnetic order. This tail is longer the lower the dimensionality of a system. On these

grounds, magnetic Cu–O planes have been investigated in a series of isostructural $R_2Cu_2O_5$ compounds and magnetic chains have been found in $Nd_2BaCuO_5$ (see, e.g., Popova 1996).

### *3. Far Infrared Spectroscopy: Detection of Magnetoelastic Transitions*

The interaction between magnetic moments and lattice phonons may result in a magnetoelastic phase transition. One of the most fascinating examples is the spin–Peierls transition that occurs in the system of linear spin $-\frac{1}{2}$ Heisenberg antiferromagnetic chains coupled to a three-dimensional phonon field. As a result of such a coupling, magnetic atoms of the chain dimerize and a spin gap opens.

Figure 6 illustrates the use of a high-resolution FTS to study the transition of such a type. It shows FIR spectra of $\alpha'$-$NaV_2O_5$ below and above the spin–Peierls-like transition ($T_c = 35$ K). Folded phonon modes of a dimerized lattice as well as a gap opening that leads to a drastic change of a phonon lineshape at the frequency of about 90 $cm^{-1}$ are clearly seen below $T_c$.

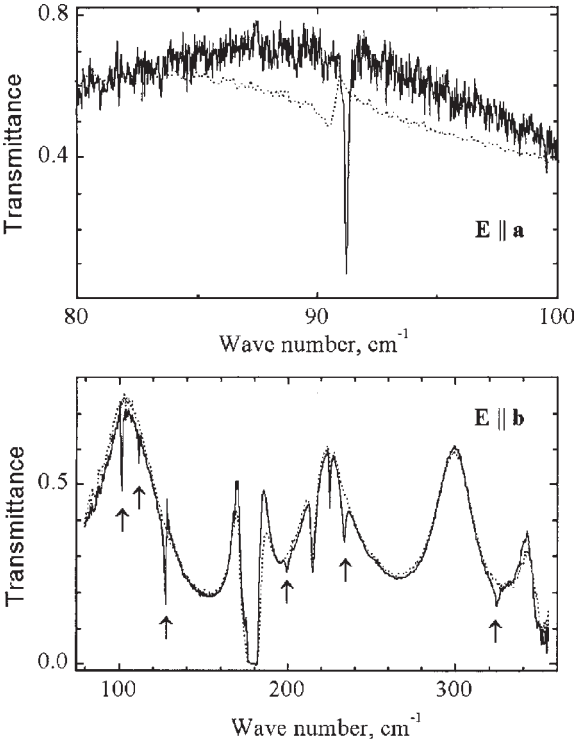

***Figure 6***
FIR transmission of $\alpha'$-$NaV_2O_5$ ($T_c = 35$ K) at 37 K $> T_c$ (dotted line) and 6 K $< T_c$ (solid line). Folded phonon modes are shown by arrows (**E**$\|$**b** polarization). Fano-type resonance (**E**$\|$**a** polarization) is due to the interference of a phonon mode with a continuum. Below $T_c$, the long-wavelength part of the continuum disappears and the phonon at 90 $cm^{-1}$ demonstrates a Lorentzian lineshape (after Popova *et al.* 1997).

## High-$T_c$ Superconductors: Electronic Structure

An understanding of the electronic structure of the high-$T_c$ cuprate superconductors must start out from an analysis of their chemical composition, valencies, structure, and binding. All cuprate high-$T_c$ superconductors are stacks of alternating anionic $CuO_2$ layers and block layers which are in gross cationic. The stacking direction is commonly taken as the crystallographic *c*-direction, and the crystal symmetry is generally derived from a simple tetragonal or a body-centered tetragonal (b.c.t.) symmetry, although it is in fact often orthorhombic due to distortions or due to vacancy ordering.

The general composition of the cuprate superconductors is

$$B^{b+}[(CuO_2)^{(2-\delta)-}]_n C^{c+}_{n-1} \quad (1)$$

where $n = 1, 2, 3, \ldots, c = 2$ or 3, and $b = c + n(2 - \delta - c)$. The block layer $B$ is a cationic metal oxide layer. It is followed by either a single $(CuO_2)^{(2-\delta)-}$ layer or a stack consisting of $n$ such layers with cations $C$ sandwiched in between. So far, the cations $C$ are $Ca^{2+}$, or $RE^{3+}$ where RE = Y, La or any of the lanthanides (see *Superconducting Thin Films: Materials, Preparation, and Properties*).

The main families of cuprate superconductors derive from

(i) $La_{2-x}Sr_xCuO_{4-y}$ which in the systematics of (1) would be $(La_{2-x}Sr_xO_{2-y})^{(2-\delta)+}$ $(CuO_2)^{(2-\delta)-}$ with $n = 1$ and $\delta \approx x$ for $y \approx 0$; related is $M_2CuO_2X_2$ or $(M_2X_2)^{(2-\delta)+}(CuO_2)^{(2-\delta)-}$ with $M = (Ca_{1-x}Na_x)$ or Sr and X = F, Cl, or Br;

(ii) $RE_1Ba_2Cu_3O_{6+x}$ which would be $(Ba_2^{2+}(CuO_{2+x})^{(3+2\delta)-})[(CuO_2)^{(2-\delta)-}]_2RE^{3+}$ with $n = 2$ and $\delta = 0$ for $x < 0.3$ and then increasing to $\delta \approx 0.2$ for $x \approx 1$; and

(iii) $B^{(2-n\delta)+}[(CuO_2)^{(2-\delta)-}]_nCa^{2+}_{n-1}$, $n = 1, 2, 3, \ldots$ with $B = (Bi, Pb)_2Sr_2O_{4+x}$ or $TlBa_2O_{2.5+x}$ or $Tl_2Ba_2O_{4+x}$ or $HgBa_2O_{2+x}$, and $\delta$ increases with increasing $x$; Tl may be replaced by B and Hg by Cu or Au; Ca may be replaced by Y, Dy, Er.

The oxygen in the metal oxide block layers $B$ is more or less volatile. Above, it is written in such a way that in all cases the doping level of the cuprate planes is $\delta = 0$ for $x = 0$ or some value of $x$ close to zero. The magnetic properties of these undoped or weakly doped cuprates is a very topical problem of its own because they are more or less ideal model systems of low-dimensional Heisenberg magnets (see Johnston 1997). This is not particularly considered here in this article. Among them are also cuprate structures which are different from the $CuO_2$ planar structure (chain and ladder structures), some of which become superconductors when doped. They are also not considered here (cf. Müller-Buschbaum (1977) for a structure chemical systematics of all cuprates).

The cation $C$ is always fully ionized; its valence orbitals are unoccupied. The metal oxide block layer $B$ is, depending on composition and on $x$, either insulating or metallic. The essential conducting component which also carries superconductivity is the $(CuO_2)^{(2-\delta)-}$ layer which is doped by charge transfer to the block layer. The doping level $\delta$ may be positive (hole doping) or negative (electron doping). Electron doping is less frequent and is found, in particular, in the family (i) with $B = (Nd_{2-x}Ce_xO_{2-y})$ or $B = (Pr_{2-x}Ce_xO_{2-y})$ instead of $B = (La_{2-x}Sr_xO_{2-y})$. The tetravalent Ce donates one electron.

In traditional metal physics, the electronic structure is characterized by a quasiparticle band structure where at low temperature, $T \to 0$, the quasiparticles have a sharp energy–momentum dispersion relation close to the chemical potential (Fermi level $\varepsilon_F$). These also develop a decay rate proportional to the square of their excitation energy, $|\varepsilon - \varepsilon_F|$, due to energy and momentum scattering. This behavior is meant if one speaks of a Fermi liquid (FL) with an arbitrary dispersion relation. The quasiparticle momenta at the Fermi level constitute the Fermi surface (FS) which is measured through quantum oscillations in the magnetic susceptibility (de Haas–van Alphen effect) or in magnetotransport. Experimental evidence on the quasiparticle dispersion relation close to the Fermi level is obtained both from thermal equilibrium properties such as specific heat or magnetic susceptibility and from transport properties. However, the high-energy electronic excitation spectrum (on an eV scale) is obtained mainly from electron removal by photoemission (hole excitations) and from electron injection by inverse photoemission, as well as from electron excitation by electron-energy-loss spectroscopy (EELS) or by x-ray absorption (XAS).

This picture remains even valid for strongly correlated metals like heavy fermion ($f$-electron) systems; only the energy–momentum dispersion relation is scaled down by up to 2 orders of magnitude. There are many experimental indications that this picture breaks down in a certain region of the phase diagram of the superconducting cuprates: while the thermal equilibrium properties are still reminiscent of a (weakly renormalized) metal, the energy dependence of the quasiparticle scattering rate seems to have a singular behavior and the quasiparticle spectral weight seems to fade away.

A generic doping level–temperature phase diagram of the layered cuprates is shown in Fig. 1. More or less understood are the undoped antiferromagnet (AF) phase ($\delta \approx 0$) as a charge transfer insulator and the FL phase ($|\delta| > 0.2$) as a normal metal. A recommended early review of the mean-field quasiparticle band structures, where the mean field is taken to be the Kohn-Sham potential of density functional theory, is that of Pickett (1989).

### 1. *The Undoped Cuprate*

For $\delta = 0$, the valence electron number per unit cell of the $(CuO_2)^{2-}$ complex is $11 + 2 \times 4 + 2 = 21$ and hence odd. The mean field band structure for an odd valence electron number per unit cell proposes a metallic state with a half-filled band at least above a possible spin magnetic order temperature. Experimentally, the undoped cuprates are insulators with a gap of $\sim$1–2 eV. Below the Néel temperature $T_N$ which, dependent on the block layer, is between 250 K and 540 K, they order antiferromagnetically with an ordered spin moment $\langle \mu \rangle (T \to 0)$ between $0.25\mu_{Bohr}$ and $0.64\mu_{Bohr}$ at the Cu site. Order is due to

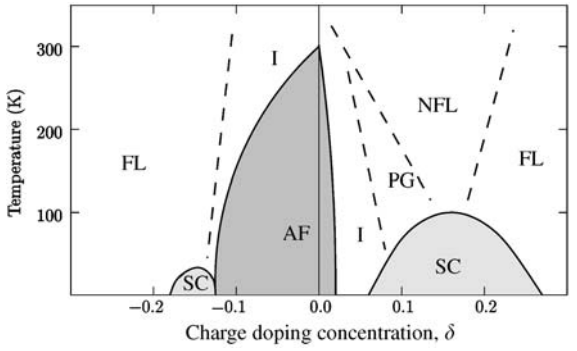

***Figure 1***
Temperature vs. doping phase diagram of electron- and hole-doped planar cuprates. Full lines are phase boundaries. Dashed lines indicate crossovers. AF: antiferromagnet, SC: superconductor, I: insulator, FL: Fermi liquid, NFL: non-Fermi liquid (maybe marginal Fermi liquid), PG: pseudo-gap phase. The left half is less explored than the right half. The maximum Néel temperature into the AF phase depends on the block layer (not generic). The temperature axis scales down with increasing disorder or dimpling of the cuprate plane. A static stripe phase with alternating high-doped metallic and low-doped AF stripes is sometimes found in the PG region. It is not known whether dynamic (fluctuating) stripes are generic in the PG region (cf. Dagotto 1994, Varma 1997, Tohyama and Maekawa 2000, Damascelli *et al*. 2003).

magnetic interlayer coupling. A two-dimensional square lattice spin $\frac{1}{2}$ Heisenberg AF would have a Néel ground state with an ordered moment of $0.307 g\mu_{\mathrm{Bohr}}$ where $g \approx 2$ is the Landé factor, but would not order at $T > 0$; it would only develop local AF correlations.

### *1.1 $CaCuO_2$ As an $n = \infty$ Model Cuprate*

The simplest planar cuprate structure is that of $CaCuO_2$ (Fig. 2). It is an infinite stack of $CuO_2$ layers and Ca layers sandwiched in between. Hence, in the systematics of Eqn. (1) one has $n = \infty$ and $B$ is absent. In reality, $Ca_{0.85}Sr_{0.15}CuO_2$ has been synthesized which is an AF insulator with the highest Néel temperature, $T_N \approx 540\,\mathrm{K}$, of all cuprates and which hardly can be doped. However, the isostructural electron-doped compound $Sr_{1-x}Nd_xCuO_2$, $x \leqslant 0.16$, was reported to be superconducting with $T_c$ up to 40 K.

It is useful to start with the band structure of $CaCuO_2$ in the local spin density approximation (LSDA) and the LSDA + $U$ approximation of density functional theory. The latter accounts in a crude manner for local electron correlations on the copper site by suppressing the $3d^{10}$-configuration in favor of the $3d^9$-configuration. The self-consistent solution of the LSDA converges towards a nonmagnetic ground state. LSDA + $U$ yields a stable AF solution. For the sake of better comparison both the LSDA and LSDA + $U$ results are presented in the AF Brillouin zone (BZ). Within the $CuO_2$ plane the AF order is checkerboard like. In $z$-direction the simplest structure of a ferromagnetic stacking of equal moments on top of each other is used in order to have the simplest unit cell and BZ geometry (both upright square bricks). Anyhow the magnetic coupling in $z$-direction is small. (In reality the AF structure has opposite moments stacked on top of each other in $z$-direction leading to a b.c.t. unit cell instead of a simple tetragonal one; due to the weak coupling in $z$-direction this does not affect any of the following considerations.) Unit cell and BZ are shown in Fig. 3 together with labels of symmetry points in the BZ.

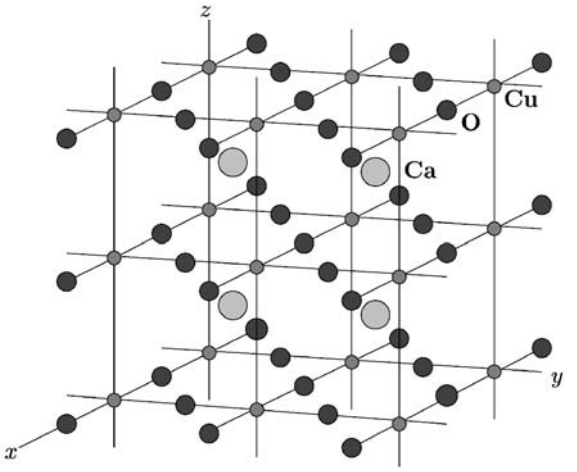

***Figure 2***
Crystal structure of $CaCuO_2$.

The LSDA band structure is shown in Fig. 4. In order to visualize the AF downfolding, the self-consistency was stopped shortly before the moment vanishes so that the potential AF splittings of bands are seen on the lines $X$–$M$ and $R$–$A$. The FS of the metallic state intersects the symmetry lines $\Gamma$–$X$ and $X$–$M$. Its back-folded image in the AF BZ also intersects $\Gamma$–$M$ (band above the AF splitting; the FS is sketched in the upper right quadrant of Fig. 3).

The relevant orbitals which form the bands crossing the Fermi level are shown in Fig. 5. Besides the shown oxygen orbital combinations, there are nonbonding combinations of $E_u$ point symmetry for both $2p_\sigma$ and in-plane $2p_\pi$ orbitals, twofold degenerate for $(k_x, k_y) = (0, 0)$, and an $A_{1g}$ nonbonding combination of $2p_\sigma$ orbitals as well as a $B_{2g}$ O–O bonding combination of in-plane $2p_\pi$ orbitals, all of which do not contribute to the bands crossing the Fermi level. Figure 6 shows the same bands as in Fig. 4, weighted

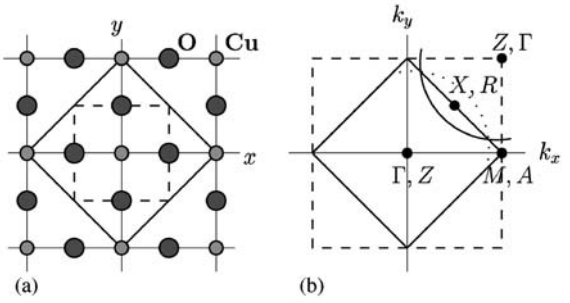

***Figure 3***
The planar $CuO_2$ structure. Nonmagnetic (dashed line) and antiferromagnetic (full line) unit cell (a) and BZ (b). In the AF unit cell the copper spin in the center of the cell is "up" and in the corners "down." The labeling of symmetry points in (b) is for the antiferromagnetic zone; the first label is for $k_z = 0$ and the second for $k_x = \pi$, X: $(k_x, k_y) = (\pi/2, \pi/2)$, M: $(k_x, k_y) = (\pi, 0)$ (in units of $1/c$ and $1/a$). The solid curve in the right upper quadrant sketches the mean-field FS of the nonmagnetic state which consists of rods around the lines $(\pm\pi, \pm\pi, k_z)$. The dotted curve sketches its back folded image in the magnetic BZ.

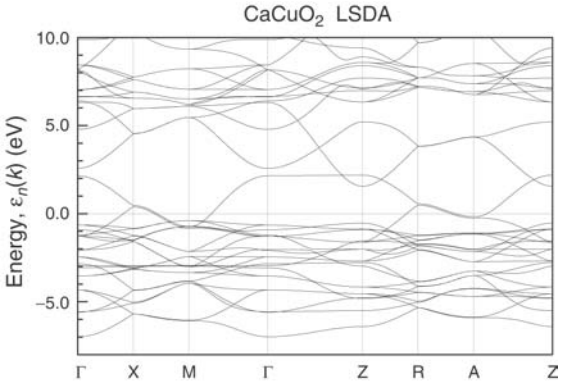

***Figure 4***
LSDA band structure of $CaCuO_2$. The Fermi level is put to zero. See Fig. 3 for the labels of symmetry $\boldsymbol{k}$-points.

by linewidth with the sums over the AF unit cell of the squares of the expansion coefficients of the Bloch state for in turn Cu-$3d_{x^2-y^2}$, O-$2p_\sigma$, in-plane O-$2p_\pi$, O-$2p_z$ (that is out-of-plane O-$2p_\pi$) and Cu-4$s$ orbitals. In the upper two panels, one recognizes a strong Cu–O covalent splitting of more than 5 eV between the lower bonding and the higher antibonding bands. A weaker peroxidic O–O covalent splitting of the in-plane O-$2p_\pi$ derived bands of $\sim 3$ eV is seen in the third panel, and a still weaker splitting of the O-$2p_z$ derived bands is found in the fourth panel. As is

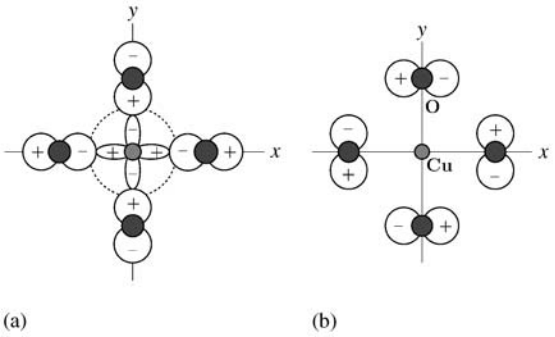

***Figure 5***
The relevant orbital combinations at $(k_x, k_y) = (\pi, \pi)$ of the nonmagnetic BZ which is equivalent to $(k_x, k_y) = (0, 0)$ of the antiferromagnetic zone (cf. Fig. 3). Oxygen $2p$-orbitals having their lobes in the direction of the Cu–O bond are called $2p_\sigma$-orbitals ($(m = 0)$-orbitals with respect to the bond direction as quantization axis), and those having their lobes perpendicular to the bond direction are called $2p_\pi$-orbitals ($(|m| = 1)$-orbitals). Antibonding means a wave function node (sign change) intersecting the bond, and bonding means no such node. (a) Full line: the antibonding Cu-$3d_{x^2-y^2}$−O-$2p_\sigma$ orbital combination of $B_{1g}$ symmetry of the point group $D_{4h}$; dotted: the Cu-4$s$ orbital of $A_{1g}$ symmetry. (b) The O–O antibonding $2p_\pi$-orbital combination of $A_{2g}$ symmetry.

clearly seen, the first two of the above listed orbitals mainly contribute to the bands crossing the Fermi level and only the third and last one contribute in addition. The Ca orbitals and the other Cu orbitals not shown in Fig. 6 do not contribute; the Ca orbitals only contribute well above the Fermi level (hence Ca is fully ionized) as do the Cu-4$p$ orbitals, and the other Cu-3$d$ orbitals only contribute well below the Fermi level. (See also Andersen *et al.* (1995) for similar results for the Y–Ba–Cu–O system; in this case there is an additional metallic $CuO_3$ block layer with additional bands crossing the Fermi level.)

It was already mentioned that due to strong electron correlations on the Cu site the LSDA band structure does not well describe the reality in which $CaCuO_2$ is an insulator. A much better description of the undoped cuprates is given by the so-called rotationally invariant LSDA + $U$ approach for which the resulting band structure is shown in Fig. 7. (The details of the calculations of the bands shown in Figs. 4–8 are given by Eschrig *et al.* 2003.) In this approach, self-consistency yields a stable AF solution with a spin moment $|\langle \mu \rangle| 0.71 \mu_{\mathrm{Bohr}}$.

Figure 8 shows the same orbital analysis for the LSDA + $U$ bands as in Fig. 6 for the LSDA bands. In the first panel, the lower and upper Hubbard bands of Cu-$3d_{x^2-y^2}$ orbitals and their hybridization with oxygen orbitals in between are clearly seen. The

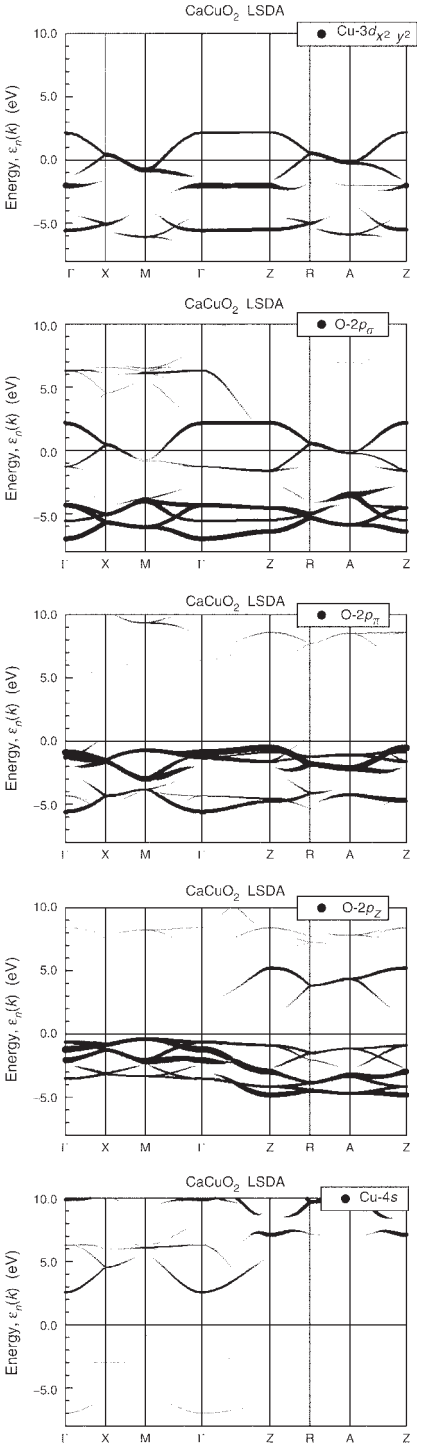

***Figure 6***
Orbital weighted band structure of Fig. 4 as explained in the text.

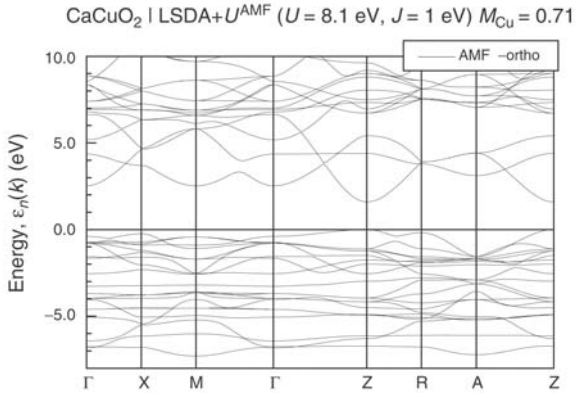

***Figure 7***
LSDA + $U$ band structure of $CaCuO_2$ (cf. Fig. 4).

highest occupied state on the line $\boldsymbol{k} = (\pi/2, \pi/2, k_z)$ (with the end points X and R) is a Cu-$3d_{x^2-y^2}$−O-$2p_\sigma$-in-plane O-$2p_\pi$ hybrid as seen in the upper three panels of Fig. 8. (The absolutely highest occupied state is a pure in-plane O-$2p_\pi$ state in a small $\boldsymbol{k}$-space region around $\boldsymbol{k} = (0,0,\pi)$ while all Cu-4$s$ contributions are now shifted away from the Fermi level.)

### *1.2 Angle Resolved Photoemission Spectroscopy on $Sr_2CuO_2Cl_2$*

There is no space here for a detailed description of the angle resolved photoemission spectroscopy (ARPES) experiment. For a clear review in relation to the cuprates, see Damascelli *et al.* (2003). The development of this experimental technique has enormously been triggered by the high-$T_c$ superconductivity physics. For high-resolution measurements on quasi-two-dimensional structures one needs (001)-crystal surfaces as perfect as possible which are available from undoped $M_2CuO_2Cl_2$, $M$ = Ca, Sr, and from doped $Bi_2Sr_2CaCu_2O_{8+x}$, because these materials are easily cleaved in ultra-high vacuum in the middle of the $M_2Cl_2$ and of the $Bi_2Sr_2O_{4+x}$ block layers.

$Sr_2CuO_2Cl_2$ consists of alternating $CuO_2$ layers and insulating $Sr_2Cl_2$ block layers. Due to the geometry of the latter, subsequent $CuO_2$ layers are shifted horizontally by ($a/2$, $a/2$) relative to each other so that the nonmagnetic structure is b.c.t. Below $T_N \approx 250$ K it orders AF with an orthorhombic magnetic unit cell. However, since there is practically no electronic coupling through the $Sr_2Cl_2$ block layer, all considerations may be related to the two-dimensional unit cell and BZ of Fig. 3 and the LSDA + $U$ band structure in the ($k_z = 0$)-plane of the BZ is practically identical with the left three panels of Figs. 7 and 8.

The quasiparticle low-energy dispersion measured by ARPES (single hole excitation) is shown in Fig. 9.

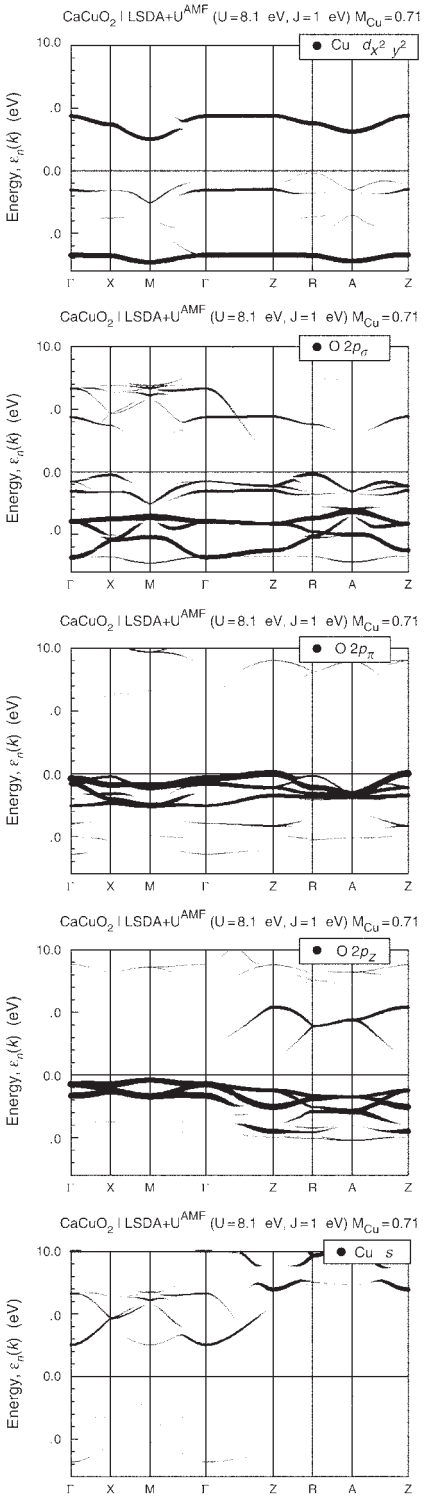

***Figure 8***
Orbital weighted LSDA + $U$ band structure of $CaCuO_2$.

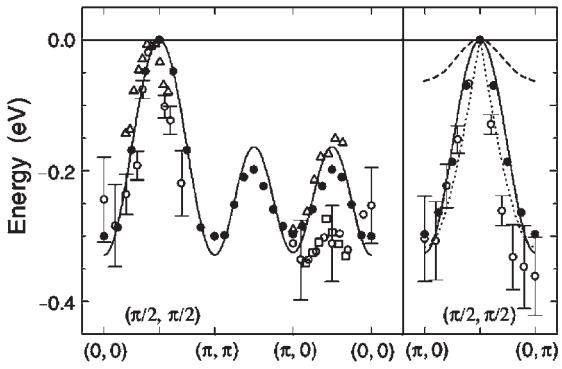

***Figure 9***
Energy dispersion of quasiparticles for $Sr_2CuO_2Cl_2$. The energy zero is put at the top of the band, $\sim 0.7$ eV below Fermi level. Open symbols: experimental data; solid circles: self-consistent Born approximation for a $t$–$t'$–$t''$–$J$ model; solid line: tight-binding fit; dashed: $t$–$J$ model; dotted: spinon model dispersion (reproduced by permission of Tohyama and Maekawa (2000) from *Supercond. Sci. Technol.* **13**, R17; ©IOP Publishing).

A detailed discussion is found in the publications of Tohyama and Maekawa (2000) and Damascelli *et al.* (2003). The left part of the experimental spectra (from (0,0) to ($\pi$/2,$\pi$/2)) compares nicely with the O-2$p_\sigma$ dominated LSDA + $U$ band on the line $\Gamma$–$X$ (second panel of Fig. 8) and the right part (from ($\pi$/2, $\pi$/2) to (0,$\pi$)) with the same LSDA + $U$ band on the line $X$–$M$. Even the reported fading ARPES intensity when going from $X$ towards $M$ (see also Ronning *et al.* 2003) agrees with the fading O-2$p_\sigma$ projection of that band. Nevertheless, the experimental bandwidth is smaller by a factor of $\sim 2$ and the situation on the line $\Gamma$–$M$ is less clear. After all, LSDA + $U$ accounts for electron correlations still rather grossly.

## 2. *Theoretical Models*

The discrepancy between mean-field band structures, predicting a metallic state for all cuprates independent of doping, and experiment calls for models of strong electron correlation to treat the electronic structure. Most of these models concentrate on the degrees of freedom provided by the orbitals Cu-3$d_{x^2-y^2}$ and O-2$p_\sigma$, although it can be inferred from Fig. 8 that the in-plane O-2$p_\pi$ orbital is likely playing a role in the low-energy excitations. Reviews on models of electron correlations in cuprates have been published, for instance, by Dagotto (1994), Varma (1997), and Maekawa and Tohyama (2001). Commonly, the hole picture is used in which the Hamiltonian acts on the "vacuum" of the Cu-3$d^{10}$–O-2$p^6$ configuration of full atomic shells and the energy axis of the band structure

is reversed compared to the electron picture of Figs. 4–9. The basic Hamiltonian first proposed by Emery (Emery model) is

$$\hat{H} = \varepsilon_d \sum_i \hat{n}_i^d + \varepsilon_p \sum_j \hat{n}_j^p - t_{dp} \sum_{\langle ij \rangle, \sigma} (\hat{p}_{j\sigma}^\dagger \hat{d}_{i\sigma} + \hat{d}_{i\sigma}^\dagger \hat{p}_{j\sigma}) - t_{pp} \sum_{\langle jj' \rangle, \sigma} \hat{p}_{j'\sigma}^\dagger \hat{p}_{j\sigma} + U_d \sum_i \hat{n}_{i\uparrow}^d \hat{n}_{i\downarrow}^d + U_p \sum_j \hat{n}_{j\uparrow}^p \hat{n}_{j\downarrow}^p + U_{dp} \sum_{\langle ij \rangle} \hat{n}_j^p \hat{n}_i^d \tag{2}$$

The on-site Cu-3$d_{x^2-y^2}$ and O-2$p_\sigma$ hole binding energies are $\varepsilon_d$ and $\varepsilon_p$, $i$ runs over the Cu sites, $j$ over the O sites, $\langle ij \rangle$ runs over Cu–O bonds, and $\langle jj' \rangle$ over O–O bonds, $\hat{n}$ are the corresponding hole occupation number operators (for spin $\uparrow$ or $\downarrow$ or the sum over both spins if not specified), $t$ are the Cu–O and O–O nearest neighbor hopping amplitudes, $\hat{d}^\dagger, \hat{d}, \hat{p}^\dagger$, and $\hat{p}$ are the Cu-3$d$ and O-2$p$ hole creation and annihilation operators, and $U$ are the on-site and Cu-3$d$–O-2$p$ Coulomb repulsion matrix elements. Standard parameters (in eV) are $\varepsilon_p - \varepsilon_d = 3.6$, $t_{dp} = 1.3$, $t_{pp} = 0.65$, $U_d = 10.5$, $U_p = 4$, and $U_{dp} = 1.2$.

The undoped cuprates have one $d$-hole per Cu atom which sits in the lower hole Hubbard $d$-band produced by Eqn. (2) (unoccupied upper electron Hubbard band of Fig. 8). The next band in energy is predominantly of oxygen character without holes present (highest occupied electron band of Fig. 8) which is of central interest, if additional holes are doped into the $CuO_2$ plane or if holes are excited from Cu to O sites. One, therefore, tries to mimic this charge transfer excitation case by an effective one-band Hubbard model

$$\hat{H} = -t \sum_{\langle ii' \rangle, \sigma} (\hat{c}_{i\sigma}^\dagger \hat{c}_{i'\sigma} + \hat{c}_{i'\sigma}^\dagger \hat{c}_{i\sigma}) + U \sum_i \hat{n}_{i\uparrow} \hat{n}_{i\downarrow} \tag{3}$$

The $\hat{c}^\dagger$ and $\hat{c}$ now create and annihilate orthogonalized molecular states on $CuO_4$ plaquettes $i$ (Wannier states), and $\hat{n}$ are their occupation number operators; $\langle ii' \rangle$ runs over nearest neighbor Cu pairs. The parameters (again in eV) to reproduce closely the low-energy spectrum of Eqn. (2) are $t = 0.43$ and $U = 5.4$.

In the subspace of the state space of avoided double occupancies of Cu sites by holes, Eqn. (3) may be canonically transformed into the $t$–$J$ Hamiltonian (with some three-center terms neglected):

$$\hat{H} = -t \sum_{\langle ii' \rangle, \sigma} (\hat{C}_{i'\sigma}^\dagger \hat{C}_{i\sigma} + \hat{C}_{i\sigma}^\dagger \hat{C}_{i'\sigma}) + J \sum_{\langle ii' \rangle} (S_{i'} \cdot S_i - \frac{1}{4} \hat{n}_{i'} \hat{n}_i) \tag{4}$$

where $\hat{C}_{i\sigma} = \hat{c}_{i\sigma}(1 - \hat{n}_{i-\sigma})$, $J = 4t^2/U$, and $\boldsymbol{S}_i$ is a spin-$\frac{1}{2}$ operator at site $i$. At half-filling, $n_{i-\sigma} = 1$, the $t$–$J$ Hamiltonian reduces to the square lattice Heisenberg Hamiltonian

$$\hat{H} = J \sum_{\langle ii' \rangle} S_{i'} \cdot S_i \tag{5}$$

The ground state of the latter is now known to be the AF Néel state. It is, however, assumed that the Néel ground state is nearly degenerate with a nearest neighbor resonating valence bond state (RVB) in which neighboring copper spins form singlets ("valence bond singlets") and the RVB state is an eigenstate of total spin, $S = 0$, in which all those singlets resonate (Baskaran *et al.* 1987). This is a state with strong local spin fluctuations which might drive the system into superconductivity. Close to half-filling, $n_{i-\sigma} \approx 1$, Zhang and Rice (1988) derived the Hamiltonian (4) directly from Eqn. (2) by projection to low-energy excitations. The spin part is obtained from the well-known superexchange interaction of the nominal Cu holes. Doped additional holes go into oxygen-dominated states and form spin singlets (Zhang–Rice singlets) with the nominally present Cu hole. If the O-hole from a singlet at site $i$ moves to site $i'$, it leaves behind a spin-$\frac{1}{2}$ Cu-hole at site $i$ and absorbs the Cu-hole present at site $i'$ into a new singlet. Total spin conservation in this process demands that the spin of the created lone Cu-hole at site $i$ has the same direction as had the spin of the previous lone Cu-hole at site $i'$ now absorbed into the new singlet. It looks as if a lone Cu-hole has moved from site $i'$ to $i$. This lone Cu-hole can only be destroyed at site $i'$ if the site had a lone hole had and no singlet, i.e., the O-hole was not occupied there, $n_{i'-\sigma} = 0$. After the creation of the lone Cu-hole at site $i$, there is again no O-hole there, $n_{i-\sigma} = 0$. On the other hand, on an AF background with nominal Cu-holes having opposite spin directions on neighboring sites, a Cu-hole moved to the neighboring site has the wrong spin direction which costs an energy $\sim J$ while $t(1 - n_{i'-\sigma})(1 - n_{i-\sigma}) \to 0$ close to half-filling. This is why the bandwidth for the O-hole motion is now $\sim J$ instead of being $\sim t$ in the absence of correlations. (Compare the dramatical reduction of bandwidth from the band crossing the Fermi level in the second panel of Fig. 6 to the corresponding highest occupied band in the second panel of Fig. 8.)

Although the model Hamiltonians (2–4) look rather simple, their excitation spectra and phase diagrams are hard to obtain and not well known.

## 3. *Doped Cuprates*

The cuprates of families (i) and (ii) may be doped continuously from the AF insulator at $\delta \approx 0$ into (and eventually beyond) the superconducting state, family (i) with both signs of $\delta$. At the Fermi level and above, spectral weight which is predominantly of in-plane O-2$p$ character is continously developing

with increasing hole doping as seen in polarization-dependent XAS and orientation-dependent EELS (Fink *et al*. 1994). With electron doping, the situation is not as clear. There is an in-plane O-2*p* pre-edge at the conduction band and a strong in-plane Cu-3*d* peak there, both indicating an upper Hubbard band, but both the EELS and XAS spectra depend in position and intensity only very weakly on doping (Fink *et al*. 1994). Below the Fermi level, ARPES seems to observe developing spectral weight $\sim 0.5\,\text{eV}$ above the valence band edge of the undoped compound but still below the Fermi level, first around $(\pi, 0)$ and at higher doping level also around $(\pi/2, \pi/2)$, for both hole and electron doping. At low doping the spectra show broad features not crossing the Fermi level and still reminiscent of the AF symmetry of the BZ, before an FS according to the full line of Fig. 3(b) starts to develop, in the hole-doped case beginning near $(\pi/2, \pi/2)$ (Damascelli *et al*. 2003).

### 3.1 Overdoped Regions

For both signs of doping charge the maximum of the transition temperature $T_c$ into the superconducting state is at $|\delta| \approx \frac{1}{6}$. As was already stated in the introduction, above this doping level, in the so-called overdoped regions, an FL is found consisting of hole-type rods around $(\pi, \pi)$ and corresponding to the nonmagnetic BZ (dashed in Fig. 3(b)). The FS and the dispersion of the occupied parts of the electron bands of $(Bi,Pb)_2Sr_2CaCu_2O_{8+\delta}$ as seen in ARPES are shown in Fig. 10. The ARPES exhibits sharp quasiparticle peaks below $T_c$ which become rather broad above $T_c$. In agreement with mean-field bands, there is a saddle point of $\varepsilon(\boldsymbol{k})$ at $(\pi, 0)$ from which the band disperses downward towards (0,0) (with a flat region close to $(\pi, 0)$ whence the saddle point is called extended) and upward towards $(\pi, \pi)$. The saddle point itself is $\sim 0.3\,\text{eV}$ below the Fermi level for electron overdoping and eventually crosses the Fermi level at hole overdoping. Compared to calculations local density approximation (LDA) the bands are renormalized by roughly a factor of 2.

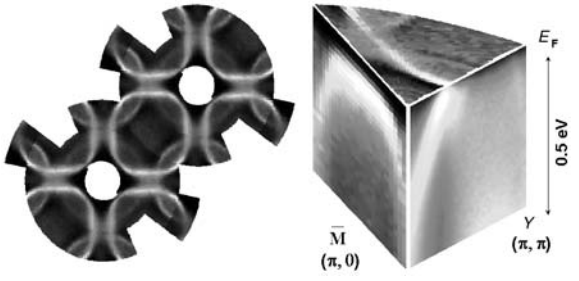

***Figure 10***
Color plot of ARPES intensity from overdoped (Bi, $Pb)_2Sr_2CaCu_2O_{8+x}$. Left panel: momentum distribution at the Fermi energy taken at 300 K and showing the hole FS rods around $(\pi,\pi)$ (center of the dark area, called *Y* in the right panel) and the "shadow FS" rods around (0,0) (center of the white spots) possibly due to AF correlations still present. Right panel: energy and momentum distribution showing also the dispersion of the bands (courtesy of J. Fink).

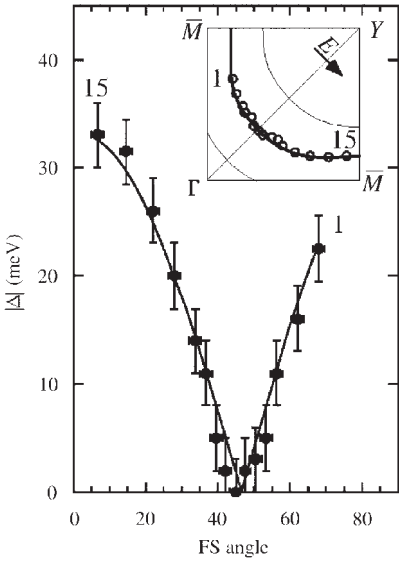

***Figure 11***
Superconducting gap measured at 13 K on $Bi_2Sr_2CaCu_2O_{8+x}$ ($T_c = 87\,\text{K}$) and plotted vs. the angle along the normal-state FS, together with a *d*-wave fit (reproduced by permission of Ding *et al*. (1996) from *Phys. Rev. B* **54**, 9678; © American Physical Society).

By very high energy resolution ARPES ($\Delta E \sim 10$-meV), the gap function $|\Delta(\boldsymbol{k})|$ on the FS of the superconducting state well below $T_c$ is measured (Fig. 11). Together with tunneling experiments which measure the phase of $\Delta$, a *d*-wave order parameter

$$\Delta(\boldsymbol{k}) = \Delta_0[\cos(k_x a) - \cos(k_y a)] \tag{6}$$

is found, where $\Delta_0$ decreases with increasing doping.

### 3.2 Bilayer Splitting in $(Bi, Pb)_2Sr_2CaCu_2O_{8+\delta}$

In the cuprate families (ii) and (iii) for $n > 1$, there are stacks of $n$ $CuO_2$-layers which in mean-field theory appear electronically coupled across the cation *C* layers even if (as is generally the case) the coupling across the block layers is negligible. Hybridization with Cu-4*s* or with in-plane O-2p$\pi$ *C*-*d* orbitals is essential in this coupling. It leads to an *n*-fold splitting of the conduction band of the $CuO_2$-layers which also survives various (but maybe not all) many-body

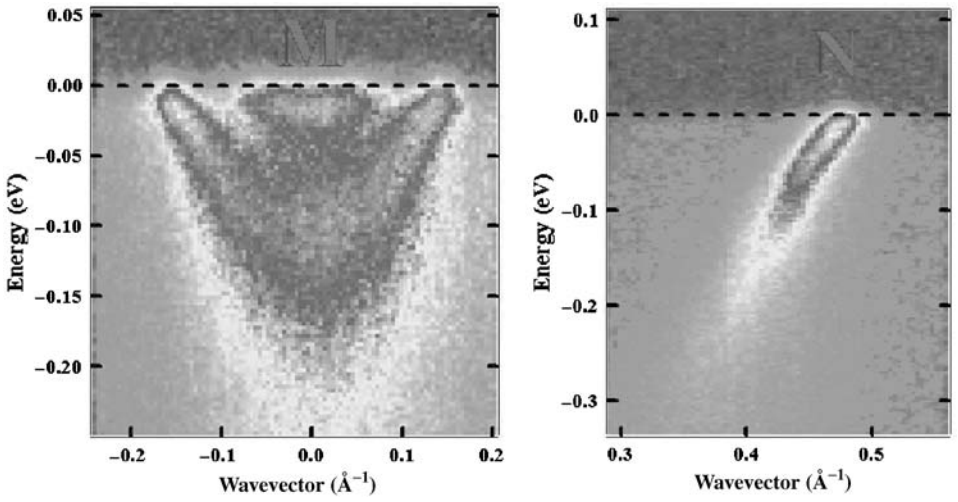

***Figure 12***
Color plot of ARPES energy–momentum distributions from overdoped $(Bi,Pb)_2Sr_2CaCu_2O_{8+x}$ in the superconducting state at 30 K. Left panel: near $(\pi,0)$ showing the bilayer splitting of the bands; right panel: nonsplit band near the nodal point $k_x = k_y$(N) of the FS (Courtesy of J. Fink).

approaches (Mori *et al*. 2002). For symmetry reasons this splitting is zero for $k_x = k_y$ and maximal at $(\pi, 0)$. It seems to have the symmetry of the superconducting order parameter which led to speculations in the literature. However, one must be cautious with this type of behavior of a number of features; it may simply be related to the mirror plane $k_x = k_y$ of the point symmetry of the crystal and need not be caused by superconducting correlations (which, of course, are also connected with this symmetry).

In particular, for $n = 2$, there is a bilayer splitting ($\sim 300$ meV in LDA) which in the case of $(Bi,Pb)_2Sr_2CaCu_2O_{8+\delta}$ has been intensively studied with ARPES and clearly found in overdoped samples at $(\pi, 0)$ with a value of 90 meV (Fig. 12). Although in underdoped samples the ARPES features are broader and the situation is not as clear, the bilayer splitting in the vicinity of $(\pi, 0)$ was clearly found there by a number of authors recently (Damascelli *et al*. 2003).

### *3.3 Underdoped Region*

The underdoped region of hole doping has been intensively studied because of two striking features (which might be related): the pseudogap and the stripe phase (see Tohyama and Maekawa 2000). It was found in many cuprates but was most intensively studied in $Bi_2Sr_2CaCu_2O_{8+\delta}$ that in the underdoped region away from the nodal point $k_x = k_y$ the ARPES peak (which in this doping region often is merely a broad hump) does not cross the FL but ends at a certain energy distance, the pseudogap value, from the latter. Often it seems to bend away from the FL again like an AF folded band. It has again the symmetry with respect to $k_x = k_y$ mentioned in the last section.

At optimal doping, $\delta \sim \frac{1}{6}$, the pseudogap equals the superconducting gap, and in the overdoped region it is absent. With $\delta$ decreasing into the underdoped region the pseudogap is rapidly increasing extrapolating to $\sim 80$ meV at very low doping. It is intriguing that the superconducting gap of the overdoped region together with the pseudogap of the underdoped region behave like the gap obtained for RVB superconductivity by Baskaran *et al*. (1987).

Particularly in the cuprate family (i) but not exclusively there, incommensurate AF correlations close to $\boldsymbol{Q} = (\pi, \pi)$ are found which sometimes condense into incommensurate long-range order accompanied by incommensurate charge order. This might be caused by strong electron–lattice interaction leading to a separation into alternating AF and charged stripes. (For instance, the doping level of the charged stripes might be pinned at a higher than the average doping due to Peierls energy gain for rational band filling values, causing low-doped stripes in between.) Whether this is a generic effect and whether it is related to superconductivity is presently unclear.

### *3.4 Single-electron Self-energy*

As was demonstrated by Norman *et al*. (1999), the self-energy of the single-electron Green's function can directly be extracted from ARPES data, if certain assumptions are made, namely that an extrinsic background can be properly subtracted and the

electronic structure has particle–hole symmetry in the close vicinity of the FS point considered.

Earlier ARPES studies of the self-energy focused on the $(\pi, 0)$ point which, however, is masked by bilayer splitting. Recently, a number of investigations (cf. Damascelli *et al*. 2003) at the nodal point $k_x = k_y$ revealed a linear temperature dependence of the imaginary part of the self-energy at optimal doping, which seems to correspond to the linear temperature dependence of the scattering rate in normal state resistivity, but which, in the ARPES results, extends deep into the superconducting state. This would be consistent with the marginal FL model (Varma 1997).

The interest into the self-energy around $(\pi, 0)$ came from the strong effect a magnetic mode at $Q = (\pi, \pi)$ would have in this region (Eschrig and Norman 2000). It would lead to the peak-dip-hump structure of the energy distribution functions measured in ARPES around $(\pi, 0)$. Much but very likely not all of this structure is now attributed to the bilayer splitting. It remains a challenge for further studies to disentangle these features.

### 4. Summary

The electronic structure of cuprate superconductors is more or less settled in the cases of undoped ($\delta \approx 0$) and overdoped ($|\delta| \gtrsim 0.2$) material. In the former case it is that of an AF charge transfer insulator which can theoretically be described by a *t–J* model Hamiltonian. It might be necessary to incorporate in-plane O-$2p_\pi$ orbitals into this model for certain considerations. In the overdoped case, a weakly renormalized LDA band structure of a Cu-$3d_{x^2-y^2}$ − O-$2p_\sigma$ band is experimentally found in the vicinity of the FL in ARPES.

At optimal doping ($\delta \approx \frac{1}{6}$) for superconductivity, experimental evidence seems to accumulate for a marginal FL state at elevated temperature, which is masked by the *d*-wave superconducting state at low temperature.

Still largely unclear is the situation in the underdoped region where several interactions seem to be interwoven leading to a complex behavior.

## High-temperature Superconductors, Cuprate: Magnetic Properties by NMR/NQR

One of the peculiar properties of cuprate high-temperature superconductors (HTSC) is their descent from antiferromagnetic (AF) parent compounds

whose magnetic order arises from $Cu^{2+}$ spins in the $CuO_2$ planes. For instance, $YBa_2Cu_3O_{7-\delta}$ is obtained by doping $YBa_2Cu_3O_6$ with oxygen while $La_{2-x}Sr_xCuO_4$ results from Sr substitution in $La_2CuO_4$. Both processes create electron holes in the $CuO_2$ planes and eventually destroy the AF long-range order. However, AF short-range order is still present in the superconductors and even in the superconducting regime. These properties make cuprate HTSC a unique class of superconductors quite different from conventional superconductors and metals. (see *Superconducting Materials, Types of*).

NMR–NQR spectroscopy has explored many aspects of HTSC and several papers have reviewed these studies: Pennington and Slichter (1990), Alloul (1991), Brinkmann and Mali (1994), Berthier *et al.* (1996), Rigamonti *et al.* (1998). The present article will update results related to magnetic properties of cuprate HTSC: relaxation and Knight shift data in the normal state, the dynamic susceptibility, the single-spin fluid model, the spin–gap effect, and some experiments in the superconducting state.

## 1. Relaxation Rates and Magnetic Shifts

The information on the microscopic magnetic behavior of cuprate HTSC is contained in the spin susceptibility $\chi(\mathbf{q},\omega)$ which depends on frequency $\omega$ and wavevector $\mathbf{q}$. $\chi$ is mainly probed by measuring relaxation times and magnetic frequency shifts. In most NMR studies of HTSC, the external magnetic field $B_0$ is sufficiently large to render the quadrupole interaction a small perturbation of the Zeeman interaction thus leading to a splitting of the NMR signal. In the case of NQR, internal magnetic fields may give rise to Zeeman perturbed NQR transitions. In nearly all cuprate HTSC, the measured NQR frequencies for both isotopes of in-plane Cu(2) are pure NQR frequencies, thus revealing the absence of long-range magnetic order in these compounds (on the time scale of NQR).

The hyperfine interaction of the nuclear magnetic moment with the local magnetic field contains a static part that induces a magnetic shift of the NMR line, and a dynamic part that causes relaxation (see *Solids, Nuclear Magnetic Resonance of*). The shift tensor consists of an orbital part being predominantly temperature independent in HTSC, and a spin part, usually called the Knight shift $\mathbf{K}^{\text{spin}}$, that is temperature dependent and is expected to vanish in the superconducting state due to singlet spin pairing. Each component of $\mathbf{K}^{\text{spin}}$ can be expressed by the hyperfine interaction tensor, $A_j$, and the static spin susceptibility: $K_{\alpha\alpha}^{\text{spin}} = (1/g\,\mu_B)\sum_j (A_j)_{\alpha\alpha}(\chi_j)_{\alpha\alpha}$.

The fluctuating part of the hyperfine interactions is the source of relaxation processes. The main contribution to the copper, oxygen, and yttrium spin–lattice relaxation in HTSC compounds arises from electron spin fluctuations. This contribution is related to the imaginary part of the dynamical spin susceptibility $\chi(\mathbf{q},\omega_0)$ and it is given by the Moriya formula:

$$\left(\frac{1}{T_1T}\right)_\alpha \equiv \frac{2W_\alpha}{T} = \frac{\gamma_n^2 k_B}{2\,\mu_B^2}\sum_{\mathbf{q},\alpha'\neq\alpha} F_{\alpha'}(\mathbf{q})\,\frac{\chi''_{\alpha'\alpha'}(\mathbf{q},\omega_0)}{\omega_0}$$

where $F_\alpha(\mathbf{q}) = \left|\sum_j A_{j,\alpha\alpha}\exp(i\mathbf{q}\cdot\mathbf{r}_j)\right|^2$ is the form factor, $\omega_0$ is the nuclear resonance frequency, $\alpha$ denotes the direction of quantization, i.e., the direction of either the maximum component of the electric field gradient tensor $V_{zz}$ in NQR or of $B_0$ in NMR experiments, and $\alpha'$ is the direction perpendicular to $\alpha$. $A_j$ is the on-site ($\mathbf{r}_j = \mathbf{0}$) and transferred ($\mathbf{r}_j \neq \mathbf{0}$) hyperfine coupling tensor for the nuclei under consideration.

Therefore, the spin–lattice relaxation time $T_1$ or better $(T_1T)^{-1}$ provides information about the $\mathbf{q}$ averaged imaginary part of $\chi(\mathbf{q},\omega_0)$. Another relaxation time, the spin–spin relaxation time $T_2$, is related to the real part of $\chi(\mathbf{q},\omega)$. In many HTSC, the dominating part of $1/T_2$, called $1/T_{2G,\text{ind}}$, is due to an enhanced indirect nuclear–nuclear spin coupling mediated by the electronic spin system; this leads to a Gaussian contribution to the spin-echo decay signal. The numerical values of the coupling tensors $A_j$, which may range up to several thousand oersteds, have been derived from various NMR experiments, in particular from magnetic shift studies (see review papers listed above).

If fluctuating electric field-gradients are present (at the Larmor frequency), additional terms would appear in the Moriya formula. Since these terms are usually small in HTSC, they are neglected; however, as will be discussed in Sect. 3, the presence of quadrupole interactions may have important consequences.

Relaxation times and Knight shift behave quite differently from corresponding data in conventional superconductors or metals. For instance, $W$ has a nonlinear temperature dependence and $K$ is temperature dependent. Furthermore, different nuclei (Cu, O, Y) display different temperature dependences which, in turn, depend on the doping level of the substance. More recent results are discussed by Berthier *et al.* (1996) and Rigamonti *et al.* (1998).

Figure 1 sketches the general behavior of $W$, $1/T_{2G,\text{ind}}$ and $K$ for Cu(2), where the temperature $T^*$ characterizes the spin–gap to be discussed in Sect. 4. When interpreting these data, one usually chooses the Mila–Rice Hamiltonian (Rigamonti *et al.* 1998) as the starting point. Then, the different temperature dependences of $W$ are attributed to differences in the form factors $F_\alpha(\mathbf{q})$ that filter the magnetic fluctuations at different points of the Brillouin zone. This explains, for instance, the striking difference of the $W$ values for copper and oxygen.

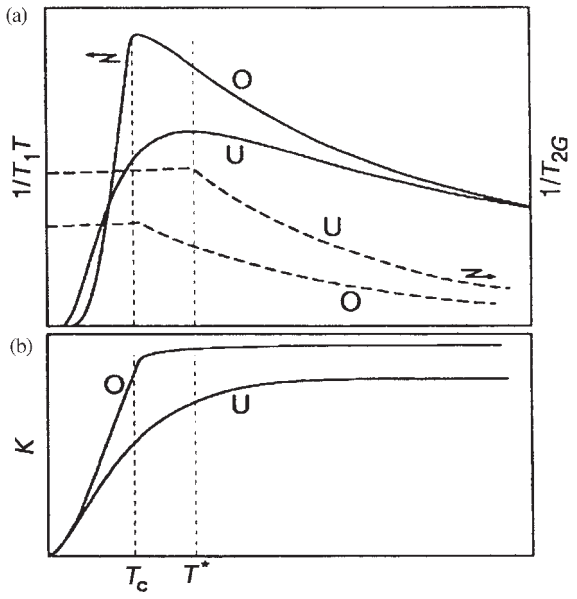

*Figure 1*
Schematic behavior of relaxation times (a) and Knight shift (b) of planar Cu in optimally (O) and underdoped (U) cuprate HTSC (reproduced by permission of Rigamonti *et al.* 1998).

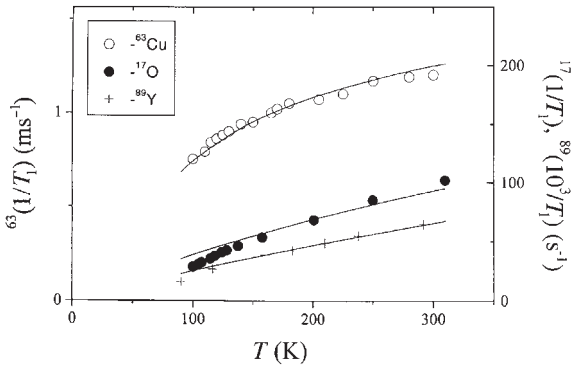

*Figure 2*
Calculated temperature dependence of the spin–lattice relaxation rates of $^{63}$Cu, $^{17}$O, and $^{89}$Y in $YBa_2Cu_3O_7$ (solid lines) compared with experimental data (Brinkmann and Zavidonov 2002).

## 2. *Calculations of the Dynamic Spin Susceptibility*

The quality of calculating $1/T_1$ is based on the knowledge of the imaginary part of the dynamic spin susceptibility $\chi''_{+-}(\mathbf{q}, \omega_0)$. Several models have been employed to calculate $1/T_1$ for the normal state of HTSC. Among these are the nearly antiferromagnetic Fermi liquid (NAFL) description of HTSC and the 2DQHAF scaling model which regards a cuprate HTSC as a disordered 2-dimensional quantum Heisenberg AF (Berthier *et al.* 1996, Rigamonti *et al.* 1998). In the NAFL model, the dynamic spin susceptibility is written, in a phenomenological approach, as the superposition of two terms, one for itinerant quasiparticles and the other for localized $Cu^{2+}$ magnetic moments. It seems that the NAFL model is rather well obeyed in overdoped cuprates while the 2DQHAF model describes underdoped cuprates (Berthier *et al.* 1996, Rigamonti *et al.* 1998).

Usually, calculations of the dynamic spin susceptibility start from the *t–J* model (Rigamonti *et al.* 1998) where *t* denotes the hopping energy of the holes and *J* represents the strong repulsion between holes residing on the same square. Then, the susceptibility is usually calculated by using various methods. However, in spite of considerable progress, all theories have some disadvantages which are mainly connected with their phenomenological character. For example, in these theories, the temperature and doping dependence of the AF correlation length, $\xi$, which is the essential parameter that governs the temperature and doping dependence of $1/T_1$, are postulated or, at best, are taken from a comparison with experiment. Expressions used for the dynamic spin susceptibility are good approximations only for wave vectors in the vicinity of the AF wave vector, thus the models provide reliable results for $1/T_1$ if $\xi$ is large. In $YBa_2Cu_3O_{7-\delta}$, for instance, $\xi$ is small and therefore a more detailed theoretical analysis of the NMR data is required.

This has been done, for instance, in an approach where $\chi''_{+-}(\mathbf{q}, \omega_0)$ is calculated within a constraint-free theory based on the presentation of the *t–J* model in terms of Hubbard operators (Brinkmann and Zavidonov 2002). Both electron and AF spin correlations were taken into account. The model is able to reproduce the main features of the temperature and doping dependences of $\xi$ in both the pure Heisenberg AF (e.g. $La_2CuO_4$) and doped compounds ($La_{2-x}Sr_xCuO_4$). Starting form these results, the factors $F(\mathbf{q})\chi''_{+-}(\mathbf{q}, \omega)/\omega$ and hence $1/T_1$ were calculated for $^{63}$Cu, $^{17}$O, and $^{89}$Y in $YBa_2Cu_3O_{7-\delta}$. Figure 2 demonstrates the good agreement with experimental data.

## 3. *The Single-spin Fluid Model*

One of the central issues in understanding the cuprate HTSC has been to determine the minimal number of electronic degrees of freedom which are necessary to describe the physics at the atomic scale of these structures. Adopting the picture of the spin-resonant singlet state with quasi-localized holes at copper (Rigamonti *et al.* 1998), only one spin degree of freedom would be necessary; this is the single-spin fluid (SSF) scenario. However, as was discussed by various

authors (e.g. Berthier *et al*. 1996), this model might be an oversimplification.

NMR provides information about oxygen and copper independently. Studies of the uniform spin susceptibility $\mathrm{Re}\{\chi(q=0,\omega=0)\}$, i.e., of the Knight shift, are in favor of the SSF model. On the other hand, oxygen and copper show a very different temperature dependence of the spin–lattice relaxation, that is of the dynamic spin susceptibility, $\mathrm{Im}\{\chi(q,\omega_L)\}$, thus suggesting independent spin degrees of freedom. However, the hyperfine field, due to antiferromagnetically correlated copper spins, could cancel at the oxygen site and this would explain the different temperature dependences within a SSF model.

There is, however, evidence that this view is incomplete. The $^{17}$O NMR in Y-based cuprate HTSC has extensively been studied by various groups. In particular, the pronounced temperature dependence of the anisotropy of the plane oxygen spin–lattice relaxation rate, $^{17}W$, is still puzzling (e.g., Suter *et al*. 1997) while the SSF model predicts an almost temperature independent rate anisotropy. Suter *et al*. (1997) pointed out that it is also very difficult to explain, within a simple SSF model, the ratio of the oxygen and the yttrium rate, namely $^{17}W/^{89}W$. Furthermore, a comparison of $^{17}$O and $^{63}$Cu NMR results from $La_{2-x}Sr_xCuO_4$ with inelastic neutron scattering data suggested that a single-band picture is inadequate (Walstedt and Cheong 1995).

Further support of this conclusion came from a study of the spin–lattice relaxation of plane oxygen in $YBa_2Cu_4O_8$ below 200 K (Suter *et al*. 2000): there is a considerable contribution of quadrupolar fluctuations (i.e., low-frequency charge fluctuations) to the total fluctuating fields. Two degrees of freedom are involved in the low-energy excitations of the electronic system, one of them is the single-spin degree, implying that the single-spin fluid model is partially correct, whereas the other one is the charge degree of freedom with predominantly oxygen character, since it is not observed at the copper sites.

## 4. The Spin-gap Effect

A dominant characteristic of the normal state of optimally doped and underdoped cuprate HTSC is the occurrence of the so-called pseudogap; its origin still remains unclear. The pseudogap refers to the transfer of low-energy excited states to higher energy. In NMR and neutron scattering experiments, the pseudogap reveals itself as a spin–gap (Brinkmann and Mali 1994, Berthier *et al*. 1996, Rigamonti *et al*. 1998). For instance, in $YBa_2Cu_4O_8$ ($T_c = 81$ K), $(T_1T)^{-1}$ of Cu(2) increases with falling temperature (see Fig. 1) and reaches a maximum at $T^*$ ($\approx 150$ K), which serves as a convenient scale for the temperature dependence of the spin–gap onset temperature. Possible relations between the spin–gap and the superconducting gap are still under debate.

A hint to the interdependence of these gaps may be found in the fact that several structure related anomalies have been observed in $YBa_2Cu_4O_8$ around a temperature $T^\dagger = 180$ K. Based on NMR–NQR studies, the anomalies were interpreted as an electronic crossover involving enhanced charge fluctuations in planes and chains (Suter *et al*. 1997). Because of the proximity of $T^\dagger$ and $T^*$, Eremin *et al*. (1997) suggested that the spin–gap effect in $YBa_2Cu_4O_8$ is caused by a transition due to a charge density wave instability. The authors explained, among others, the strong temperature dependence of the magnetic shift of Cu(2) nuclei and predicted a dependence of $T^*$ on the isotope mass.

Such an isotope effect has been found in a high-accuracy NQR $T_1$ study of the $^{63}$Cu(2) nuclei, supplemented by susceptibility measurements, on $^{16}$O and $^{18}$O exchanged $YBa_2Cu_4O_8$ samples (Raffa *et al*. 1998). The isotope exponents, defined as $\alpha = -\Delta\ln(T^*)/\Delta\ln(m)$ for $T^*$ and correspondingly for $T_c$, are $\alpha_{T^*} = 0.061(8)$ and $\alpha_{T_c} = 0.056(12)$. The agreement of the exponents, within the experimental error, suggest a common origin, or at least a relation, for the superconducting and the spin-gap. This result is contrary to a recent $^{89}$Y magnetic shift study in $YBa_2Cu_4O_8$ which reported the absence of an isotope effect in the pseudogap (Williams *et al*. 1998). However, Mali *et al*. (2001), by extending the work of Raffa *et al*. (1998) to the $^{63}$Cu(2) Knight shift, again found an isotope effect on the spin–gap; both exponents have the same sign. Hence, the controversy on this topic continues.

When $T_c$ is approached from above, one expects enhanced superconducting pairing fluctuations which may, in the presence of strong magnetic fields, influence various normal-state properties, including spin–lattice relaxation (Rigamonti *et al*. 1998). These effects can be used to clarify the origin of the pseudogap (Eschrig *et al*. 1999). Previous experimental results and the corresponding conclusions on the $^{63}$Cu(2) relaxation rate in $YBa_2Cu_3O_{7-\delta}$ have been controversial (Rigamonti *et al*. 1998, Gorni *et al*. 2001). Latest high-precision measurements (Gorni *et al*. 2001) found the relaxation rate to be field independent (from 0 T up to 14.8 T) in the normal state; a field dependence develops only below $T_c$. A field independent $^{63}$Cu(2) relaxation has also been observed in the normal state of $YBa_2Cu_4O_8$ (Brinkmann and Mali 1994).

## 5. The Superconducting State

Again, as in the normal state, magnetic properties of the HTSC are probed mainly via the magnetic shift $K$ and relaxation rates, in particular $W$ and $1/T_{2G}$. The temperature dependence of $K$ below $T_c$ is in accord with a carrier pairing into singlet-spin states and supports the model of $d$ wave pairing. The temperature

dependence of $1/T_{2G}$ is also in accord with this model. The temperature dependence of $W$ is close to a $T^3$ behavior. The anisotropy of $\chi(\mathbf{q},\omega)$ is studied by measuring $W$ with the magnetic field parallel and perpendicular to the $c$ axis; the field dependence is explored by comparing NQR and NMR values. The theoretical interpretations are mostly based on models of phenomenological character. Special magnetic effects arise from substituting Cu(2) by diamagnetic Zn and lead to deviations from the $T^3$ law.

The lattice and dynamics of flux lines (FL) in the superconducting state have attracted special attention. A summary of related NMR experiments is found in Rigamonti *et al*. (1998). NMR spectra and the relaxation times $T_1$ and $T_2$ are employed to study statics and dynamics of the FL and their field and temperature dependence. For instance, the temperature dependence of the field distribution inside the bulk $YBa_2Cu_4O_8$, together with a partial melting of the FL lattice, can be inferred from the $^{89}Y$ linewidth. $^{17}O$ spectra demonstrate, for a certain temperature range, the coexistence of liquid and solid vortex behavior, e.g., in $YBa_2Cu_3O_7$. The ideal tool to study the FL motion is spin–lattice relaxation: correlation times and pinning barriers can be estimated, for instance in $YBa_2Cu_4O_8$.

Very promising are recent studies to explore the vortex core structure by site-selective and spatially resolved experiments. For instance, $1/T_1$ and $1/T_2$ increase for nuclei close to the vortex core. An NMR imaging experiment has spatially resolved the electronic structure inside and outside vortex cores in near-optimally doped $YBa_2Cu_3O_{7-\delta}$: strong AF fluctuations are found outside the cores whereas inside unusual electronic states are detected (Mitrović *et al*. 2001). Site-selective $1/T_1$ measurements in $YBa_2Cu_4O_8$ illustrate that the simple interpretation of the data by the density of states of the Doppler-shifted quasiparticles of a $d$ superconductor is problematic (Kakuyanagi *et al*. 2002).

## 6. Conclusion

NMR and NQR have proven to be suitable tools to investigate the dynamic susceptibility in cuprate HTSC. Experimental results quite often agree with phenomenological models of the susceptibility; but the theoretical approaches still need further refinements to interpret details satisfactorily. The problems of the single-spin fluid model are not yet settled and the spin–gap is still a matter of debate, in particular its relation to other characteristic temperatures of the HTSC. NMR–NQR studies of the superconducting state seem to be an expanding and promising field of research.

# High-temperature Superconductors: Thin Films and Multilayers

Since 1986, when high-$T_c$ superconductivity was discovered, stunning achievements have been made in the fabrication of films and multilayers based on these superconducting cuprates despite their complex crystal structures (see also *Superconducting Thin Films: Materials, Preparation, and Properties*, *Superconducting Thin Films: Multilayers*). In this article the key morphologic and electronic properties of high-$T_c$ superconducting thin films, particularly of $YBa_2Cu_3O_{7-\delta}$, and multilayers are described.

Efforts to produce thin films of cuprate superconductors rapidly followed their discovery. The first polycrystalline films of a high-$T_c$ superconductor, $(La,Sr)_2CuO_4$, were deposited by sputtering in February, 1987 (Koinuma *et al.* 1987, Nagata *et al.* 1987). In March, 1987 epitaxial $(La,Sr)_2CuO_4$ films were prepared by sputtering on (100)$SrTiO_3$ substrates (Suzuki and Murakami 1987). Although the latter films were superconducting as grown, their $T_c$ improved greatly after a high-temperature anneal. Later that same month the first superconducting films with a zero resistance critical temperature $T_{c0}$ exceeding the boiling point of nitrogen, 77 K, were grown (Laibowitz *et al.* 1987). These were polycrystalline $YBa_2Cu_3O_{7-\delta}$ films deposited by e-beam evaporation and annealed at high temperatures. In April 1987, the first epitaxial $YBa_2Cu_3O_{7-\delta}$ films were fabricated (Chaudhari *et al.* 1987). This was accomplished by depositing amorphous Y-Ba-Cu-O films via e-beam evaporation on a (100)$SrTiO_3$ substrate and subsequently crystallizing the $YBa_2Cu_3O_{7-\delta}$ film by solid-phase epitaxial regrowth during a high-temperature annealing step.

These were the first superconductors in any form with critical current densities $J_c$ exceeding $10^6\,A\,cm^{-2}$ at 4.2 K, thereby demonstrating the commercial utility of high-$T_c$ superconductivity as well as the importance of epitaxy in producing high-$T_c$ films with useful electrical transport properties. The progress did not stop there. Soon, epitaxial films with good electrical properties, of $YBa_2Cu_3O_{7-\delta}$ (Terashima *et al.* 1988) and other high-$T_c$ superconductors were grown *in situ*, directly in their crystalline state (i.e., without the need of an ex situ annealing step following deposition) on a wide variety of substrates including sapphire, silicon, GaAs, and even on polycrystalline substrates such as stainless steel and alumina, through the use of a highly-textured, intermediate buffer layer. Today, excellent films of a multitude of high $T_c$ compounds are produced by a variety of vapor-phase techniques (see also *Superconducting Thin Films: Materials, Preparation, and Properties*, *Superconducting Thin Films: Multilayers*). Wafer sizes have reached diameters of 8 inches (20.32 cm), and films are deposited in scalable and continuous processes over lengths of up to a meter (Foltyn *et al.* 1999, Park *et al.* 1999).

Due to their outstanding electrical transport characteristics (high $T_c$, high $J_c$, low surface resistance $R_s$), epitaxial films and multilayers, incorporating in some cases Josephson junctions, are very useful for applications involving high-$T_c$ superconductors, including microwave filters, magnetometers, digital circuits, and fault current limiters. Films have also been used with remarkable success to investigate fundamental properties and application-related aspects of high-$T_c$ superconductivity, e.g., analysis of the order parameter symmetry (Tsuei *et al.* 1994, Chaudhari and Lin 1994, Mannhart *et al.* 1996) and measurements of the transport properties of grain boundaries (Hilgenkamp and Mannhart 2001). In addition, the technology developed for the growth of cuprate superconductor films has enabled rapid progress in the deposition of films of other multicomponent oxides including ferroelectrics (Waser *et al.* (eds.) 2001) and manganates that exhibit colossal magnetoresistance (Helmolt *et al.* 1993).

As it is impossible to provide a complete overview of the field within the space available, we have restricted our discussion of the field of high-$T_c$ films and focus on a few illustrative examples based mainly on $YBa_2Cu_3O_{7-\delta}$. We regret that it is impossible to include all of the important work contributed by the large number of groups active in this relatively new and rapidly progressing field (see also *Superconducting Thin Films: Materials, Preparation, and Properties*, *Superconducting Thin Films: Multilayers*). Additional information can be found in other review papers on high-$T_c$ films and multilayers (Humphreys *et al.* 1990, Lemberger 1992, Somekh *et al.* 1992, Matijasevic and Bozovic 1996, Bozovic and Eckstein 1996, Triscone and Fischer 1997, Wördenweber 1999).

## 1. Substrates for Superconducting Films

A crucial starting point in the growth of high-$T_c$ thin films and multilayers is the selection of the substrate material and its preparation. As large-area single crystal substrates of high-$T_c$ superconductors, a necessity for homoepitaxial growth, are not commercially available, other substrate materials must be used. The ideal substrate is both chemically and structurally compatible with the epilayer. Other

factors, including commercial availability, cost, the potential for integration with other device technologies, thermal expansion coefficient, dielectric constant, and the dielectric loss tangent at microwave frequencies (for high-frequency operation of superconducting circuits) must also be considered (Hollmann *et al.* 1994, Phillips 1996). Unlike the heteroepitaxial growth of semiconductors, where it is imperative to choose a well lattice-matched substrate in order to avoid undesired dislocations in the grown structures, dislocations in superconductors and especially in high-$T_c$ superconductors are effective vortex pinning sites and lead to significantly higher critical current densities (Mannhart *et al.* 1992, Dam *et al.* 1999). Thus, a relatively large lattice mismatch between high-$T_c$ superconductors and substrate materials is, in principle, permissible. Thermal expansion mismatches on the other hand, particularly those that lead to the film being in a state of tension upon cooling (i.e., substrates with smaller thermal expansion coefficients), can lead to film cracking.

The perovskites $SrTiO_3$, $LaAlO_3$, and $NdGaO_3$ have good structural and chemical match to the copper-containing high-$T_c$ superconductors. The excellent structural and chemical match of $SrTiO_3$ to the cuprate superconductors immediately made it the substrate of choice for epitaxial growth (Suzuki and Murakami 1987, Chaudhari *et al.* 1987), and for many purposes it remains the reference substrate. However, the high loss tangent of $SrTiO_3$ bars it from high-frequency applications. $LaAlO_3$ has the lowest loss tangent of these perovskite substrates and is available in diameters as large as 100 mm. MgO has even lower dielectric loss, but the multiple in-plane epitaxial orientations that often exist in oxide superconductor films grown on MgO causes undesirable high-angle grain boundaries in the films. This results in lower critical currents and higher surface resistances (Laderman *et al.* 1991).

The extremely low dielectric loss of sapphire ($Al_2O_3$) makes it an attractive material for high frequency applications, especially when a device structure with a high quality factor $Q$ is desired. It also has high thermal conductivity at low temperature and is available in large sizes. However, its anisotropic dielectric properties complicate device design and the direct growth of high-$T_c$ superconductors on sapphire is plagued by chemical reactions. Several barrier layers, including $SrTiO_3$, $CaTiO_3$, MgO, $Y_2O_3$-$ZrO_2$, and $CeO_2$, have been implemented to circumvent this reaction. Of these, $CeO_2$ and $CaTiO_3$ barrier layers on sapphire appear to be the most promising. The surface resistance at microwave frequencies of $YBa_2Cu_3O_{7-\delta}$ films grown on these latter barrier layers on sapphire is comparable to the best values obtained on any other substrate (Merchant *et al.* 1992).

The integration of high-$T_c$ superconductor layers with silicon and GaAs substrates is desirable to form superconductor-semiconductor hybrid electronics and monolithic microwave integrated circuits (MMIC). The direct growth of cuprate superconductors on silicon or GaAs results in an interface reaction and significant diffusion tails into both substrate and film. However, suitable barrier layers have been found. Critical current densities exceeding $10^6\,A\,cm^{-2}$ at 77 K have been achieved in $YBa_2Cu_3O_{7-\delta}/Y_2O_3$–$ZrO_2$/Si and $YBa_2Cu_3O_{7-\delta}$/MgO/GaAs films (Fork 1994). Due to the higher thermal expansion coefficient of GaAs compared to silicon, crack-free $YBa_2Cu_3O_{7-\delta}$ films may be prepared up to a thickness about five times greater than on silicon substrates, where the onset of cracking is about 50 nm (Fork 1994). Another way to overcome the thermal expansion problem when integrating with silicon is to grow on silicon-on-sapphire, where crack-free $YBa_2Cu_3O_{7-\delta}$ films more than 400 nm thick and critical current densities of $4.6 \times 10^6\,A\,cm^{-2}$ at 77 K have been demonstrated (Fork *et al.* 1991). In light of the desirable high-frequency properties of sapphire substrates and the progress that has been made in integrating them with high-$T_c$ superconductors, sapphire substrates may be the best substrate choice for monolithic superconductor–semiconductor electronics.

Epitaxial growth of high-$T_c$ films on single crystalline substrates used to be the only way to realize $J_c$ values in excess of $10^6\,A\,cm^{-2}$ at 77 K. However, the ion-beam-assisted deposition (IBAD) process (Iijima *et al.* 1992) and the rolling-assisted, biaxially-textured, substrates (RABiTS) process (Goyal *et al.* 1996, Norton *et al.* 1996) now allow comparable $J_c$ to be achieved in $YBa_2Cu_3O_{7-\delta}$ films deposited on either roll-textured strips of metals (e.g., nickel alloys) using RABiTS or on polycrystalline or amorphous substrates using IBAD. This freedom from single crystal substrates offers incredible flexibility in the integration of high-$T_c$ superconductors films with other materials.

$SrTiO_3$ was not only the first substrate on which epitaxial high-$T_c$ superconductor films were grown (Suzuki and Murakami 1987), it has also become the best studied and most advanced perovskite substrate in terms of substrate preparation. As the results below describe, it is possible to prepare atomically flat (100)$SrTiO_3$ substrates with relatively straight unit-cell-high steps, where the entire surface is terminated at the $TiO_2$ layer (Kawasaki *et al.* 1994, Koster *et al.* 1998). Initiating growth on a flat substrate of known termination is key to understanding and eventually controlling the nucleation and growth of high-$T_c$ superconductor films and crucial to the preparation of high-$T_c$ multilayers with structural control at the atomic-layer level.

The surfaces of chem-mechanically polished (100)$SrTiO_3$ substrates (as received from the vendor) and imaged by atomic force microscopy (AFM) and reflection high-energy electron diffraction (RHEED) are shown in Figs. 1(a) and 2(a), respectively. These images are indicative of the untreated $SrTiO_3$ surfaces

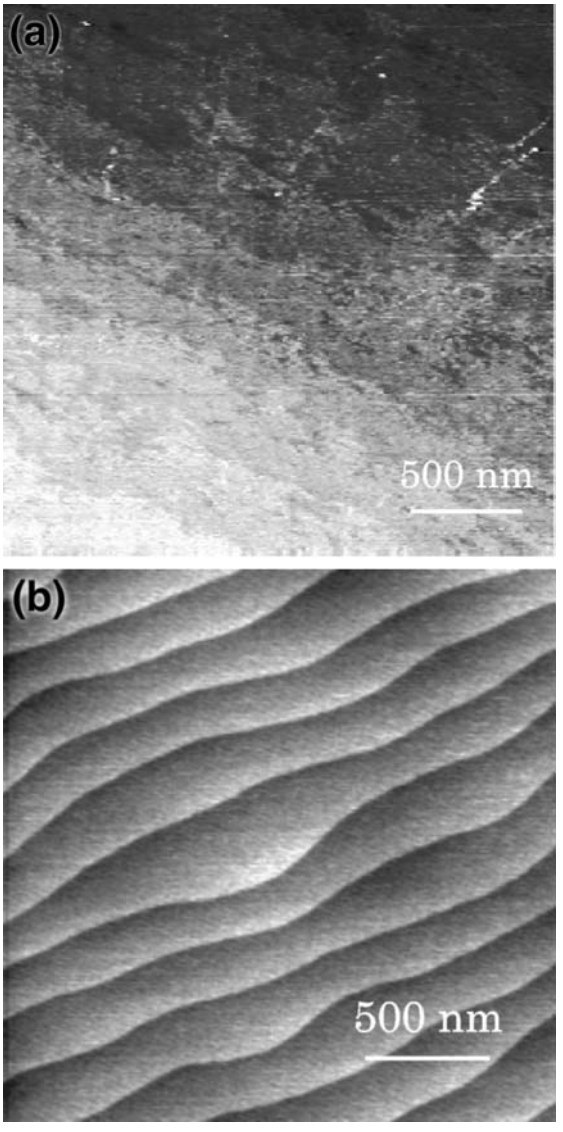

***Figure 1***
AFM images of (100)$SrTiO_3$ substrate surfaces (a) as-received, following a brief heating to $\sim$650 °C in vacuum, and (b) following water soak, buffered-HF etch, and oxygen anneal surface preparation. The vendor of both substrates was ESCETE Single Crystal Technology (reproduced by permission of the American Institute of Physics from *Appl. Phys. Lett.*, 1998, **73**, 2920–2).

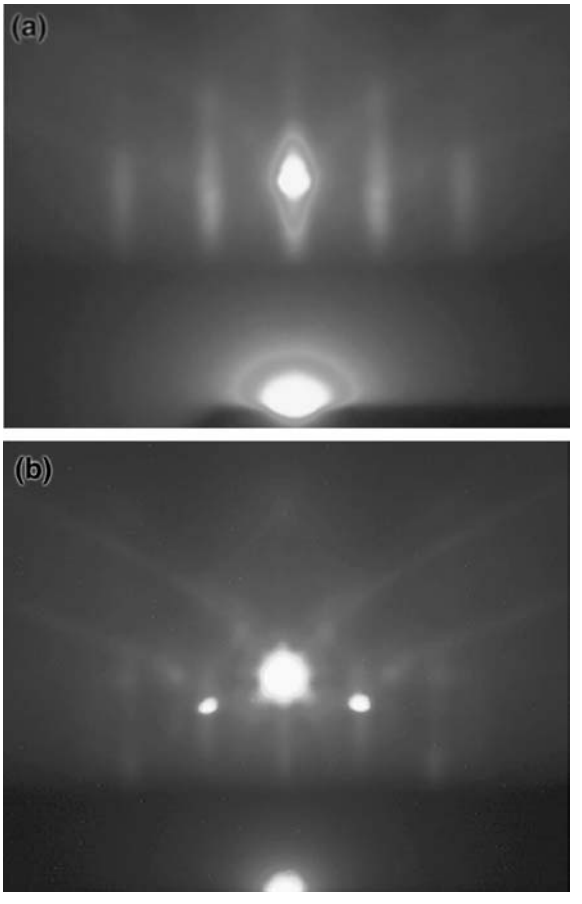

***Figure 2***
RHEED images taken at $\sim$650 °C in 15 Pa oxygen of (100)$SrTiO_3$ substrate surfaces (a) as-received and (b) following water soak, buffered-HF etch, and oxygen anneal surface preparation. The vendor of both substrates was ESCETE Single Crystal Technology (reproduced by permission of the American Institute of Physics from *Appl. Phys. Lett.*, 1998, **73**, 2920–2 and of Elsevier Science from *Appl. Surf. Sci.*, 1999, **138–9**, 17–23, respectively).

on which most high-$T_c$ films and multilayers have been grown to date. (100)$SrTiO_3$ can terminate with either the SrO layer or the $TiO_2$ layer and the co-axial impact-collision ion scattering spectroscopy (CAICISS) spectrum in Fig. 3(a) reveals that chem-mechanically polished substrates have mixed SrO and $TiO_2$ termination. The mixed termination remains even after annealing the as-received (100)$SrTiO_3$ surface in oxygen at high temperatures, as shown in Fig. 3(b). However, etching the (100)$SrTiO_3$ in buffered-HF results in a fully $TiO_2$-terminated (100)$SrTiO_3$ surface as revealed by the CAICISS spectra in Fig. 3(c). This buffered-HF process (Kawasaki *et al.* 1994), which has since been enhanced (Koster *et al.* 1998), also makes the surface smoother and more regular as can be seen in the AFM image in Fig. 1(b) and inferred from the RHEED pattern in Fig. 2(b).

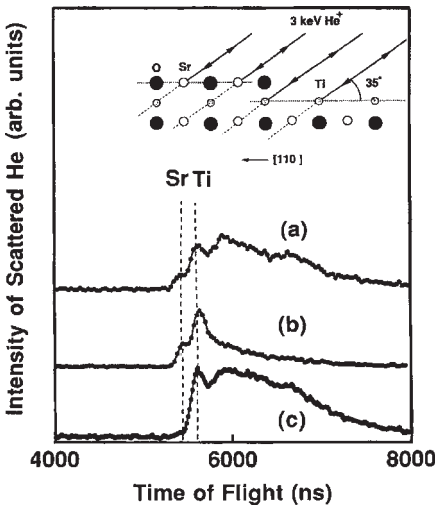

***Figure 3***
CAICISS time-of-flight spectra taken at an incident angle of 35° along the [110] azimuth of (100)$SrTiO_3$ substrate surfaces (a) as-received, (b) following a 1000 °C anneal in 1 atm. oxygen for 10 h, and (c) following a buffered-HF etch surface preparation. The geometry of the measurement is shown schematically in the upper inset for a $SrTiO_3$(100) surface terminated by SrO as well as $TiO_2$ monolayers. The vendor of all three substrates was Shinkosha (reproduced by permission of the American Institute of Physics from *Appl. Phys. Lett.*, 1994, **65**, 3197–9 and of the American Institute for the Advancement of Science from *Science*, 1994, **266**, 1540–2, respectively).

## 2. *Properties of $YBa_2Cu_3O_{7-\delta}$*

### *2.1 Structural Characterization*

Improvements in electronic and photonic materials are usually associated with lower defect densities, e.g., lower concentrations of unwanted impurities, dislocations, grain boundaries, twin boundaries, stacking faults, and inclusions, and improved crystalline order. High-$T_c$ superconductors are an exciting case in which defects—of the right kind—are often desired to dramatically improve properties. A clear example of the beneficial potential of such defects is the enhancement of the self-field $J_c$ of single crystals of $YBa_2Cu_3O_{7-\delta}$ (as well as single crystals of all other high-$T_c$ superconductors studied to date) by over five fold at 4 K and over ten fold at 77 K by subjecting them to heavy-ion irradiation (Civale *et al.* 1991). Although improved, the self-field $J_c$ values of these bombarded single crystals are still an order of magnitude lower than the best films at 77 K, indicating that the films are riddled with even more defects that enhance $J_c$.

Unraveling which of the defects in the films are beneficial and which are detrimental to a particular property has been accomplished by correlating transport measurements with structural characterization. In this section we describe some of the defects that exist in high $T_c$ thin films and multilayers, focusing on $YBa_2Cu_3O_{7-\delta}$ films in which the *c*-axis is oriented normal to the plane of the substrate (*c*-axis $YBa_2Cu_3O_{7-\delta}$ films). We concentrate on $YBa_2Cu_3O_{7-\delta}$ as it is the best studied of all high-$T_c$ superconductors and on *c*-axis films as this is generally the most relevant orientation for applications. Note, however, that for most studies and applications there is no obvious reason why yttrium should be the best rare earth (*Re*) to utilize in superconducting $ReBa_2Cu_3O_{7-\delta}$ films. Indeed, the usage of $NdBa_2Cu_3O_{7-\delta}$ and $SmBa_2Cu_3O_{7-\delta}$ films is increasing as they tend to have smoother surfaces and can have slightly higher $T_c$ values than $YBa_2Cu_3O_{7-\delta}$.

#### *(a) Transmission electron microscopy (TEM)*

A cross-sectional transmission electron micrograph of a *c*-axis $YBa_2Cu_3O_{7-\delta}$ film grown by PLD on (100)$SrTiO_3$ is shown in Fig. 4 (Eibl and Roas 1990). The dark lines running vertically in this bright-field TEM image are threading dislocations. These dislocations originate in the vicinity of the interface and extend through the film. Although the Burgers vector of the dislocations in Fig. 4 was not determined, subsequent TEM studies of the threading dislocations in $YBa_2Cu_3O_{7-\delta}$ films grown by PLD on (100) MgO found similar dislocation densities and suggested the Burgers vector to be either [101], [011], or [111] (Aindow and Yeadon 1994, Yeadon *et al.* 1995). Note that when such a threading dislocation intersects the film surface its Burgers vector has a screw component. As described in the next section, atomic force microscopy (AFM) and scanning tunneling microscopy (STM) studies reveal that $YBa_2Cu_3O_{7-\delta}$ films typically contain comparable densities of dislocations with a screw component at the film surface; thus it is likely that the threading dislocations imaged in Fig. 4 have a Burgers vector with a screw component.

Another important issue that TEM studies have clarified is the chemistry of the interface between high-$T_c$ films and various substrates (Wen *et al.* 1993). Due

***Figure 4***
Cross-sectional transmission electron micrograph of a $YBa_2Cu_3O_{7-\delta}$ film epitaxially grown on (100)$SrTiO_3$ by PLD showing $\sim 10^9$ threading dislocations $cm^{-2}$ (reproduced by permission of Materials Research Society from *J. Mater. Res.*, 1990, **5**, 2620–32).

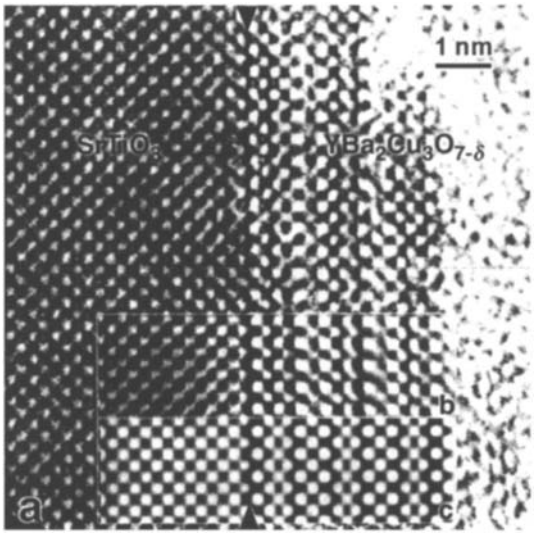

***Figure 5***
High-resolution cross-sectional TEM of the (001)$YBa_2Cu_3O_{7-\delta}$/(100)$SrTiO_3$ interface showing the $TiO_2$-termination layer of the (100)$SrTiO_3$ substrate and the BaO-$CuO_2$-Y- … starting layer sequence of the $YBa_2Cu_3O_{7-\delta}$ film. The arrows indicate the position of the interface. Regions a, b, and c are the observed image, the averaged image, and the calculated image (reproduced by permission of Elsevier Science from *Physica C*, 1993, **205**, 354–62).

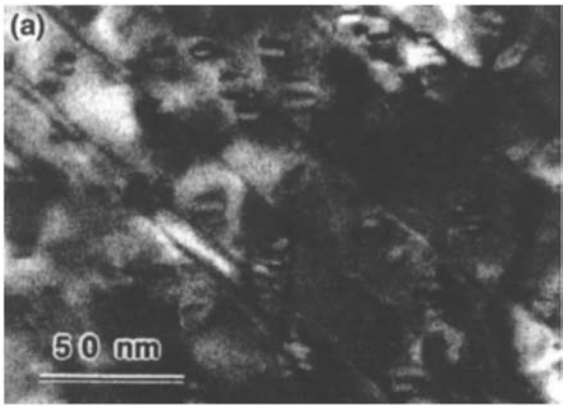

***Figure 6***
TEM image of a $Y_2O_3$ precipitate in sputtered $YBa_2Cu_3O_{7-\delta}$ film. A planar-view image in which the $\sim 10^{11}$ $Y_2O_3$ precipitates per $cm^2$ give rise to the Moiré fringes (reproduced by permission of the American Institute of Physics from *Appl. Phys. Lett*., 1992, **60**, 1016–18).

to the layered structure of all cuprate superconductors, it is unclear at which specific layer(s) growth will be initiated, and whether this depends on the type of substrate or deposition method. A high-resolution TEM image of the interface between a *c*-axis $YBa_2Cu_3O_{7-\delta}$ film and the (100)$SrTiO_3$ substrate upon which it was epitaxially grown is shown in Fig. 5. Analysis of the interface using TEM image simulations allowed the starting layer sequence of the $YBa_2Cu_3O_{7-\delta}$ film to be determined. For *c*-axis $YBa_2Cu_3O_{7-\delta}$ grown on $TiO_2$-terminated (100)Sr $TiO_3$, the $YBa_2Cu_3O_{7-\delta}$ starts with the BaO monolayer followed by the $CuO_2$, Y, $CuO_2$, BaO, CuO, … monolayers of the $YBa_2Cu_3O_{7-\delta}$ structure, respectively. This result was found to be independent of the type of codeposition method used to deposit the $YBa_2Cu_3O_{7-\delta}$ film (Wen *et al*. 1993). However, the initial monolayer of a *c*-axis $YBa_2Cu_3O_{7-\delta}$ film does depend on the substrate—both the material and its terminating monolayer.

Due to the narrow composition range within which the $YBa_2Cu_3O_{7-\delta}$ phase exists, $YBa_2Cu_3O_{7-\delta}$ films often contain impurity phases. CuO, $Y_2O_3$, and $YCuO_2$ are often seen in epitaxial films produced by *in situ* methods (Catana *et al*. 1993). Other impurity phases including BaO, "$YBa_3Cu_2O_x$" (which is probably either $YBa_4Cu_3O_{8.5+\delta}$ or $YBa_6Cu_3O_{10+\delta}$), and $Y_2BaCuO_5$ have also been reported. Some of these inclusions can be quite small and epitaxially oriented to the surrounding $YBa_2Cu_3O_{7-\delta}$ matrix as is the case for the $Y_2O_3$ precipitates shown in Fig. 6.

*(b) AFM and STM*

The morphologies of *c*-axis oriented $YBa_2Cu_3O_{7-\delta}$ films grown by different vapor phase methods on a variety of substrates exhibit remarkable similarity, indicating that the same growth mechanisms are operative (Hawley *et al*. 1991, Gerber *et al*. 1991, Raistrick and Hawley 1994, Schlom *et al*. 1994). The growth process may generally be described as ledge growth, emphasizing the energetic preference of the depositing species to attach to existing ledges (step edges), which propagate laterally across the substrate surface as they accommodate species. Depending on the substrate, its misorientation, the $YBa_2Cu_3O_{7-\delta}$ film thickness, and growth conditions, three different growth modes are seen in *c*-axis $YBa_2Cu_3O_{7-\delta}$ films: spiral growth, layer-by-layer growth, and step-flow growth. In all three cases STM and AFM reveal a surface morphology containing closely spaced steps. These steps, which have a height equal to the *c*-axis length of $YBa_2Cu_3O_{7-\delta}$ (1.17 nm), or an integral multiple of it, separate (001)$YBa_2Cu_3O_{7-\delta}$ terraces. These terraces are typically only a few tens of nanometers wide, indicating the length scale over which such *c*-axis $YBa_2Cu_3O_{7-\delta}$ films are atomically flat. The steps expose (100) and (010) $YBa_2Cu_3O_{7-\delta}$ faces, which often account for 5–10% of the surface area of *c*-axis oriented $YBa_2Cu_3O_{7-\delta}$ films.

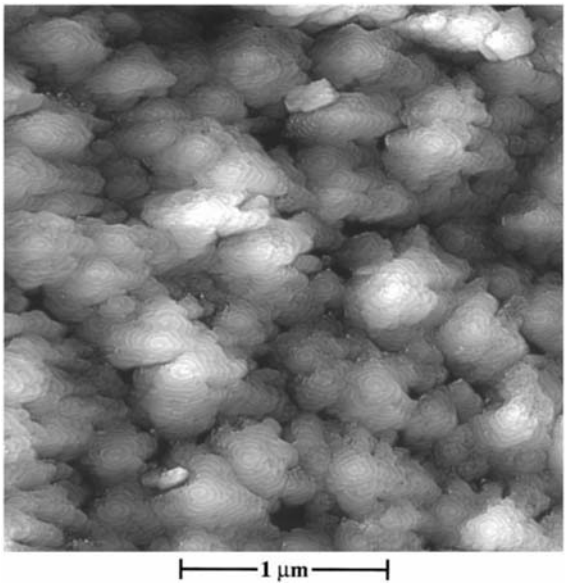

***Figure 7***
STM image of a *c*-axis oriented, ~120 nm thick $YBa_2Cu_3O_{7-\delta}$ film sputtered on a (100)$SrTiO_3$ substrate. Growth spirals emanating from dislocations with a screw component indicate a density $(1.4 \pm 0.2) \times 10^9\,cm^{-2}$ of dislocations with a screw component at the film surface (after Schlom *et al.* 1994).

A representative example of the morphology of a *c*-axis $YBa_2Cu_3O_{7-\delta}$ film grown under conditions yielding high $T_{c0}$ (typically 88–90 K) and high $J_c$ (typically $5 \times 10^6\,A\,cm^{-2}$ at 77 K) on a well-oriented (100) perovskite substrate is shown in Fig. 7 (Schlom *et al.* 1992). The film surface is seen to contain many growth spirals (typically $10^8$–$10^{10}\,cm^{-2}$); a close-up of a single growth spiral is shown in Fig. 8. Each spiral emanates from the point at which a dislocation with a screw component intersects the film surface. The resulting well-known spiral growth mechanism (Frank 1949), in which dislocations with a screw component provide energetically-favorable attachment sites at the step edges that emerge from them, occurs frequently in the growth of layered materials.

A consequence of this growth mechanism is that the film surfaces are *not* atomically flat over large distances; instead, the (001) $YBa_2Cu_3O_{7-\delta}$ surface consists of mounds, each typically 300 nm in diameter. The surface roughness depends on growth conditions, but height variations of 5–10% of the film thickness (for films 10–200 nm thick) from the top of each mound to its intersection with the neighboring mound are typical in films made by gas phase codeposition techniques on all of the common substrates. Figure 9 shows the surface of a *c*-axis

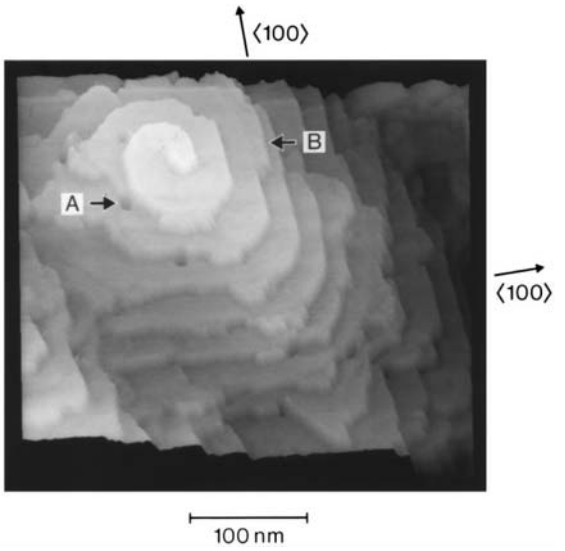

***Figure 8***
STM image of a *c*-axis oriented ~150 nm thick $YBa_2Cu_3O_{7-\delta}$ film sputtered on a $SrTiO_3$ substrate. The image shows a growth spiral with a step height of one unit cell (~1.2 nm). The small dark spots such as the one pointed to by arrow A are either holes or isolated insulating regions (e.g., $Y_2O_3$ precipitates). Clumps of material with irregular shape, for example at arrow B, are present at the step edges. The in-plane ⟨100⟩ directions are indicated (from Schlom *et al.* 1992).

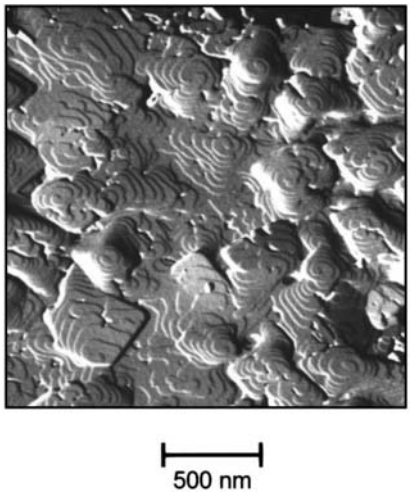

***Figure 9***
AFM image of a *c*-axis oriented $YBa_2Cu_3O_{7-\delta}$ film grown by off-axis PLD on a (100)MgO substrate. The film is characterized by growth spirals emanating from dislocations with a screw component.

$YBa_2Cu_3O_{7-\delta}$ film grown on (100)MgO; again the growth mode is seen to be spiral growth. How the plethora of dislocations with a screw component are nucleated is not established, although several mechanisms have been proposed (Schlom *et al*. 1992, Burger *et al*. 1994, Schlom *et al*. 1994).

For *c*-axis $YBa_2Cu_3O_{7-\delta}$ films thinner than 10 to 20 nm (Burger *et al*. 1994, Schlom *et al*. 1994), films grown on $YBa_2Cu_3O_{7-\delta}$ substrates (Shimizu *et al*. 1994), or films grown by PLD under conditions where species reach the substrate with significant kinetic energies (Raistrick and Hawley 1994, Dam *et al*. 1998), a layer-by-layer growth mode (also known as "birth and spread") is possible. An example of this growth mode is shown in Fig. 10. The observed morphology, which has been described as "Tower of Hanoi" or "layer-cake-like," is indicative of a growth mode dominated by two-dimensional nucleation coupled with an Ehrlich–Schwoebel step-edge barrier to the diffusion of species from the higher terraces to the incomplete lower terraces. As the surfaces of homoepitaxial $YBa_2Cu_3O_{7-\delta}$ films are free of these high stacks of incomplete terraces (Shimizu *et al*. 1994), the step-edge barrier present in heteroepitaxial growth might be induced by lattice mismatch with the substrate.

If the substrate is misoriented sufficiently (typically a few degrees from the low-index plane on which spiral growth occurs), the growth mode of *c*-axis $YBa_2Cu_3O_{7-\delta}$ changes from spiral growth to step-flow growth (Schlom *et al*. 1992). Step-flow growth occurs by the collective propagation of the terraces

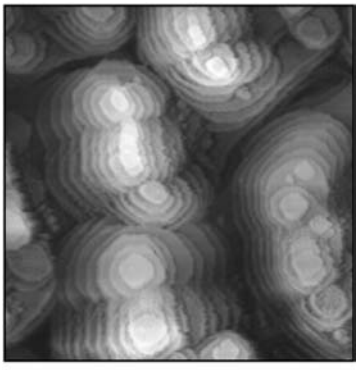

***Figure 10***
STM image of a *c*-axis oriented $\sim$150 nm thick $YBa_2Cu_3O_{7-\delta}$ film grown on (100)$SrTiO_3$ by PLD. The growth mounds referred to as "wedding cake" towers or "Tower of Hanoi" structures are free of spirals and indicate that the growth mode involves two-dimensional nucleation of unit-cell-high layers and their lateral outgrowth.

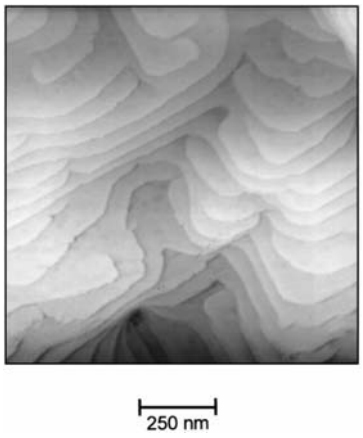

***Figure 11***
STM image of a *c*-axis oriented $\sim$130 nm thick $YBa_2Cu_3O_{7-\delta}$ film sputtered on a vicinal $SrTiO_3$ substrate (misoriented by $\sim 3^\circ$ from (100)) at a substrate temperature of $\sim 750\,^\circ$C. The surface morphology of the film is characterized by growth steps originating from the substrate tilt and from dislocations with a screw component. This image shows the cross-over from spiral growth to step flow (after Mannhart *et al*. 1994).

across the substrate surface. The terraces on vicinal substrate surfaces accommodate the tilt of the substrate and are energetically-favorable incorporation sites. This cross-over in growth mode can be seen in Figs. 11 and 12. In Fig. 11 the misorientation of the substrate is such that both spiral growth and step-flow growth modes are operative. At larger misorientation or higher substrate temperature, as shown in Fig. 12, the growth mode has become purely step-flow.

The impurity phases that occur in $YBa_2Cu_3O_{7-\delta}$ films and have been conclusively identified by TEM, have characteristic morphologies that can be distinguished by AFM (Catana *et al*. 1993). An example is shown in Fig. 13 in which the most common impurity phases found in $YBa_2Cu_3O_{7-\delta}$ films with good transport properties i.e., CuO, $Y_2O_3$, and $YCuO_2$, are seen.

### *(c) RHEED*

A powerful *in situ* analysis tool used during the growth of high-$T_c$ films is RHEED. The sensitivity of RHEED to surface structure is ideal for monitoring the growth process, and RHEED, in particular, has been key to the atomic-layer engineering of oxide superconductors. RHEED patterns themselves reveal the formation of impurity phases, the in-plane orientation relationship between film and substrate or between the many layers in a multilayer, and allow the relaxation of in-plane lattice constants to be followed in real-time. Growth conditions may be adjusted *during growth* in response to the RHEED pattern.

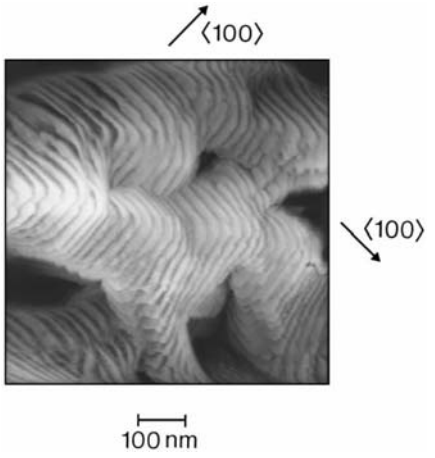

***Figure 12***
STM image of a *c*-axis oriented, ~130 nm thick $YBa_2Cu_3O_{7-\delta}$ film sputtered on a vicinal (100)$SrTiO_3$ substrate (misoriented by 2.3° from (100)) at a substrate temperature of ~780 °C. The surface morphology is dominated by steps between (001)$YBa_2Cu_3O_{7-\delta}$ terraces which accommodate the substrate tilt. The $YBa_2Cu_3O_{7-\delta}$ is growing by step flow. The in-plane ⟨100⟩ directions are indicated (after Schlom *et al.* 1992).

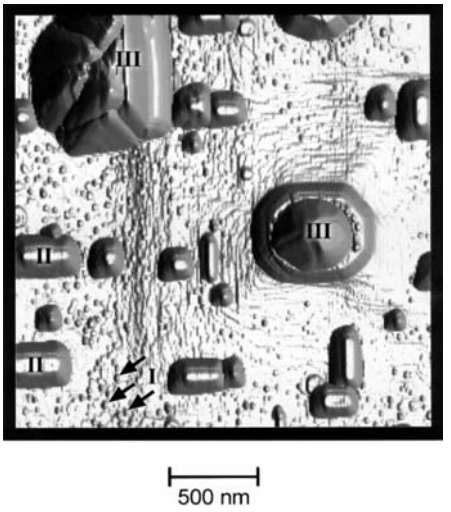

***Figure 13***
AFM image of the (001) surface of a ~100 nm thick sputtered $YBa_2Cu_3O_{7-\delta}$ film showing densely distributed outgrowths of three different types: (I) a-oriented $Y_2O_3$), (II) $YCuO_2$ and (110)-oriented $Y_2O_3$, (III) agglomerates of CuO, $Y_2O_3$, and a-oriented $YBa_2Cu_3O_{7-\delta}$) (reproduced by permission of the American Institute of Physics from *Appl. Phys. Lett.* **63**, 553–5).

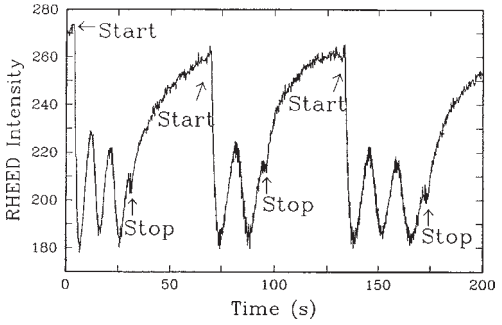

***Figure 14***
Time dependence of the specular RHEED beam intensity during deposition of a $YBa_2Cu_3O_{7-\delta}$ film on (100)$SrTiO_3$ with a $PrBa_2Cu_3O_{7-\delta}$ buffer grown by growth-interrupted PLD. The growth rate was changed after the first three layers (reproduced by permission of the American Institute of Physics from *Phys. Rev. B*, 1994, **49**, 3483–91).

Oscillations in the intensity of the RHEED pattern allow the thickness of the growing film to be precisely monitored. In deposition techniques where the species are codeposited, the intensity of the RHEED pattern oscillates as shown in Fig. 14. The period of these RHEED oscillations corresponds to a deposited thickness of an electrically neutral formula unit of each compound (Terashima *et al.* 1990).

For the growth of *c*-axis oriented high-$T_c$ superconductor films, this amounts to one *c*-axis unit cell thickness for $YBa_2Cu_3O_{7-\delta}$ and other high-$T_c$ materials (e.g., (Ba,K)$BiO_3$ and $TlBa_2Ca_{n-}Cu_nO_{2n+3}$) whose unit cells contain one formula unit, and one half the *c*-axis unit cell thickness for doped $La_2CuO_4$ and other high-$T_c$ materials (e.g., $Bi_2Sr_2Ca_{n-1}Cu_nO_{2n+4}$ and $Tl_2Ba_2Ca_{n-1}Cu_nO_{2n+4}$) whose unit cells contain two formula units. This minimum growth unit determined by RHEED oscillations is consistent with the step heights that have been observed by STM observations on the surfaces of high-$T_c$ superconductor films and single crystals.

RHEED has traditionally been limited to high-vacuum deposition techniques like molecular beam epitaxy (MBE) and ion-beam sputtering, however, using differential pumping this technique has been extended to PLD (see *Superconducting Thin Films: Materials, Preparation, and Properties*, *Superconducting Thin Films: Multilayers*, Karl and Stritzker 1992, Frey *et al.* 1994, Rijnders *et al.* 1997). The rate of recovery of the RHEED intensity when growth is interrupted (between the stop and start marks in Fig. 14) provides information on surface diffusion and has been studied as a function of substrate temperature, oxidant pressure, and monolayer coverage. These observations have led to major improvements in PLD by interrupting and resuming deposition depending

on the RHEED intensity, in order to optimize the smoothness of the films grown (Frey *et al.* 1994, Koster *et al.* 1999).

### 2.2 Transport Properties

For most studies or applications epitaxial films are required, rather than polycrystalline ones that contain large-angle grain boundaries. This is due to the fact that generally grain boundaries reduce the $J_c$ of high-$T_c$ superconductors and increase their surface resistance (Hilgenkamp and Mannhart 2000). A plot showing the $J_c$ reduction that occurs in $YBa_2Cu_3O_{7-\delta}$ films due to grain boundaries of different angles and different types is shown in Fig. 15. Grain boundaries have also been correlated with an increase in the surface resistance of epitaxial $YBa_2Cu_3O_{7-\delta}$ films (Laderman *et al.* 1991, Lauder *et al.* 1998); this correlation is illustrated in Fig. 16.

The challenges associated with the growth of epitaxial superconducting cuprate films have resulted in such drastic improvements in the deposition technology for multicomponent oxide films, that a large number of groups now routinely grow high-$T_c$ films with superb properties. Of particular significance for basic studies and applications are the $J_c$ and $R_s$ of the films, discussed below. It is important to note that the electrical transport properties, including $T_c$, $J_c$, and $R_s$, depend in different ways on the microstructure and composition of the films. For example, the highest $J_c$ values are obtained in films with a huge density of dislocations, which pin vortices strongly and thus support more current before the resistive losses caused by the movement of vortices set in. These

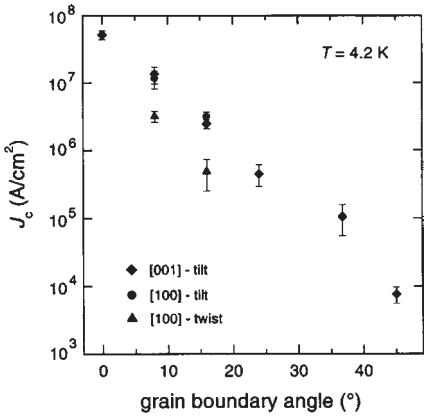

***Figure 15***
The intergrain $J_c$ in $YBa_2Cu_3O_{7-\delta}$ films as a function of grain boundary misorientation angle $\theta$ for three different types of grain boundaries: [001] symmetric tilt boundaries (♦), [100] symmetric tilt boundaries (•), and [100] twist boundaries (▲) (after Goetz *et al.* 2000).

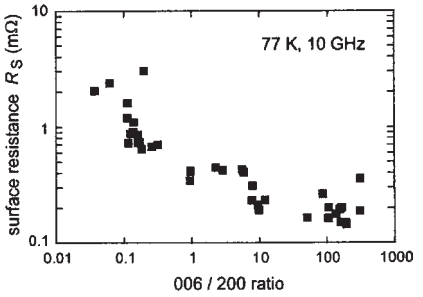

***Figure 16***
Surface resistance at 77 K and 10 GHz for $YBa_2Cu_3O_{7-\delta}$ films as a function of the intensity of the 006 and 200 X-ray reflections. The 006/200 ratio increases as the amount of *a*-axis grains decreases in the *c*-axis oriented films and is therefore indicative of the number of grain boundaries (reproduced by permission of VCH Verlagsgesellschaft from *Adv. Mater.*, 1998, **10**, 1249–54).

pinning sites, however, reduce $T_c$. This illustrates that it is not possible to optimize all transport properties with one type of film.

As the density of dislocations and other defects in epitaxial $YBa_2Cu_3O_{7-\delta}$ films is always large compared to that of single crystals, single crystals outperform films in those aspects for which a minimum defect density is key, such as mean free path or $T_c$. On the other hand, due to their defect structure, films have much higher critical current densities than single crystals. $J_c$ for single crystals are typically in the low $10^5\,A\,cm^{-2}$ range at 77 K and in the low $10^6\,A\,cm^{-2}$ range at 4 K (Worthington *et al.* 1987). These $J_c$ values can be increased significantly through the introduction of defects into single crystals, e.g., via irradiation with heavy ions (Civale *et al.* 1991).

The critical current density routinely achieved with *c*-axis oriented epitaxial $YBa_2Cu_3O_{7-\delta}$ films is an impressive $5 \times 10^7\,A\,cm^{-2}$ at 4.2 K and $5 \times 10^6\,A\,cm^{-2}$ at 77 K, as shown in Fig. 17. The critical current density is limited by the onset of flux flow, rather than by Josephson decoupling or depairing. As the $YBa_2Cu_3O_{7-\delta}$ films are usually highly twinned, this behavior demonstrates that twin boundaries do not act as Josephson junctions. At first current densities above $10^6\,A\,cm^{-2}$ (77 K) could only be achieved by films grown on single crystalline $SrTiO_3$ or other perovskite substrates, but now such $J_c$ values are readily obtained in films grown on a large variety of other substrate materials, including sapphire, silicon, silicon-on-sapphire, GaAs, and flexible tapes of stainless steel or nickel, covered by buffer layers such as yttria-stabilized cubic zirconia ($Y_2O_3$–$ZrO_2$), MgO, or $CeO_2$. Such high current densities have been obtained in scalable processes on long, flexible tapes (Foltyn *et al.* 1999, Park *et al.* 1999), or on 8 inch wafers, where a $J_c$

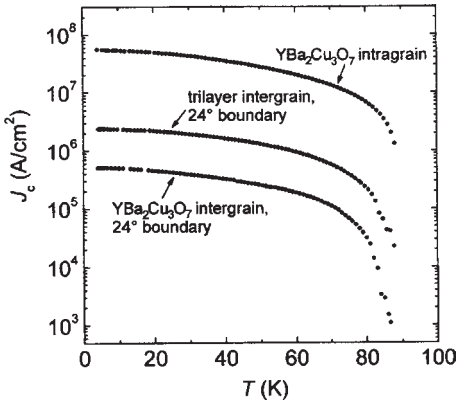

*Figure 17*
Temperature dependence of the critical current density flowing in the a,b-plane of a $\sim 150$ nm thick, *c*-axis oriented $YBa_2Cu_3O_{7-\delta}$ film. Also shown are the critical current densities across a symmetric 24° [001] tilt grain boundary in a $YBa_2Cu_3O_{7-\delta}$ film and in a $Y_{0.7}Ca_{0.3}Ba_2Cu_3O_{7-\delta}/YBa_2Cu_3O_{7-\delta}/Y_{0.7}Ca_{0.3}Ba_2Cu_3O_{7-\delta}$ trilayer.

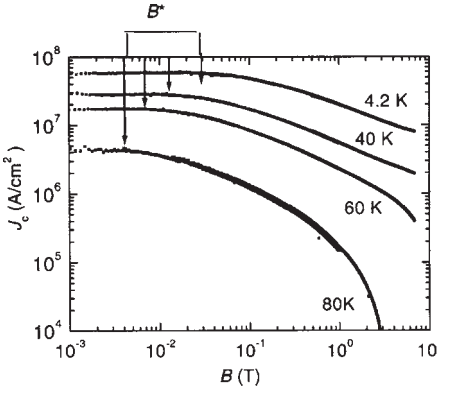

*Figure 18*
Superconducting critical current density of a *c*-axis oriented $YBa_2Cu_3O_{7-\delta}$ film grown by PLD with a dislocation density $n_{disl} = 6 \times 10^8\,cm^{-2}$ at various temperatures as a function of magnetic flux density $B$ applied along the c-direction. The critical current density was measured magnetically using a torque magnetometer. The arrows indicate the field strength of the characteristic field $B^*$ (reproduced by permission of Macmillan Magazines Ltd. from *Nature*, 1999, **399**, 439–42).

of $3 \times 10^6\,A\,cm^{-2}$ at 77 K varying by only $\pm 5\%$ over the whole wafer area has been achieved (W. Prusseit, personal communication, 2000).

The high critical current densities of $YBa_2Cu_3O_{7-\delta}$ films in the (001) plane are caused by strong pinning of vortices at dislocation cores and weaker pinning at other defects, such as oxygen vacancies and the defects that surround inclusions (Mannhart *et al.* 1992, Douwes *et al.* 1993, Dam *et al.* 1999). This is demonstrated by Figs. 18 and 19. In Fig. 18 the critical current density of a $YBa_2Cu_3O_{7-\delta}$ film is plotted for various temperatures as a function of applied magnetic field. Clearly, as a function of applied field, $J_c$ stays almost constant up to a characteristic field $B^*$, above which $J_c$ starts to drop rapidly. As shown in Fig. 19, $B^*$ depends almost linearly on the dislocation density in the film, providing evidence that below $B^*$ the flux lines are pinned at the dislocations. At field strengths exceeding $B^*$, the excessive flux lines are only weakly pinned and $J_c$ is reduced.

For microwave applications, $YBa_2Cu_3O_{7-\delta}$ films have to be grown *c*-axis oriented on substrates with low dielectric losses such as MgO, $LaAlO_3$, or $CeO_2$-buffered sapphire. Since grain boundaries cause substantial microwave losses (see for example Habib *et al.* 1998), the films have to be as devoid of grain boundaries as possible. The microwave surface resistance $R_s$ for such films is shown in Fig. 20. In this figure, $R_s$ is plotted as a function of frequency $f$ in comparison to the surface resistance of copper, niobium, $Nb_3Sn$, and polycrystalline $YBa_2Cu_3O_{7-\delta}$. As can be seen in the figure, at 77 K the surface resistance of $YBa_2Cu_3O_{7-\delta}$ is smaller than $R_s$ of copper for

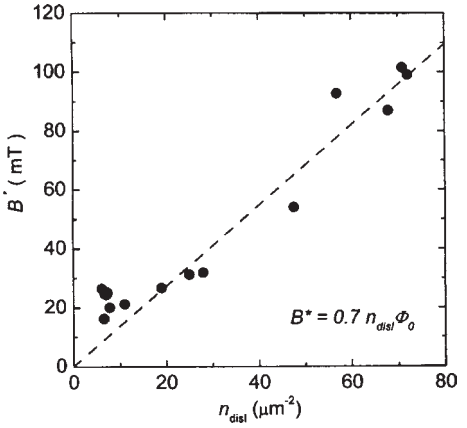

*Figure 19*
The characteristic magnetic flux density $B^*$ as a function of the dislocation density $n_{disl}$ for $YBa_2Cu_3O_{7-\delta}$ films grown by sputtering and by PLD (reproduced by permission of Macmillan Magazines Ltd. from *Nature*, 1999, **399**, 439–42).

frequencies below 200 GHz, though still larger than the surface resistance of the conventional superconductors that are measured at much lower temperatures. Good films reach values around 200–300 μΩ at 10 GHz and 77 K. $YBa_2Cu_3O_{7-\delta}$ films have been fabricated in which these values are nearly independent

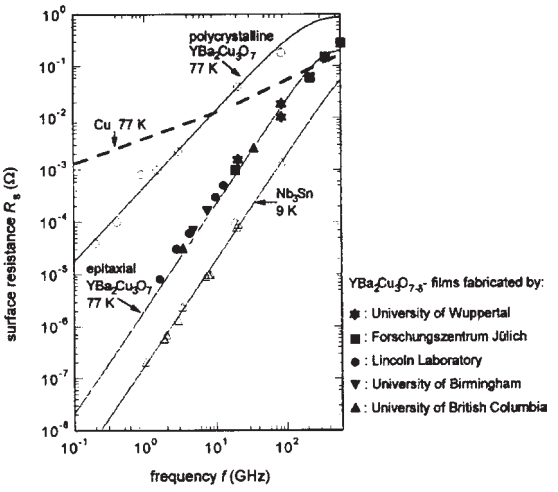

***Figure 20***
Frequency dependence of the surface resistance $R_s$ at 77 K of high-quality $YBa_2Cu_3O_{7-\delta}$ epitaxial films fabricated by various laboratories compared to polycrystalline $YBa_2Cu_3O_{7-\delta}$ samples and copper. Also shown are the data of $Nb_3Sn$ at 9 K. Note that the data for the $Nb_3Sn$ samples have been taken at a reduced temperature $T/T_c \approx 0.5$, whereas the $YBa_2Cu_3O_{7-\delta}$ samples have been measured at $T/T_c \approx 0.85$ (reproduced by permission of Springer-Verlag from "High-Temperature-Superconductor Thin Films at Microwave Frequencies (Springer Tracts in Modern Physics 155)," 1999.)

of the applied microwave power for rf magnetic field strengths of up to 17 mT at 77 K (Zaitsev *et al.* 1998).

$R_s$ increases with frequency, characteristically varying as $f^2$. At low temperatures the surface resistance of $YBa_2Cu_3O_{7-\delta}$ films saturates at values of about 20 μΩ at 10 GHz, which is much larger than the achievable losses for niobium or $Nb_3Sn$ (Chaloupka and Müller 1991, Hensen *et al.* 1997, Hein 1999). It has been shown that the microwave losses are consistent with the d-wave pairing symmetry of $YBa_2Cu_3O_{7-\delta}$ (Hensen *et al.* 1997).

An excellent discussion of the microwave properties of $YBa_2Cu_3O_{7-\delta}$ films as well as $Tl_2Sr_2CaCu_2O_{8+x}$ films (which are also frequently used for microwave applications) is given in (Hein 1999).

## 3. *Multilayers and Superlattices*

High-$T_c$ films, which themselves have a layered perovskite structure, naturally suggest interspersing other layers to form a multilayer. Such multilayers can be divided into three types:

(i) the combination of relatively thick layers of different compounds, as is done in the integration of a high-$T_c$ layer with an insulating layer to make a pick-up coil of a SQUID (see *SQUIDs: The Instrument*);

(ii) the integration of thinner layers of known compounds as is done in artificial superlattices or in the fabrication of sandwich-type *SIS* or *SNS* Josephson junctions in which two relatively thick high-$T_c$ layers are separated by a thin barrier layer of an insulator or conductor; and

(iii) the extreme case in which the high-$T_c$ structures are altered on the atomic-layer level and the multilayers produced can be regarded as new high-$T_c$ phases.

Examples of multilayers consisting of relatively thick layers of different compounds are $PrBa_2Cu_3O_{7-\delta}/YBa_2Cu_3O_{7-\delta}$ bilayers (Poppe *et al.* 1989) and field-effect devices in which high-$T_c$ films are layered with highly insulating $SrTiO_3$ films (Mannhart *et al.* 1991). By cutting diffusion paths by means of artificial interfaces in $YBa_2Cu_3O_{7-\delta}/Ba_xSr_{1-x}TiO_3/YBa_2Cu_3O_{7-\delta}$ samples, interlayer resistivities as high as $3 \times 10^{13}\,\Omega \cdot cm$ have been achieved (Frey *et al.* 1996). As multilayer technology is an essential advantage for many applications, multilayers have been grown for a variety of studies and applications, e.g., for superconducting quantum interference devices (SQUIDs) (Koelle *et al.* 1999) or for tunable microwave components (Boikov *et al.* 1995). In many cases it has turned out to be difficult to fabricate operating multilayers with a high yield; some of the associated problems are discussed by Wellstood *et al.* (1994).

Superlattices were first deposited by Triscone and coworkers, who grew *c*–axis oriented $YBa_2Cu_3O_{7-\delta}/DYBa_2Cu_3O_{7-\delta}$ structures with periods as small as 2.4 nm by sputtering (Triscone *et al.* 1989). Soon thereafter, *a*-axis oriented superlattices consisting of $YBa_2Cu_3O_{7-\delta}/PrBa_2Cu_3O_{7-\delta}$ layers were deposited (Eom *et al.* 1991). Superlattices involving high-$T_c$ superconductors have been applied to many studies of the physics of high-$T_c$ superconductors, especially studies of the dimensionality of high-$T_c$ superconductivity (Triscone *et al.* 1990, Lowndes *et al.* 1990, Kanai *et al.* 1990), experiments concerning the physics of Abrikosov vortices (Suzuki *et al.* 1994) or of phonons in high-$T_c$ superconductors (Storozhuk *et al.* 1995). In 1999, doping superlattices consisting of $YBa_2Cu_3O_{7-\delta}/Y_{1-x}Ca_xBa_2Cu_3O_{7-\delta}$ were deposited to successfully enhance the grain boundary critical current density in $YBa_2Cu_3O_{7-\delta}$ films as shown in Fig. 17 (Hammerl *et al.* 2000). Superlattices containing other functional materials, such as the CMR-manganates, have also been grown (Jakob *et al.* 1995).

A very advanced example of multilayers are those that are engineered on literally the atomic level. MBE has been particularly successful in creating such multilayers. This has been used to make device structures with selectively doped barriers, barriers of new

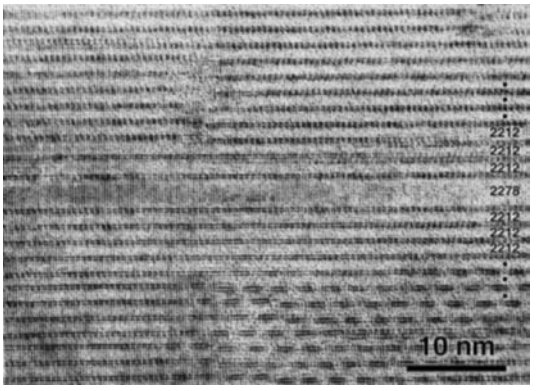

***Figure 21***
Cross-sectional TEM image of a formula-unit-thick layer of $Bi_2Sr_2Ca_7Cu_8O_{20}$ (2278) sandwiched between thick layers of $Bi_2Sr_2CaCu_2O_8$ (2212) (reproduced by permission of Plenum Publishing Corporation from Bozovic *et al*. 1994).

materials, as well as new high-$T_c$ materials (see *Superconducting Thin Films: Materials, Preparation, and Properties*, *Superconducting Thin Films: Multilayers*, Eckstein and Bozovic 1995, Schlom and Harris 1995). An example is shown in Fig. 21 in which a single formula-unit-thick layer of $Bi_2Sr_2Ca_7Cu_8O_{20}$ (2278) has been grown between thick layers of the superconductor $Bi_2Sr_2CaCu_2O_8$ (2212).

## 4. Summary and Outlook

As we have described in this article, films and multilayers containing a great number of high-$T_c$ compounds are grown routinely and have exceptional properties—well beyond all expectations when high-$T_c$ superconductivity was discovered in 1986. Multilayers have progressed from combining known materials to literally engineering new materials at the atomic-layer level.

The progress achieved and the knowledge acquired will be applied in the future to the growth of films and heterostructures of other oxide or nitride compounds, into which high-$T_c$ superconducting films will be embedded. As in semiconductors, through doping and material selection, the functionality of individual layers can be tailored in heterostructures. It is expected that the challenges and the potential benefits of such heterostructures will provoke further improvements in the control of film growth.

## 5. Acknowledgments

We gratefully acknowledge our many collaborators with whom, beginning in early 1987, we have worked on the properties of high-$T_c$ superconducting thin films and multilayers, especially D. Anselmetti, J.G. Bednorz, I. Bozovic, A. Catana, P. Chaudhari, Ch. Gerber, J. N. Eckstein, T. Frey, J. S. Harris, Jr., E. S. Hellman, H. Hilgenkamp, K. A. Müller, and C. C. Tsuei. We also thank D. H. A. Blank, B. Dam, O. Eibl, D. Face, S. Foltyn, B. Götz, G. Hammerl, M. Hein, K. E. Myers, W. Prusseit, C. W. Schneider, J.-M. Triscone, M. Yoshimoto, and H. Zandbergen for providing us with original figures or data of their work for use in this article, and to K. Wiedenmann and M. A. Zurbuchen for their skillful assistance. DGS acknowledges the support of DOE through grant DE-FG02-97ER45638 and a research fellowship from the Alexander von Humboldt Foundation during the preparation of this article during his sabbatical stay at Augsburg University. JM acknowledges the support of the BMBF (project 13N6918/1).

# High-temperature Superconductors: Transport Phenomena

The discovery of high-temperature superconductors in 1986 by Bednorz and Müller (1988) started a worldwide explosive growth of research and development in the field of superconductivity. The discovered new class of superconductors shows a critical temperature $T_c$ for the appearance of superconductivity much higher than for the superconductors known before. The value of $T_c$ even exceeds the boiling point (77.3 K) of liquid nitrogen, a result highly important for the technical applications of superconductors. The discovered new class of superconductors are cuprate perovskites with electronic properties which depend sensitively on the admixture of specific doping elements. Up to now the highest critical temperature $T_c$ was observed for the cuprate $HgBa_2Ca_2Cu_3O_{8+\delta}$ with $T_c = 133$ K at room pressure (Tinkham 1996, Waldram 1996).

The common structural element of the copper perovskites are the copper oxide planes in which the superconducting properties are believed to originate. The crystallographic unit cell contains varying numbers of $CuO_2$ planes, depending on the particular oxide compound. Because of the different possible chemical composition there are five main families of high-temperature superconductors, the "parent compounds" of which are listed in Table 1.

In addition to the high values of the critical temperature $T_c$ and the strong anisotropy due to the prominent role of the $CuO_2$ planes, the third novel feature of the cuprate superconductors is the small value of the superconducting coherence length $\xi$. The length $\xi$ indicates the size of the wave function representing a Cooper pair, i.e., the elementary constituent of superconductivity. The coherence length reaches values as small as only 1–2 nm. Hence, the upper critical magnetic field $B_{c2}$ attains values as high as $B_{c2} = \varphi_0/2\pi\xi^2 = 100$–$200$ T. Here, $\varphi_0 = h/2e = 2.07 \times 10^{-15}$ Vs is the magnetic flux quantum ($h$ Planck's constant, $e$ elementary charge). The small values of the coherence length in the cuprate superconductors have other important consequences: The number of overlapping Cooper pairs within a "coherence volume" $\frac{4}{3}\pi\xi^3$ is about 20, whereas in the classical superconductors it is about $1 \times 10^6$ times larger (since $\xi$ is up to 100 times larger than in the cuprates). Furthermore, the small values of $\xi$ result in a high sensitivity of the superconducting properties of the cuprates to atomic size defects such as, for example, oxygen vacancies (Poole *et al.* 1995).

***Table 1***
Parent compounds of the five main families of the cuprate superconductors.

| | $T_c$ (K) |
|---|---|
| $La_{2-x}Sr_xCuO_4$ | 38 |
| $YBa_2Cu_3O_{7-\delta}$ | 93 |
| $Bi_2Sr_2CaCu_2O_{8+x}$ | 94 |
| $Tl_2Ba_2Ca_2Cu_3O_{10+x}$ | 125 |
| $HgBa_2Ca_2Cu_3O_{8+\delta}$ | 133 |

## *1. Normal-state Transport Properties*

The undoped cuprate perovskites are antiferromagnetic electric insulators, the antiferromagnetism resulting from the arrangement of localized spins on the Cu atoms of the $CuO_2$ planes. Superconductivity only appears after doping, and there exists an optimum doping concentration for each cuprate, where a maximum value of $T_c$ is obtained. Most high-temperature superconductors require hole doping. However, a few electron-doped oxide superconductors have also been found. In many cases doping is accomplished by the variation of the oxygen stoichiometry. Hence, during the preparation of the high-temperature superconductors the oxygen concentration must be carefully controlled (Levin *et al.* 1991, Pickett 1989).

The normal-state *electric resistivity* of the optimally doped high-temperature superconductors is several orders of magnitude larger than in a typical metal. Furthermore, it is highly anisotropic. The electric conduction occurs mainly within the $CuO_2$ planes (oriented parallel to the crystallographic *ab* planes), whereas in the perpendicular direction (along the

crystallographic $c$ axis) it is strongly reduced. The corresponding resistivity values are referred to as $\rho_{ab}$ and $\rho_c$, respectively. Near room temperature for a typical cuprate such as $YBa_2Cu_3O_{7-\delta}$ we have the values $\rho_{ab} = 200$–$500\,\mu\Omega$cm, compared to $\rho = 2$–$5\,\mu\Omega$cm for a typical metal. The ratio $\rho_c/\rho_{ab}$ of the anisotropy near room temperature ranges from 30–60 for $YBa_2Cu_3O_{7-\delta}$ up to $1 \times 10^5$ for $Bi_2Sr_2CaCu_2O_8$. The fact, that near room temperature $\rho_{ab}$ is about 100 times larger than the resistivity in a typical metal, is partly due to the lower charge carrier concentration and the pronounced anisotropy in the cuprate.

Above the critical temperature $T_c$ near optimum doping the normal-state resistivity of many cuprate superconductors increases linearly with temperature. A prominent exception is the electron-doped cuprate $Nd_{2-x}Ce_xCuO_y$ showing $\rho_{ab} \sim T^2$ near optimum doping. This normal-state resistive behavior can be qualitatively explained in terms of the nature of the scattering processes and the electronic density of states (DOS). It is now well established that in the cuprates the electron scattering processes are dominated by the electron–electron interaction, in contrast to electron–phonon scattering prevailing in metals. An important piece of evidence for this scattering behavior comes from the pronounced increase of the electron mean free path with decreasing temperature below $T_c$ as soon as the quasi-particles (as scattering partners) are frozen out because of the opening of the energy gap. With decreasing temperature this also leads to a sharp upwards turn of the thermal conductivity $\kappa(T)$ at $T_c$. The thermal conductivity then passes through a maximum near $T_c/2$. If the electron–phonon interaction would dominate, such an abrupt change of the temperature dependence of the electron mean free path at $T_c$ would not be expected.

The $\rho_{ab} \sim T^2$ behavior observed near optimum doping in $Nd_{2-x}Ce_xCuO_y$ is well consistent with the electron–electron interaction as the dominant scattering mechanism. On the other hand, the linear temperature dependence $\rho_{ab} \sim T$ found usually in the optimally hole-doped cuprates can be qualitatively explained by a sharp peak (Van Hove singularity) in the electronic DOS near the Fermi energy $E_F$. The additional phase space for scattering within this peak region then leads to the proportionality for the scattering rate $\tau^{-1} \sim k_B T$ (marginal Fermi liquid), instead of the usual Fermi liquid behavior $\tau^{-1} \sim (k_B T)^2$. Here, $k_B$ is Boltzmann's constant (Newns *et al.* 1993).

The normal-state *thermopower* (Seebeck coefficient) represents a transport property depending highly sensitively on the electronic structure and the doping level of the cuprates. There exists an interesting correlation between the thermopower and the critical temperature $T_c$. Depending on the doping level, the thermopower at room temperature of different $p$ doped systems follows a universal curve traversing zero at optimum doping (corresponding to the maximum value of $T_c$). The typical temperature

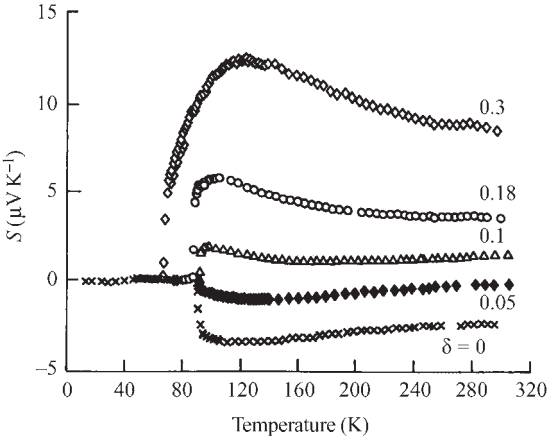

***Figure 1***
Thermopower $S$ of the cuprate $YBa_2Cu_3O_{7-\delta}$ versus temperature for different values $\delta$ of the oxygen depletion (after Cooper *et al.* 1991).

dependence of the thermopower shows an increase of its absolute value above $T_c$, turning into a flat curve with falling tendency at higher temperatures. This behavior is strongly different from the proportionality to $T$ expected in the limit of a wide ($\gg k_B T$) conduction band. A typical series of curves is shown in Fig. 1 for $YBa_2Cu_3O_{7-\delta}$ at different levels $\delta$ of oxygen depletion (Cooper *et al.* 1991).

This dependence of the thermopower on the temperature and the doping level can be understood from standard transport theory in combination with the sharp peak in the electronic DOS near the Fermi level. For the (positive) holes the thermopower is

$$S = \frac{\dfrac{k_B}{|e|} \displaystyle\int \sigma_E \frac{\partial f}{\partial E} \frac{E - E_F}{k_B T}\, dE}{\displaystyle\int \sigma_E \frac{\partial f}{\partial E}\, dE} \qquad (1)$$

with the electric conductivity given by

$$\sigma = -\int \sigma_E \frac{\partial f}{\partial E}\, dE \qquad (2)$$

(Kubo–Greenwood formula). Here $f$ is the Fermi function, and $\sigma_E$ contains the density of states and the scattering processes. We emphasize that, because of the sharp peak in the electronic DOS near $E_F$, the derivative $\partial f/\partial E$ changes only little in the relevant energy interval. From Eqn. (1) we can predict the following qualitative behavior.

If $E_F$ is smaller (larger) than the energy of the DOS peak, the contribution with $E - E_F > 0$ ($< 0$) dominates and the thermopower will be positive (negative). Hence, the sign reversal of the thermopower is

expected, when the Fermi energy coincides with the energy of the DOS peak. Alternatively, according to the "Van Hove scenario" of high-temperature superconductivity this location of the Fermi level corresponds exactly to the optimum doping level yielding the maximum value of $T_c$. The experiments performed with different $p$ doped cuprate systems at varying doping levels mentioned above well confirmed these ideas (Newns *et al.* 1993).

In the orthorhombic form of the cuprate $YBa_2Cu_3O_{7-\delta}$ one of the copper oxide planes per elementary cell contains CuO chains along the $b$ axis, but not along the $a$ axis. This introduces some anisotropy of the transport properties even within the $ab$ planes, in addition to the large anisotropy between the $ab$ plane and the $c$ direction.

The normal state *Hall effect* represents a complicated subject. However, it is this effect that led to the concepts of "hole-doped" and "electron-doped" cuprate superconductors. The Hall coefficient $R_H = 1/nq$ yields information on the nature of the charge carriers involved in the electronic transport. Here $n$ and $q$ are the concentration and elementary charge of the charge carriers, respectively. For hole-doped conductors $R_H$ is positive, whereas for electron-doped materials it is negative. For the magnetic field orientation in $c$ direction in most of the high-temperature superconductors $R_H$ is positive, indicating hole doping. Compounds derived from $Nd_2CuO_4$ by substitutional alloying ($Nd_{2-x}Ce_xCuO_y$) are the major exception and show electron doping. In the latter case of $Nd_{2-x}Ce_xCuO_y$ an additional complication arises from the fact that a two-band model appears to be necessary, with an electron-like and a hole-like section, for describing the electronic properties.

An unexpected result of the Hall effect measurements is the observed strong temperature dependence of the Hall coefficient, especially near optimum doping. Such a temperature dependence does not arise in a canonical Fermi liquid. In $YBa_2Cu_3O_7$, the most intensively studied cuprate superconductor, for the inverse Hall coefficient the relation $R_H^{-1} = \alpha + \beta T$ has been found, where $\alpha$ and $\beta$ are constants. An interesting quantity is the Hall angle, $\theta_H$, the angle between the electric current density and the total electric field, which is given by $\tan\theta_H = R_H B/\rho$. From electronic transport theory, one finds that $\tan\theta_H$ is equal to $\langle \omega_c \tau \rangle$, a weighted average for the dominant conducting particles of the product of their cyclotron frequency $\omega_c = qB/m^*$ for the electron orbits in the magnetic field and their scattering time $\tau$ ($m^*$ = effective mass).

Hence, $\cot\theta_H$ is expected to be proportional to the scattering rate $\tau^{-1}$. In $YBa_2Cu_3O_{7-\delta}$ across the whole of the metallic doping range the relation $\cot\theta_H = \alpha + \beta T^2$ is valid in good approximation, again, $\alpha$ and $\beta$ being constants. We conclude that the scattering rate also shows this $\alpha + \beta T^2$ temperature dependence. Noting $R_H^{-1} \sim n$ and $\rho \sim (n\tau)^{-1}$, we see that the linear temperature dependence of $R_H^{-1}$ and the $(\alpha + \beta T^2)$ behavior of the scattering rate appear consistent with the linear temperature dependence of the resistance observed in many cuprates discussed above. We emphasize that we must restrict our discussion to rough and qualitative remarks only, leaving out many details of the electronic structure of these materials.

## 2. *Granular Structure*

Except for the highly specialized procedures for material fabrication developed for the growth of axis-oriented epitaxial films and single crystals, the high-temperature superconductors are usually prepared as ceramics with a granular structure. Within the grain boundary regions superconductivity is strongly weakened or even totally absent. Hence, the grain boundaries in the cuprate superconductors have to date presented a challenging technological problem. It still is an important goal of the present technological developments to minimize the residual electric resistance due to the grain boundaries as much as possible. Recently, special doping processes for the grain boundaries in order to improve the electric conductivity in these regions have been discussed. The important quantity to deal with is the critical current density at which a specific nonzero electric field is generated in the superconductor, resulting in power dissipation. The current flow pattern in a multigranular superconductor has been treated in analogy to the structure of a brick wall (*brick wall model*). In addition to the granular structure, the poor ductility of the cuprate superconductors continues to represent a severe obstacle, in particular for the technological power applications.

For the applications of high-temperature superconductors in microelectronics the critical current density in thin films has received a large amount of attention. Here $c$ axis oriented epitaxial films of $YBa_2Cu_3O_{7-\delta}$ clearly represent the work horse. At 77 K and in zero magnetic field, critical current densities of $1 \times 10^6$–$1 \times 10^7$ $Acm^{-2}$ have been achieved, a highly impressive result of the associated materials science.

Whereas the grain boundaries in the cuprate superconductors are clearly detrimental to many technical applications, in one specific case they turned out to be extremely useful and they represent a well controllable and stable Josephson junction. The grain boundary Josephson junctions are fabricated by growing an epitaxial superconducting cuprate film on a bicrystal acting as the substrate. The grain boundary separating the two single-crystalline pieces of the substrate is then transferred to the epitaxial film deposited subsequently on the bicrystalline substrate. In this way, during recent years Josephson devices and superconducting quantum interferometers (SQUIDs)

operating up to 77 K have been fabricated (see *Josephson Junctions: High-$T_c$*).

### 3. Current-induced Vortex Motion

In a magnetic field in the range between the lower and upper critical field, $B_{c1}$ and $B_{c2}$, respectively, below the critical temperature $T_c$ the superconducting mixed state is established. In the mixed state the superconductor is penetrated by a more or less perfectly ordered 2D lattice of flux lines, each flux line carrying a single magnetic flux quantum $\varphi_0$. The regularity of this lattice depends on the spatial homogeneity of the superconductor. The following will be restricted to the case where the magnetic field and, hence, the flux lines, are oriented along the crystallographic $c$ axis. In this case the flux lines degenerate into stacks of pancake vortices (or point vortices) attached to the $CuO_2$ planes constituting the superconducting structural elements of the cuprates. Under the influence of an external force the flux lines or pancake vortices can be set into motion. This vortex motion represents one of the most important processes in superconductors, since it results in an electric field of quantum mechanical origin and thereby destroys superconductivity (Huebener 2001).

An electric transport current of density $\underline{j}$ generates the *Lorentz force* $\underline{j} \times \underline{\varphi}_0$ per unit length of flux line. The dynamic state of the vortex lattice is determined by the force equation:

$$\underline{j} \times \underline{\varphi}_0 - \eta \underline{v}_\varphi - \alpha(\underline{v}_\varphi \times n) + \underline{f}_p = 0 \qquad (3)$$

The Lorentz force is balanced by the damping force $\eta \underline{v}_\varphi$, the Hall force $\alpha(\underline{v}_\varphi \times \underline{n})$, and the pinning force $\underline{f}_p$. $\underline{v}_\varphi$ is the vortex velocity, $\eta$ and $\alpha$ are damping coefficients, $\underline{n}$ is a unit vector in magnetic field direction. Vortex motion always results in an electric field $\underline{E}$ according to the equation:

$$\underline{E} = -\underline{v}_\varphi \times \underline{B} \qquad (4)$$

Equation (4) is derived from the phase change of the macroscopic wave function describing the Cooper pair condensate, effected by the vortex motion. (It is intimately connected with the Josephson voltage frequency relation.) In the absence of the Hall force and the pinning force we see from Eqns. (3) and (4) that $\underline{v}_\varphi$ is perpendicular to $\underline{j}$ and, therefore, $\underline{E}$ is parallel to $\underline{j}$. As a result power dissipation $\underline{E} \times \underline{j}$ per unit volume occurs, and superconductivity is destroyed. It is this mechanism of current induced vortex motion and the appearance of flux-flow resistance which represent the main challenge to maintaining superconductivity. Because of the three characteristic novel features of the high-temperature superconductors (high critical temperature, small coherence length, and large anisotropy) vortex motion and the appearance of flux-flow resistance is highly facilitated in the cuprates and turns out to be an even more challenging issue than in the classical superconductors.

It is the pinning force in Eqn. (3) which can result in a strong reduction of vortex motion and, hence, contributes to sustaining superconductivity at finite electric transport current. Flux pinning is accomplished by material inhomogeneities (pinning centers) causing a local depression of the Gibbs free energy density of the vortex lattice. Because of the short coherence length in the cuprates, atomic size defects, such as oxygen vacancies in the $CuO_2$ planes or defects produced by substitutional alloying, already act as important pinning centers. The pinning force eventually acting on the vortex lattice results from the combination of the elementary pinning interaction between a vortex and the pinning center with the elastic properties of the vortex lattice. The elastic properties come in, since the vortex lattice must be deformed in order to accommodate the spatial configuration of the pinning sites. Because of this, flux pinning turns out to be a highly complex phenomenon. However, because of its extreme importance for the technical applications of the cuprate superconductors, the subject of flux pinning has recently attracted a large amount of research and development.

If the damping force $\eta \underline{v}_\varphi$ and the pinning force would be absent in Eqn. (3), the vortices would move parallel to the current density $\underline{j}$, the electric field $\underline{E}$ would be perpendicular to $\underline{j}$ (pure Hall electric field), and the power dissipation $\underline{j} \times \underline{E}$ would vanish. However, for this to happen the quasi-particle scattering time $\tau$ must approach the limit $\tau \to \infty$.

According to the Bardeen–Stephen model, valid for the classical superconductors and serving, at best, as a qualitative orientation for the high-temperature superconductors, the flux-flow resistivity $\rho_f$ is given by

$$\rho_f = \rho_n \frac{B}{B_{c2}}$$

where $\rho_n$ is the normal-state resistivity. In this model the vortex core is taken as a normal-state cylinder of radius $\xi$. The ratio $B/B_{c2}$ then represents the volume fraction of this normal phase. For the damping coefficient $\eta$ one finds $\eta = \varphi_0 B_{c2}/\rho_n$. In the current-induced flux-flow state the Hall angle $\theta_H$ is given by $\tan \theta_H = \omega_c \cdot \tau$, similar to the situation in the normal state. In the superconducting mixed state of the cuprates the Hall angle is generally small (typically $\tan \theta_H \approx 1 \times 10^{-2}$), and dissipative vortex motion perpendicular to the electric current direction dominates.

In contrast to the classical superconductors, in the cuprate superconductors the description of the vortex core as a normal-state cylinder of radius $\xi$ is only a rough approximation. Here also the symmetry of the pair wave function must be discussed. It is now well established that in the p-doped cuprates the pair wave

function shows d-wave symmetry, with four node lines where the gap energy reaches zero. This has important consequences for the quasi-particle scattering in the mixed state. However, at present the experimental and theoretical clarification of this point is still in progress. Another new aspect of quasi-particle scattering originates from the extremely short coherence length and the corresponding small vortex-core diameter in the cuprates. As a result, quantum effects of the electronic structure of the vortex cores (quantum confinement) can become important. The description of the vortex core as a normal-state cylinder of radius $\xi$ is then highly inadequate. At least in the limit $T \ll T_c$ this can lead to a strong reduction of the phase space available for quasi-particle scattering. Again, at present this issue is still under experimental and theoretical investigation (Huebener 2001).

The peculiar features of the high-temperature superconductors (high critical temperature, short coherence length, and anisotropy leading to the pancake-vortex structure) have important consequences for the dynamic properties of the vortex lattice. There exists an irreversibility line in the phase space of magnetic field and temperature, above which the magnetization is perfectly reversible with no detectable flux pinning. Alternatively, below this line the magnetization becomes hysteretic, and the equilibrium vortex distribution cannot be established any more because of flux pinning. From these observations in the 1990s the new concept of "vortex matter" evolved, with a liquid, glassy, and crystalline state, displaying a complex phase diagram. These novel features strongly influence the transport processes associated with vortex motion.

An immediate result of the different phases of vortex matter appearing in the mixed state is the broadening of the resistive transition in a magnetic field. Whereas in the classical superconductors the drop in the electric resistivity due to the onset of superconductivity is usually shifted to lower temperatures with increasing magnetic field, in high-temperature superconductors the resistively measured onset temperature of superconductivity is only weakly magnetic field dependent, but the transition curve is broadened instead, and the broadening increases strongly with increasing magnetic field. A typical case is shown in Fig. 2a for an epitaxial $c$ axis oriented $YBa_2Cu_3O_{7-\delta}$ film for magnetic fields ranging from 0 to 12 $T$ and oriented in $c$ direction. An exception from this broadening of the resistive transition in a magnetic field has been observed for the electron-doped cuprate superconductor $Nd_{2-x}Ce_xCuO_{4\pm y}$ in the whole doping regime from slightly underdoped to slightly overdoped. Here the whole resistive transition curve is shifted to lower temperatures with increasing magnetic field, more like in classical superconductors.

The motion of the vortex lattice due to the Lorentz force of an electric transport current is accompanied by the transport of entropy carried by the vortex

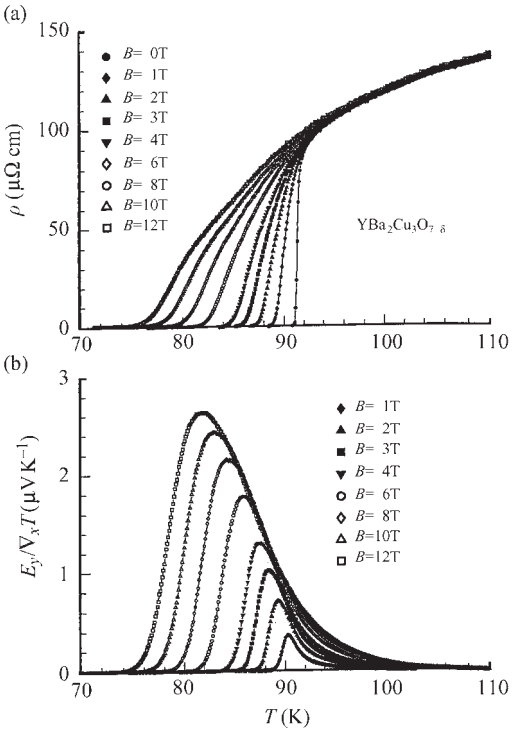

***Figure 2***
(a) Flux-flow resistivity of the cuprate superconductor $YBa_2Cu_3O_{7-\delta}$ versus temperature for different magnetic fields oriented in c direction. (b) Normalized Nernst electric field $E_y/\nabla_x T$ versus temperature for the same sample and magnetic fields as in (a).

lattice. This entropy transport causes a temperature gradient perpendicular to the directions of the electric current and magnetic field. It is referred to as the Ettinghausen effect and has been observed in a number of high-temperature superconductors. If the electric current density $j_x$ is assumed in $x$ direction and the magnetic flux density $B_z$ in $z$ direction, the heat current density $U_y$ in $y$ direction associated with the entropy transport is

$$U_y = \varepsilon B_z \kappa j_x \tag{5}$$

Here $\varepsilon$ is the Ettinghausen coefficient and $\kappa$ the heat conductivity. The Ettinghausen effect represents one of the major observations supporting the concept of vortex motion as the mechanism generating the electric resistance in the superconducting mixed state.

The experiments on the flux-flow Hall effect in the cuprate superconductors indicated an unexpected reversal of the sign of the Hall voltage at temperatures below the superconducting transition. This effect has been observed in different materials and appears to

represent an intrinsic property. A satisfactory theoretical understanding of this effect has not yet been reached, and the theoretical discussions are still controversial.

## 4. Vortex Motion in a Temperature Gradient

In a temperature gradient applied to a superconductor in the mixed state the thermal force $-S_\varphi \mathrm{grad} T$ acts on the vortex structure, driving the magnetic flux quanta from the hot to the cold side of the specimen. Here $S_\varphi$ is the transport entropy per unit length of flux line. The thermal force is the driving force in all thermal diffusion phenomena, and the transport entropy represents a characteristic property of the specific type of particle under consideration. (The heat current density $U$ carried by a flux-line lattice moving with velocity $\underline{v}_\varphi$ is $U = nTS_\varphi \underline{v}_\varphi$, where $n = B/\varphi_0$ is the density of flux lines.) For treating the dynamic state of the vortex lattice driven by a temperature gradient, in Eqn. (3) the Lorentz force $\underline{j} \times \underline{\varphi}_0$ must be replaced by the thermal force $-S_\varphi \mathrm{grad} T$. If we neglect the Hall effect and flux pinning, take the temperature gradient in $x$ direction and the magnetic field in $z$ direction, we see from Eqn. (4) that the resulting flux-flow electric field is oriented in $y$ direction. This electric field $E_y$ is given by

$$E_y = \nu B_z \frac{\partial T}{\partial x} \tag{6}$$

and the effect is referred to as the Nernst effect. $\nu$ is the Nernst coefficient. The Ettinghausen coefficient $\varepsilon$ and the Nernst coefficient $\nu$ are coupled through the Bridgman relation of irreversible thermodynamics

$$T\nu = \varepsilon\kappa \tag{7}$$

The Nernst effect has been investigated in the mixed state of a number of high-temperature superconductors. In Fig. 2(b) we show typical results obtained for the same epitaxial $YBa_2Cu_3O_{7-\delta}$ film and the same magnetic fields as in Fig. 2(a). In the normal state sufficiently far above $T_c$ (of about 91 K in this case) the Nernst electric field $E_y$ is seen to be negligible. With decreasing temperature $E_y$ increases and passes through a maximum. As one expects because of the flux-flow process, $E_y$ increases with increasing flux density $B$. On the low-temperature end of the curves the Nernst electric field $E_y$ and the resistivity vanish because of flux pinning. From Fig. 2(b) we see also, that the flux-flow Nernst effect clearly extends to temperatures well above the critical temperature $T_c$ measured at zero magnetic field.

This is due to fluctuation effects, which become stronger with increasing magnetic field. These fluctuation effects can be measured with high accuracy, since the Nernst effect is negligible in the normal state, and a special subtraction procedure is not necessary. Because of the small coherence length, high critical temperature, and large anisotropy in the cuprate, superconductor fluctuations play a much more prominent role than in the classical superconductors. Hence, this subject has received much experimental and theoretical attention.

In thermal diffusion experiments the high sensitivity of the properties of a superconductor to the temperature represents an important point, and the application of a large temperature gradient to the sample often causes complications. However, an interesting exception is a geometry, where the sample dimension in the direction of the temperature gradient is kept small, e.g., about 100 μm. In this case a large temperature gradient can be achieved even for a small temperature difference between the hot and the cold side of the sample.

In our discussion of the thermal diffusion of magnetic flux quanta we have neglected the Hall force $\alpha(\underline{v}_\varphi \times \underline{n})$. However, if we include the latter force, a finite Hall angle of the resulting vortex velocity $\underline{v}_\varphi$ appears, generating a component $v_{\varphi y}$ perpendicular to the direction of the temperature gradient. This velocity component $v_{\varphi y}$ produces a longitudinal electric field component $E_x$, i.e., a contribution to the *Seebeck effect*. Furthermore, in the superconducting mixed state the responses of the quasi-particles to the applied temperature gradient also must be discussed, in addition to that of the magnetic flux quanta. However, this subject is beyond the scope of this article, and we refer to the treatments by Huebener (1995, 2001).

## 5. Concluding Remarks

Since their discovery in 1986 the cuprate superconductors have attracted a large amount of research and engineering developments worldwide. One of the main reasons for this strong interest has been the fact that in many cuprates the critical temperature of superconductivity is well above the boiling point of liquid nitrogen. The layered crystallographic structure of these materials with the $CuO_2$ planes represents the most prominent characteristic feature dominating the electronic properties. The undoped cuprate perovskites are antiferromagnetic electric insulators and become electric conductors and superconductors only by doping. Most high-temperature superconductors are p doped, but n doping also leads to superconductivity in some cases. While superconductivity is based on Cooper pairs as in the classical superconductors, the pairing mechanism still remains unclear.

It is now well established that in the hole-doped cuprates the pair wave function shows d-wave symmetry, whereas the symmetry is not yet as clearly known in the electron-doped cuprates. In many ways the normal-state electronic transport properties do

not show the canonical Fermi liquid behavior well known for metallic conductors. However, these properties of the normal state continue to provide clues regarding the superconducting pairing mechanism. The critical temperature value of many high-temperature superconductors above the boiling point of liquid nitrogen clearly represents an important asset for practical applications. However, the granular structure and poor ductility still provides a challenge for a technology based on these materials.

## Intermediate Valence Systems

The group of rare-earth elements comprise the series from lanthanum (atomic number 57) to lutetium (atomic number 71), where the electronic configuration (EC) gradually changes from [Xe]$4f^0 5d^1 6s^2$ to [Xe]$4f^{14} 5d^1 6s^2$, respectively (see *Localized 4f and 5f Moments: Magnetism*). Light elements of this series like cerium, elements with a nearly half-filled 4*f* shell like samarium and europium, or with an almost filled 4*f* shell like thulium and ytterbium may, however, deviate from such a well-defined EC with integer valency. As a result, the ions exhibit intermediate valence (IV), representing a homogeneous quantum mechanical mixture of two consecutive integer valence configurations. Not only are rare-earth systems known to show such valence instabilities, but about 40 elements (3*d*, 4*d*, 5*d*, 5*f*) and their compounds can emerge in noninteger valency.

A necessary condition for nonintegral valence to occur is that two bounding states of the rare earth, i.e., $4f^n(5d6s)^m$ and $4f^{n-1}(5d6s)^{m+1}$, are nearly degenerate. The system may then lower its energy by adopting a mixture of both EC and an additional degree of freedom is acquired. On each 4*f* site charge fluctuations appear between these configurations on a typical time scale $\tau_{cf}$. Experiments probing such samples on scales much shorter than $\tau_{cf}$ (like XPS) allow it to observe both configurations, while experiments with a much longer time scale (like Mössbauer effect) reveal just the intermediate configuration. In these systems, the 4*f* level is pinned to the Fermi energy $E_F$, provoking *f* electrons to escape into the conduction band. Hence, the lifetime of the state becomes limited and the former localized level acquires a narrow width $\Delta$ with some dispersion and is, therefore, occupied by a nonintegral number of electrons. The inverse of $\Delta$ is then given by $\tau_{cf} \sim \Delta/\hbar$.

IV is derived from a quantum mechanical hybridization of two consecutive states $a_n|f^n\rangle$ and $a_{n-1}|f^{n-1}\rangle$ (Lawrence *et al.* 1981), which can no longer be considered as a simple superposition. Rather, fluctuations between both states modify physical properties in a fundamental manner. Features like quenched magnetic moments, an enhanced Pauli susceptibility, and a large electronic contribution to the specific heat may become obvious, which otherwise cannot be found in both integer valent states involved.

Such homogeneously mixed systems are distinguished from the classical "mixed valence" phases like $Fe_3O_4$ or $Sm_3S_4$, where at crystallographic inequivalent lattice sites the cations exhibit different oxidation states with distinct electronic configurations.

A lattice-related aspect of IV materials is a soft bulk modulus, indicating the large compressibility of such systems (Wachter 1994). Since the ionic radius of IV materials cannot be considered as a "hard sphere" as for integral valent materials, pressure will change the degree of IV and thus change the *f* occupation, which in turn is related to the ionic radius. If a pressure induced transition towards an IV state is of first order, the bulk modulus $B_0$ becomes infinitely small, and as a consequence, the compressibility $\kappa \equiv 1/B_0$ diverges.

IV systems are also known for a negative elastic constant $c_{12}$ which ensures (in the case of cubic crystals) that even under applied uniaxial pressure the crystal structure is preserved as it was firstly observed in TmSe (Batlogg *et al.* 1979). The negative value of $c_{12}$ also causes a negative Poison ratio $c_{12}/(c_{11}+c_{12})$. Measurements of the phonon dispersion relation in IV materials show a common softening of the acoustic and the optical phonon branches when compared to stable isostructural nonmagnetic systems. Moreover, well-defined crystal field (CF) splitting of the 4*f* state has not been found in IV systems yet studied.

### 1. Some Theoretical Aspects

The physics of intermediate valent materials is usually accounted for in terms of the periodic (Anderson model 1961, see also *Electron Systems: Strong Correlations*).

A schematic representation of the DOS for the impurity version of the Anderson model is drawn in Fig. 1(a). For large Coulomb repulsion *U* the *f* spectral weight is split into two parts located at $E_{4f}$ (binding energy of the localized 4*f* electrons) and $E_{4f}+U$, having a width $\Delta \sim V^2/W$ ($V$ is the hybridization strength and $W$ is the conduction electron bandwidth). Due to the removal of spin degrees of freedom, a narrow many body resonance occurs in the vicinity of the Fermi energy $E_F$ as a consequence of the crossing of the *d*- and *f* bands at the Fermi energy (Martin 1982). IV follows immediately from the Anderson Hamiltonian for $E_{4f} \to E_F$. The Kondo effect, on the contrary, is described by this model, if $E_{4f}$ and $E_{4f}+U$ are well separated from the Fermi level (see *Kondo Systems and Heavy Fermions: Transport Phenomena*).

In the case of a periodic arrangement of the magnetic ions, a two peak structure with a gap develops as a result of the *f*-*d* hybridization (Fig. 1(b)). This hybridization gap is complete if $V$ is $\vec{k}$-independent. However, if $V$ vanishes at certain points at the Brillouin zone, the gapping may become incomplete.

If the *f* and *d* electron count is even, and if there are no other electrons in the conduction band, the application of Luttinger's theorem causes $E_F$ to be

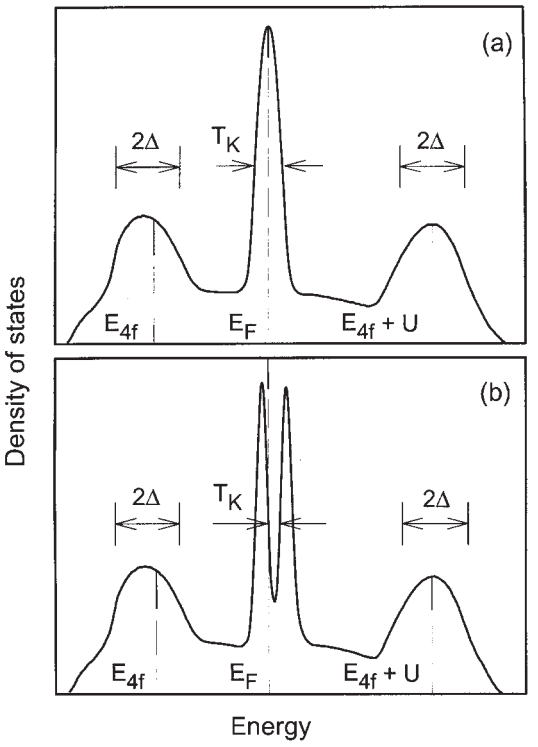

***Figure 1***
Schematic spectrum of the density of states of (a) the impurity Kondo case and (b) the Kondo lattice. The scale $T_K$ is expanded for clarity.

centered in this gap and the material will be an IV isolator for $T \to 0$. In fact, many examples of IV semiconductors are known, possessing an even electron count such as $YbB_{12}$ with 52 valence electrons per formula unit and an energy gap $E_g \sim 5.2$ meV (Moser *et al.* 1985). Temperatures of the order of 100 K are then sufficient to smear out the gap and thermally activate a huge number of carriers. Such thermal excitations destroy the intersite quantum coherence, responsible for the hybridization gap.

For an odd electron count, the Fermi energy should be situated in one of the density peaks above or below the gap, hence the material will demean as an IV and heavy fermion metal for $T \to 0$.

## 2. *Experimental Evidence of Intermediate Valence*

In general, the lattice parameters of an isotypic series of rare-earth intermetallics smoothly decrease from lanthanum to lutetium. This is attributed to the lanthanide contraction and ascribed to the fact that though the electron count of the 4*f* shell increases, it cannot completely screen the increase in the nuclear charge and, therefore, the outer electrons become constricted. However, compounds with cerium, samarium, europium, thulium, or ytterbium may significantly deviate from this simple dependence since their valency can be larger or smaller than three, thus cause a decrease or an increase of the unit cell volume, respectively.

### 2.1 *Samarium and Thulium Monochalcogenides*

The monochalcogenides SmS, SmSe, and SmTe crystallize in the f.c.c. structure and are characterized by a semiconducting behavior owing to an energy gap $E_g$ between the $4f^6$ and the 5*d* state of about 0.15, 0.45, and 0.65 eV, respectively (Wachter 1994). CF interaction of cubic symmetry splits the 5*d* orbital into the lower lying $t_{2g}$ band and the $e_g$ band.

The magnetic susceptibility of this series behaves like an inhomogeneous mixing of $Sm^{2+}$ and $Sm^{3+}$, but the finite values for $T \to 0$ imply that the ground state is homogeneous. The valence fluctuations render the mixture homogeneous; hence the $f^5$ spin memory is lost when the configuration fluctuates (Lawrence *et al.* 1981).

Pressure applied to such narrow bandgap systems can give rise to a semiconductor-metal instability. In fact, a first order transition was deduced for SmS at $p_c = 6.5$ kbar (Jayaraman *et al.* 1970), accompanied by a volume change of about 20%. Slightly above $p_c$, SmS turns golden as the plasma edge moves into visible and IV occurs. For SmSe and SmTe the pressure-induced valence transition is continuous and is found at significant higher values of pressure, i.e., 45 and 60 kbar, respectively (Bucher *et al.* 1971).

The approach of the ions due to applied pressure cause the Coulomb potential to increase. Thus CF splitting of the 5*d* band grows and eventually leads to an overlap with the $4f^6$ state. Accordingly, the bandgap closes and 4*f* electrons empty into the *d* states. Upon the enhanced number of conduction electrons, the lattice starts to shrink, so CF splitting strengthens further, resulting in some avalanche effect and a first order phase transition. Since the reduced lattice parameter stiffens the lattice as a whole, the trivalent state is not attained. Rather, the process stops at $v = 2.75$ (Kaindl *et al.* 1984) where the gain in electronic energy is compensated by the increase of the lattice energy. In the case of SmSe and SmTe, the gap in the density of states at $E_F$ closes before the lattice softens, and consequently only a second-order phase transition is observed.

In the case of Tm, both EC, i.e., $Tm^{2+}$ ($J = 7/2$) and $Tm^{3+}$ ($J = 6$) result in a magnetic ground state. Such systems can exhibit long-range magnetic order even in the IV state, which is in contrast to those based on cerium, samarium, europium, or ytterbium. The thulium monochalcogenides are of particular interest. Binary compounds range from metallic

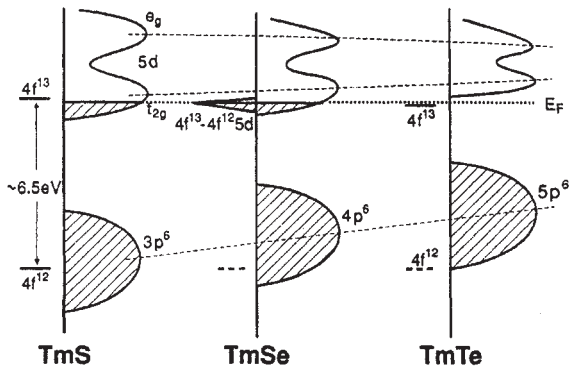

*Figure 2*
Electronic structure and density of states of the Tm monochalcogenides normalized to the Fermi energy $E_F$ (dotted line). The dashed lines through the density of state peaks serve as a guide to the eyes.

trivalent TmS over IV TmSe to semiconducting divalent TmTe.

A sketch of the electronic structure and the density of states of this series is shown in Fig. 2 (Wachter 1994).There is a cross-over from metallic (TmSe) to isolating behavior (TmTe). The latter exhibits the divalent $4f^{13}$ EC, where the localized $4f$ state is separated by an energy gap $E_g \sim 0.3$ eV from the bottom of the $5d$-$t_{2g}$ band.

When proceeding from TmTe to TmSe or TmS, the lattice constant shrinks, thus producing chemical pressure onto the Tm cation. Therefore, crystal field splitting of the $5d$ band increases. The bottom of the conduction band (mostly $5d$-$t_{2g}$ states) may then overlap with the $4f^{13}$ level and $4f$ electrons will spill into the conduction band.

Stoichiometric TmSe orders antiferromagnetically below $T_N = 2.9$ K (Bjerrum-Moller *et al.* 1977). The electrical resistivity in both the paramagnetically and the magnetically ordered state shows thermally activated behavior. According to Luttinger's theorem, TmSe should be a metal since the compound is an odd electron system in both EC, $4f^{13}$ and $4f^{12}5d$. Antiferromagnetic order below 2.9 k, however, enlarges the magnetic unit cell which contains an even number (26) of electrons. The hybridization gap can then exist with $E_F$ just in the center, and the system should behave isolating. However, at $\mu_0 H = 0.5$ T, TmSe becomes ferromagnetic, thus the folding of the Brillouin zone vanishes. Consequently, TmSe behaves metallic and the system is an IV ferromagnet (Batlogg *et al.* 1977).

As for many other IV compounds with the Fermi level within the hybridization gap, pressure applied to TmSe ($p_c \sim 30$ kbar) will close the bandgap primarily due to the growing overlap of the crystal field split $5d$ band with the $4f^{13}$state (Wachter 1994).

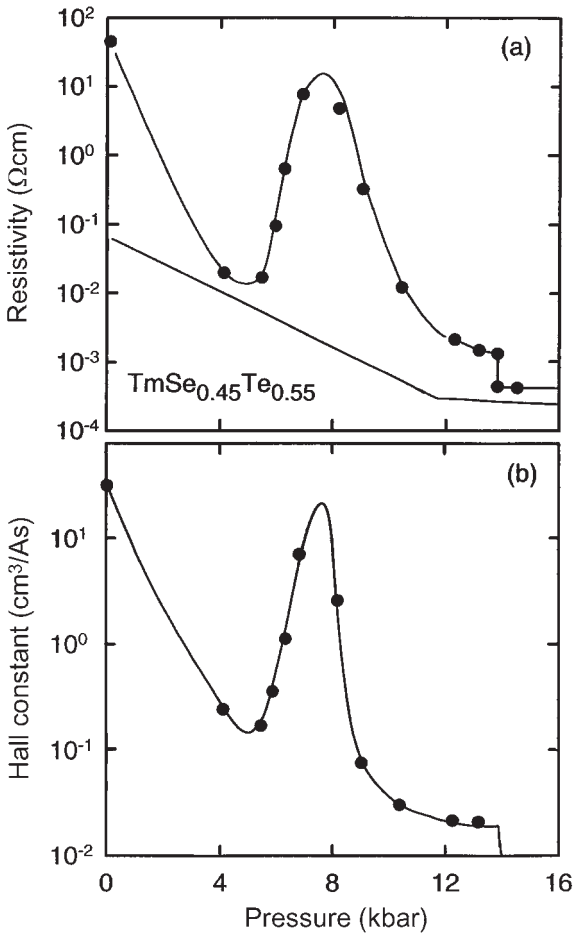

*Figure 3*
(a) Pressure dependence of the resistivity of $TmSe_{0.45}Te_{0.55}$ at 300 K (lower curve) and at 4.2 K (upper curve). At 300 K the semiconducting to metal transition is at $p_c = 11.5$ kbar and for $T = 4.2$ K at $p_c \sim 14$ kbar. (b) Pressure-dependent Hall constant $R_H$ at 4.2 K.

Besides, the pseudobinary $TmSe_{1-x}Te_x$ allows to realize a novel feature in condensed matter physics, the excitonic insulator, which is characterized by a Bose-Einstein condensation of quasi-particles into a coherent exciton phase (Neuenschwander and Wachter 1990). Figure 3 shows the pressure dependence of the electrical resistivity of $TmSe_{0.45}Te_{0.55}$ at high and low temperatures and the Hall constant. The most striking feature with respect to the resistivity at $T = 4$ K is that after the expected initial decrease of $\rho(p)$, a rapid rise in a narrow pressure range from about 5 kbar to 8 kbar occurs. Beyond this pressure, the resistivity decreases again and furthermore exhibits a first order phase transition near $p = 14$ kbar.

### *2.2 Cerium and Ytterbium Systems*

A large number of cerium compounds and alloys exhibit an EC ranging between the $4f^1$ and the $4f^0$ state, thus behaving as IV materials. The most striking feature of IV, however, occurs in f.c.c. cerium as a response to applied pressure. At a temperature-dependent critical pressure ($p_c = 7$ kbar at room temperature, Franceschi and Olcese 1969) cerium crosses over from the $\gamma$ state (lattice parameter $a = 5.15$ Å) to the $\alpha$ state ($a = 4.85$ Å). This transition is accompanied by a volume change of about 15% which does not, however, distort the cubic crystal symmetry. While the $\gamma$ state is primarily trivalent ($4f^1(5d6s)^3$), the $\alpha$ state behaves almost tetravalent ($4f^0(5d6s)^4$), with a valence $v = 3.67$ (Koskenmaki 1978).

Intermediate valence in ytterbium systems is constrained by divalent ytterbium (EC $4f^{14}$) and trivalent Yb (EC $4f^{13}$). While the former is a nonmagnetic state, the latter is magnetic with a total angular momentum $J = 7/2$. Pressure can be used to subtly tune the valence of the ytterbium ion and eventually drive it towards the trivalent magnetic ground state. For proper ytterbium compounds and alloys, intermediate valence is then completely adjustable from the $Yb^{2+}$ towards $Yb^{3+}$ state (Bauer *et al.* 1995).

In addition to pressure, temperature may also cause a dramatic alteration of the ytterbium valence. A temperature driven first order type of transition, as shown in Fig. 4, has been observed for $YbCu_4In$ (Felner and Nowik 1986). The particular transition temperature $T_v$, however, depends sensitively on details of the stoichiometry (Löffert *et al.* 1999). Qualitatively, the high-temperature state corresponds to the magnetic $Yb^{3+}$ while the low-temperature state is the nonmagnetic $Yb^{2+}$. Quantitatively, however, the valence at $T_v$ only changes by about 0.2, and the principal effect observed is the nearly complete Kondo compensation of the local moment of ytterbium. This scenario is rendered also from the change of the Kondo temperature, which is small for $T > T_v$ ($T_K^+ \sim 25$ K), but substantially larger for $T < T_v$ ($T_K^- \sim 500$ K) (Cornelius *et al.* 1997).

Concomitantly, there is a large change in the carrier density which occurs at the phase transition, from trivalent semimetallic behavior at high temperature to IV metallic behavior at low temperatures. Although the change of the volume at $T = T_v$ (about 0.5%) is reminiscent of the $\gamma-\alpha$ transition of cerium, a "Kondo volume expansion" in $YbCu_4In$ would require an extraordinary and unrealistic large Grüneisen parameter $\Omega = -\delta \ln T_K / \delta \ln V \sim 4000$ in order to match the conditions of the Kondo volume collapse of cerium.

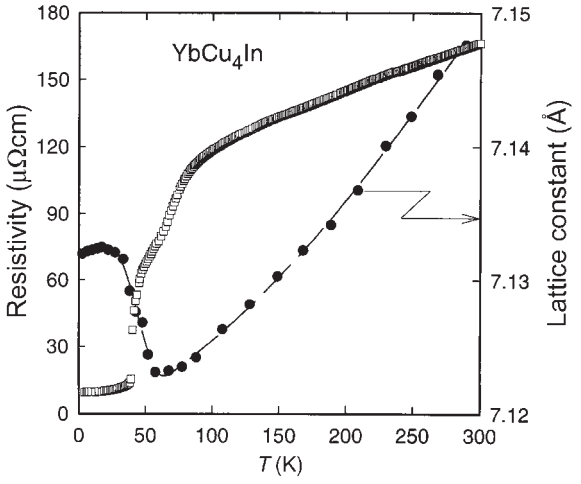

***Figure 4***
Temperature-dependent resistivity $\rho$ (left axis) and lattice constant $a$ (right axis) of $YbCu_4In$.

## *3. Concluding Remarks*

Several rare earth, actinide, and transition metal compounds are characterized by two almost degenerate consecutive $f$ or $d$ levels. Their electronic configuration results from a quantum mechanical mixture of both levels, causing the valence of such systems to adopt noninteger numbers. This hybridization distinguishes IV materials from the classical type of "mixed valent" behavior due to inequivalent lattice sites with different oxidation states.

Intermediate valence can originate in a number of outstanding low temperature features of physical properties. Among them are significantly enhanced Sommerfeld values of the specific heat and Pauli susceptibility, a temperature dependent cross-over from a magnetic to a nonmagnetic state, pressure driven semiconductor to metal transitions, or the formation of an excitonic insulating state.

## Intermetallic Compounds: Electrical Resistivity

The aim of this article is to show what information can be obtained about the properties of intermetallics from resistivity measurements. The influence of scattering of conduction electrons by impurities, lattice vibrations (phonons), and magnetic moments will be discussed in detail. It will also be shown how changes in the crystallographic structure and in the spin arrangements (magnetic phase transitions) are manifested in the temperature variation of resistivity.

The temperature variation of the electrical resistivity ($\rho(T)$) of different binary yttrium–transition metal compounds is shown in Fig. 1. All these compounds crystallize in the cubic Laves phase structure where the rare-earth (RE) atoms form a diamond lattice.

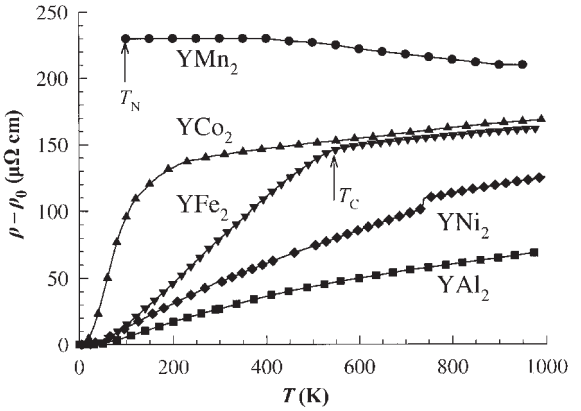

***Figure 1***
Temperature dependence of the electrical resistivity of yttrium-based cubic Laves phase compounds with 3d transition metals (manganese, iron, cobalt, and nickel) and aluminum.

The remaining space inside the cell is occupied by regular tetrahedrons consisting of the transition metal atoms or aluminum (see below). Figure 1 shows the remarkable variety of behavior within this family of Laves phases when the measurements are performed across an extended temperature range up to 1000 K. With the exception of $YMn_2$, the residual resistivity ($\rho_0$) has been subtracted from the $\rho$ vs. $T$ curves.

The reasons for choosing mainly Laves phases to demonstrate the temperature dependence of $\rho$ are as follows:

(i) These compounds have a cubic structure, and therefore the anisotropy of the resistivity in the different crystallographic directions can be neglected.

(ii) The physical properties of these yttrium-based intermetallics are known in great detail, and hence a deeper understanding of the resistivity behavior can be expected. As a consequence, general conclusions can be drawn from a discussion of $\rho(T)$ data.

(iii) More than 730 binary and ternary compounds have been shown to have a cubic Laves phase structure (e.g., Villars 1997), and all have been partially investigated with respect to their physical properties.

Referring to Fig. 1, we note the following.

*$YAl_2$.* This is a Pauli paramagnetic compound with a weakly temperature-dependent susceptibility. At room temperature $\chi = 0.106 \times 10^{-3}$ emu mol$^{-1}$. Band-structure calculations reveal a moderately enhanced electronic density of states (DOS) at the Fermi level owing to Y($4d$) states. Investigations of the lattice dynamics have revealed a phonon DOS (PDOS) ranging up to about 30 meV; the center of gravity of the PDOS is approximately 15 meV. $YAl_2$ is an ideal prototype for demonstrating the electron–phonon scattering mechanism, which in the simplest approximation can be described by the Bloch–Grüneisen relationship.

*$YNi_2$*. The resistivity curve of this nonmagnetic compound has been selected in order to demonstrate the influence of a temperature-induced structural transition on the electrical resistivity (Gratz *et al.* 1996). A detailed discussion of the influence of phase transitions on $\rho$ vs. $T$ by means of the pseudobinary $LaAg_xIn_{1-x}$ series is given below.

*$YCo_2$*. From a magnetic point of view this is a paramagnetic compound. However, the susceptibility is strongly enhanced and has a maximum in the $\chi$ vs. $T$ plot around room temperature. It has been shown that $YCo_2$ belongs to the group of cobalt-based compounds whose properties are strongly influenced by spin fluctuations (see *Spin Fluctuations*). A comparison of the $\rho$ vs. $T$ plot for $YAl_2$ and $YCo_2$ clearly shows the strong influence of spin-fluctuation scattering processes on the resistivity, giving rise to the pronounced negative curvature of $\rho(T)$ around room temperature in $YCo_2$.

*$YFe_2$*. This compound represents a ferromagnetic Laves phase with a Curie temperature of 550 K. Studies of the magnetic properties reveal the localized character of the iron moments which are coupled via a direct 3*d*–3*d* interaction. The breakdown of the long-range magnetic order at $T_C$ can clearly be seen in the kink of the $\rho(T)$ curve at 550 K.

*$YMn_2$*. Among all these compounds, $YMn_2$ exhibits the most complex magnetic properties. There is an antiferromagnetic transition of a first-order type around 110 K (Néel temperature). This magnetic transition is accompanied by a very large volume expansion (about 5%) and a distortion of the cubic unit cell. The enormous volume expansion prevents resistivity experiments in the magnetically ordered state since the sample falls apart. The arrangement of the manganese magnetic moments appears to be sinusoidally modulated along the [111] direction with a very long periodicity. The manganese moments show pronounced temperature dependence. They change from approximately 2.2 $\mu_B$ f.u.$^{-1}$ at 4 K, decreasing to 1.7 $\mu_B$ f.u.$^{-1}$ at the Néel temperature, and then increasing to 2 $\mu_B$ f.u.$^{-1}$ at room temperature. The complex magnetic behavior of $YMn_2$ is still a matter of discussion. The $\rho(T)$ curve of $YMn_2$ has been included in order to show that even in a compound with such a relatively simple crystal structure (cubic Laves phase) a temperature variation of the resistivity can be observed for which it is difficult to give a qualitative explanation. This $\rho(T)$ curve is characterized by values of more than 200 $\mu\Omega$ cm, and a decrease in the whole temperature range above its Néel temperature up to 1000 K. The Boltzmann equation and scattering mechanism conditions are provided in *Boltzmann Equation and Scattering Mechanisms*, detailing the circumstances under which the Boltzmann formalism is no longer applicable, and $YMn_2$ is a good example of this. A rigorous quantum mechanical treatment would be necessary to give at least a qualitative explanation for this $\rho(T)$ dependence.

## 1. Analysis of Resistivity Data

A quantitative analysis of resistivity data is in practice only possible if the sum rule can be used (Matthiessen's rule) (see *Boltzmann Equation and Scattering Mechanisms*). This is because a calculation of the temperature dependence of the resistivity in reality is only practicable for a single scattering mechanism (e.g., for the electron–phonon scattering) otherwise the mathematical complexity would be too great. However, the measured temperature dependence of the resistivity (total resistivity) is the result of all the various scattering processes.

Under the assumption that Matthiessen's rule is valid, the total resistivity is simply the sum of all the calculated terms

$$\rho_{tot} = \rho_0 + \rho_{ph} + \rho_{mag} \qquad (1)$$

where the subscripts denote the residual resistivity (0), the resistivity owing to phonon scattering (ph) and the resistivity owing to spin-dependent scattering (magnetic scattering processes, mag). If the calculated total and experimental resistivities are in agreement, all the underlying assumptions and the procedure of the calculation can be taken as being confirmed. If, however, there is no agreement between theory and experiment it is necessary to check whether the experimental conditions (and/or the assumptions) are correct. One of the most serious experimental problems is the correct determination of the sample geometry (sample cross-section), especially if the sample material is brittle and the measured cross-section is uncertain owing to cracks inside the sample. This can be the case for many samples. When the true sample geometry is not known it is often helpful to consider the temperature variation of the normalized resistivity, i.e., $\rho(T)/\rho(300\,K)$ vs. $T$.

In cases where the conditions for Matthiessen's rule are not fulfilled, i.e., the individual scattering processes are coupled, a quantitative analysis of the resistivity data becomes intractable. Finally, it should be emphasized that for resistivity values of the order of 250 $\mu\Omega$ cm and higher, the whole concept of the Boltzmann formalism is not applicable. An estimation of the mean free path, $\lambda$, of the conduction electrons reveals that in these cases values of $\lambda$ are comparable to the size of the interatomic distances. A rigorous quantum mechanical treatment of the transport phenomena may then lead to useful results (Kubo 1959).

### 1.1 Scattering Mechanism

#### (a) Impurity scattering

In a nonmagnetic, single-phase sample where scattering contributions from vacancies and dislocations are negligible, the residual resistivity ($\rho_0$) is solely because of a low concentration of foreign impurity atoms. With the exception of the lowest

temperatures, $\rho_0$ is much smaller than the temperature-dependent phonon term ($\rho_{ph}$), and scattering of electrons by impurity defects is invariably elastic. As the temperature rises, $\rho_0$ remains constant (see *Boltzmann Equation and Scattering Mechanisms*) and $\rho_{ph}$ increases rapidly. The effect of the variable "impurity" scattering can best be seen in pseudobinary systems. The concentration dependence of $\rho_0$ vs. the concentration of the partner element of three different pseudobinary systems is shown in Fig. 2. The simplest example represents the $Lu_{1-x}Y_xAg$ system, which crystallizes in the cubic CsCl-type structure over the whole concentration range. The $\rho_0$ vs. $x$ curve is parabolic (see Fig. 2(a)), in good agreement with the so-called Nordheim rule, which states that the composition-dependent part of $\rho_0$ is proportional to $x(1-x)$, where $x$ is the composition. However, these contributions to $\rho_0$ caused by dislocations, stacking faults, etc., are superimposed in any case.

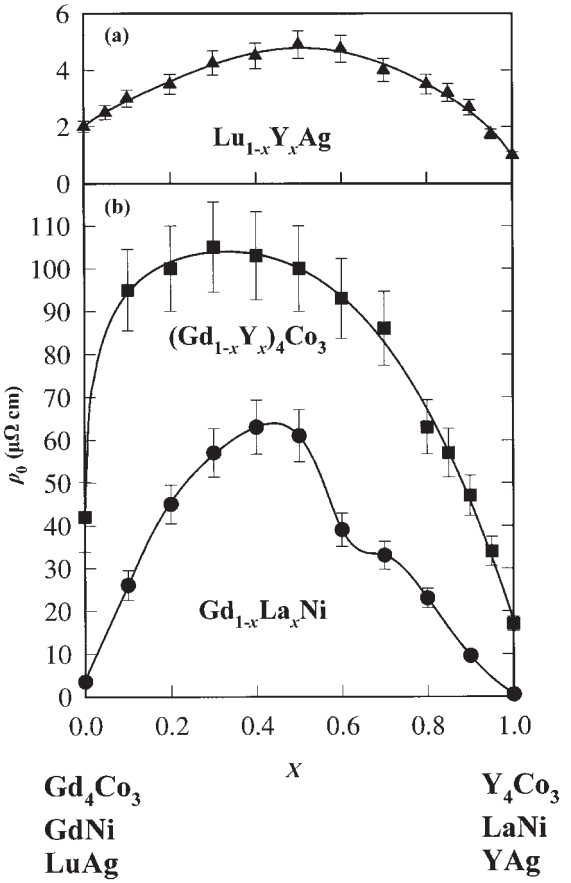

***Figure 2***
Concentration dependence of the residual resistivity ($\rho_0$) of three pseudobinary systems with different crystal structures: (a) $Lu_{1-x}Y_xAg$ (cubic CsCl-type structure); (b) $Gd_{1-x}La_xNi$ (orthorhombic CBr-type structure) and $(Gd_{1-x}Y_x)_4Co_3$ (hexagonal $Ho_4Co_3$-type structure). A ferromagnetic order exists in $Gd_{1-x}La_xNi$ for $0 \leqslant x < 0.7$ (Gratz *et al.* 1986), and in $(Gd_{1-x}Y_x)_4Co_3$ for $0 \leqslant x \leqslant 1.0$ (Gratz *et al.* 1980). Solid lines are guides for the eyes.

If one of the lattice sites is statistically occupied by a magnetic ion, then a further contribution to $\rho_0$ appears owing to the disorder in the magnetic moment arrangement. As an example, the pseudobinary $Gd_{1-x}La_xNi$ system is shown in Fig. 2(b). This system crystallizes in the orthorhombic CBr-type structure. Gadolinium bears a magnetic moment, leading to a long-range ferromagnetic order for gadolinium concentrations higher than 30% (Gratz *et al.* 1986). As can be seen from Fig. 2(b), there is a discontinuity in $\rho_0$ vs. $x$ at about the onset of ferromagnetism. The increase of $\rho_0$ in the ordered state is obviously because of the domain wall scattering and the disorder in the magnetic moment arrangement within the domains if not all of the RE places are uniformly occupied by gadolinium atoms. Note that $\rho_0$ is very small in the boundary compound GdNi. The third pseudobinary system, $(Gd_{1-x}Y_x)_4Co_3$ crystallizes in the hexagonal $Ho_4Co_3$-type structure. In this system a linear increase of the Curie temperature with the gadolinium content has been found, with the highest ordering temperature for $Gd_4Co_3$ ($T_C = 220\,K$) (Gratz *et al.* 1980). The asymmetric shape of the $\rho_0$ vs. $x$ curve is referred to the increasing disorder in the magnetic subsystem which exists even at the lowest temperatures. Note that $Gd_4Co_3$ again shows a comparatively low $\rho_0$ value.

### *(b) Electron–phonon scattering*

When an electron interacts with a quantized lattice vibration of frequency $\omega$, an energy quantum, $\hbar\omega$, is exchanged and such events are inelastic. Assuming that the conduction electrons are part of one and the same s-conduction band and they are scattered into vacant energy states within the same band, then the $\rho_{ph}(T)$ dependence can be approximated by the Bloch–Grüneisen law, derived using a Debye phonon spectrum and a spherical Fermi surface.

This is expressed by (Blatt 1968)

$$\rho_{ph} = 4R_\Theta \left(\frac{T}{\Theta}\right)^5 \int_0^{\Theta/T} \frac{x^5 dx}{(e^x - 1)(1 - e^{-x})} \qquad (2)$$

where the constant $R_\Theta$ includes, among other fundamental physical quantities, the electron–phonon coupling constant, an average atomic mass of the different types of atoms, and the Debye temperature $\Theta$ (see *Boltzmann Equation and Scattering Mechanisms*).

In order to demonstrate what can be concluded from a fit of Eqn. (2) to experimental data, the temperature variation of the resistivity of three cubic Laves phases ($YAl_2$, $LaAl_2$, $LuAl_2$) have been

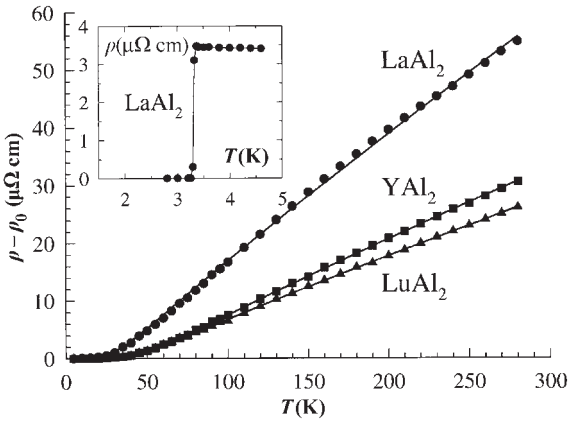

***Figure 3***
Temperature dependence of the electrical resistivity of three nonmagnetic $RAl_2$ cubic Laves phases ($\rho_0$ values are subtracted). The solid lines depict the temperature dependence according to the Bloch–Grüneisen relationship, with the fit parameters given in Table 1. The inset shows the superconducting transition of $LaAl_2$ in $\rho$ vs. $T$ at 3.3 K (Bauer *et al.* 1985).

***Table 1***
Fit parameters obtained by a fit of $\rho(T) = \rho_0 + \rho_{ph}(T)$ to the experimental resistivity data, with $\rho_{ph}(T)$ from the Bloch–Grüneisen law (see Eqn. (2)). $\rho_0$, $\Theta$, and $R_\Theta$ are the residual resistivity, the Debye temperature, and the prefactor in the Bloch–Grüneisen law (which depends on the electron–phonon interaction strength).

| Compound | $\rho_0$ (μΩ cm) | $\Theta$ (K) | $R_\Theta$ (μΩ cm) |
|---|---|---|---|
| $LuAl_2$ | 7.0 | 275 | 24 |
| $YAl_2$ | 4.4 | 310 | 35 |
| $LaAl_2$ | 3.1 | 205 | 45 |

selected and their $\rho(T)$ curves are depicted in Fig. 3 (Bauer *et al.* 1985). In a fit of the function $\rho(T) = \rho_0 + \rho_{ph}$ to these experimental data (given by the solid lines in Fig. 3), $\rho_0$, $R_\Theta$, and $\Theta$ are used as fit parameters. These values are listed in Table 1.

One can ask if these fit parameters have any significance. (Note that $R_\Theta$ gives the resistivity at the corresponding Debye temperature of a material.) A closer inspection of these parameters reveals an interesting picture, with a much higher Debye temperature obtained for $YAl_2$ ($\Theta = 310$ K), which is related to the higher frequency of the yttrium-dominated optical phonon modes. By contrast, $LuAl_2$ (owing to the larger atomic mass of lutetium) has a lower Debye temperature ($\Theta = 275$ K). The much smaller Debye temperature in $LaAl_2$ ($\Theta = 205$ K), the high $R_\Theta$ value (45 μΩ cm), plus the stronger curvature of the experimental $\rho(T)$ data at elevated temperatures (see Fig. 3) are indicative of a strong electron–phonon coupling. This is a necessary condition for superconductivity and we note that superconductivity is observed in $LaAl_2$ below 3.3 K (Fig. 3 inset).

There are two mechanisms thought to be responsible for the stronger electron–phonon interaction in $LaAl_2$, which might also occur in other lanthanum-based compounds (see below). The first of these comes from band-structure studies. It follows from the calculation that the electronic DOS at $E_F$ is enhanced owing to the proximity of the empty 4*f* band at the Fermi level (Hasegawa and Yanase 1980). The second mechanism comes from studies of the lattice dynamics by inelastic neutron diffraction, which reveal soft phonon modes in $LaAl_2$ (Yeh *et al.* 1981). In this investigation the lattice dynamics of $YAl_2$ and $LaAl_2$ have been compared, and it is shown that the phonon DOS has a pronounced gap at about 17 meV in $LaAl_2$. The trends outlined above have also been observed for LaAg, which is isostructural with YAg and LuAg (Bauer *et al.* 1986).

In conclusion, measurements of the resistivity provide a rough estimate of the electron–phonon interaction strength, especially for cases where isostructural compounds may be compared.

### *(c) Investigation of structural transitions using resistivity measurements*

Changes of the crystal structure influence the resistivity, since if there is a change in symmetry then the lattice dynamics (described by the phonon dispersion relationship) will change resulting from the different interatomic distances in the emerging structure. In addition, changes in structure will be accompanied by a change in the electronic properties (described in the electronic band structure). An example revealing the influence of structural transitions on the resistivity is provided by $LaAg_xIn_{1-x}$. These pseudobinary compounds crystallize in the cubic CsCl-type structure at room temperature. For $x < 0.95$ the compounds undergo a temperature-induced structural transition (Ihrig *et al.* 1973). Figure 4 shows the resistivity for some $x$ values of this pseudobinary system. The hysteresis in the $\rho(T)$ curves indicates a first-order structural transition. Studies of the lattice dynamics reveal a soft mode in the phonon spectrum (Knorr *et al.* 1980). The underlying mechanism of the anomalies in $\rho(T)$ are a result of a change in the electron–phonon scattering mechanism for the two different structures leading to a destabilization of the cubic structure. These curves present convincing examples that such a martensitic type of transition can be investigated using resistivity measurements.

### *(d) Spin-dependent scattering*

The third term on the right-hand side of Eqn. (1), $\rho_{mag}$, is introduced to describe spin-dependent

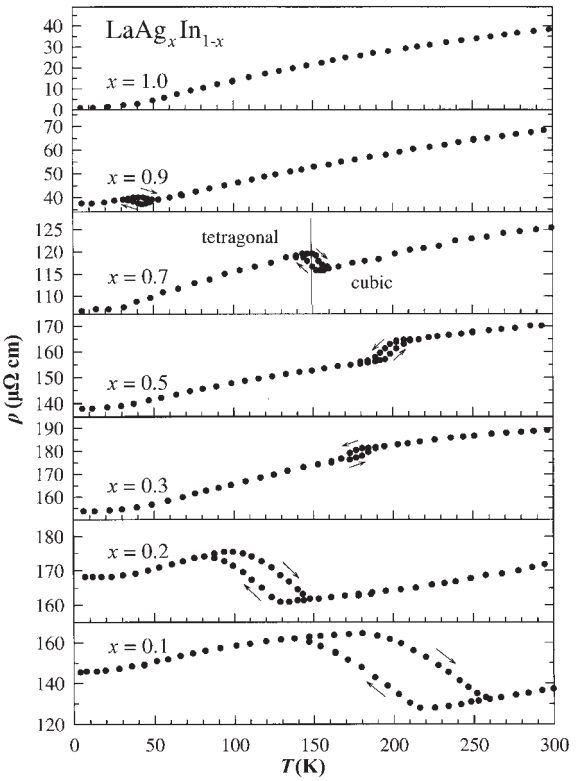

***Figure 4***
Temperature dependence of the electrical resistivity of the pseudobinary $LaAg_xIn_{1-x}$ series. The hysteresis in the $\rho(T)$ curves indicates structural transitions of martensitic origin.

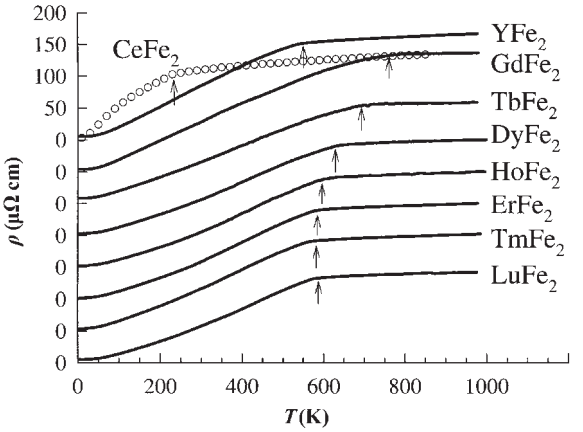

***Figure 5***
Temperature dependence of the electrical resistivity of $RFe_2$ Laves phases in the range up to 1000 K (Gratz *et al.* 1989). The arrows indicate the Curie temperatures (note there is a shift of the zero points).

scattering phenomena. These interactions between the conduction electron system and the matrix naturally depend on the magnetic state of the lattice. Assuming that the lattice contains magnetic ions (e.g., RE ions), any disorder in the arrangement of the associated moments will give rise to magnetic scattering. $RFe_2$ (R being a heavy RE element) has been selected as an example of the temperature variation of the resistivity in compounds with stable magnetic moments in both sublattices of the Laves phase (Gratz *et al.* 1989). The series is not complete since single-phase samples of light RE elements (praseodymium, neodymium, and samarium) are exceptionally difficult to prepare, with the exception of $CeFe_2$ which is included in the discussion. Among this series there are two examples ($YFe_2$ and $LuFe_2$) where only the iron moments determine the magnetism. In all the others the RE 4*f* moments *and* the iron moments are involved in magnetism as well as in the scattering of the conduction electrons.

The localization of the iron moments owing to the itinerant character of the 3*d* electrons are less pronounced than the 4*f* moments. However, the iron moments are much more localized than the cobalt moments in the $RCo_2$ compounds (see below). The temperature variation of the resistivity of these ferrimagnetic compounds (the RE and iron moments are coupled antiparallel, see *Alloys of 4f (R) and 3d (T) Elements: Magnetism*) is shown in Fig. 5. The kinks in the $\rho$ vs. $T$ curves indicate the Curie temperatures, with the arrows showing the temperature at which there is an inflection point in $d\rho/dT$ vs. $T$. The high magnetic ordering temperature of $RFe_2$ is mainly because of the strong interaction between nearest-neighbor iron atoms (these have a separation almost identical to that in elemental iron). There is an increase in $T_C$ when proceeding from $LuFe_2$ to $GdFe_2$ owing to the additional 4*f*–4*f* interaction, which is largest for the gadolinium compound. With the exception of $CeFe_2$, the $\rho(T)$ curves fit to the theoretical $\rho(T)$ curves for a magnetic compound in *Boltzmann Equation and Scattering Mechanisms*.

The $\rho_{spd}$ values (obtained by an extrapolation from high temperatures to $T=0$) vs. the deGennes factor, $(g-1)^2J(J+1)$, for the different $RFe_2$ compounds are given in Fig. 6. It is evident that there is no proportionality $\rho_{spd} \propto (g-1)^2J(J+1)$, since the $\rho_{spd}$ values in the $RFe_2$ series are dominated by the 3*d* moment scattering, which is, however, constant within the series. Many RE compounds with nonmagnetic partner elements (e.g., $RAl_2$) do show the proportionality $\rho_{spd} \propto (g-1)^2J(J+1)$. Examples of these are $RAl_2$ and RPt, both of which are included in Fig. 6. At low temperatures in magnetically ordered compounds ($T \ll T_{ord}$) spin waves are often important and spin-wave scattering will dominate the low-temperature increase in $\rho$ vs. $T$. In the case of ferromagnetism, the

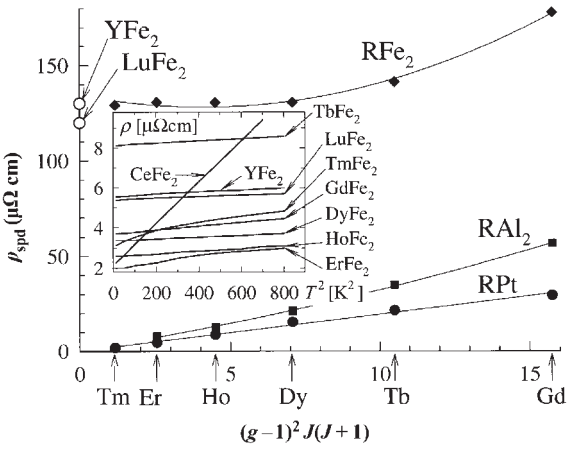

***Figure 6***
$\rho_{spd}$ as a function of the deGennes factor $(g-1)^2J(J+1)$ for $RFe_2$, $RAl_2$, and RPt. The inset shows $\rho$ vs. $T^2$ in the low-temperature region for $RFe_2$.

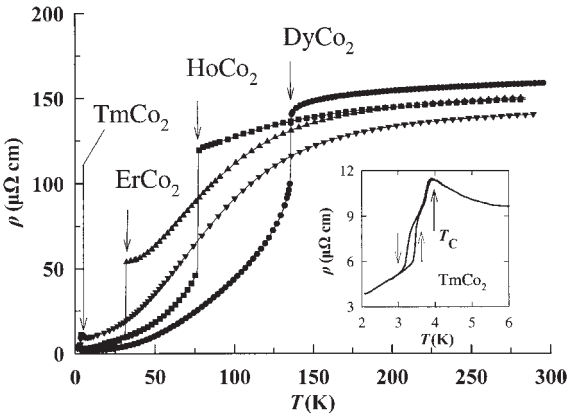

***Figure 7***
Temperature dependence of the electrical resistivity of $RCo_2$ Laves phases (Gratz *et al.* 1995). The arrows indicate the magnetic transition at $T_C$ (first-order type transitions). The inset shows details for $TmCo_2$ at low temperatures (the hysteresis is owing to a further magnetic transition at 3.2 K).

spin-wave dispersion is given by $\hbar\omega = Dq^2$ (where $D$ is the spin-wave stiffness and $q$ the wave vector). For $RFe_2$ this relationship is obviously fulfilled since there is a $T^2$ dependence of $\rho_{mag}$ (Fig. 6 inset) (Gratz *et al.* 1989). The curvature in $\rho$ vs. $T^2$ for $TmFe_2$ and $ErFe_2$ is because of low-lying crystal field excitations.

It can be asked why $CeFe_2$ does not fit into the general behavior of these $RFe_2$ compounds. In early investigations the unusual situation of $CeFe_2$ had been noted (the much smaller Curie temperature ($T_C = 270$ K), the strongly enhanced electronic specific heat coefficient ($\gamma_{el} = 56\,mJ\,mol^{-1}\,K^{-2}$), etc.). Eriksson *et al.* (1988) suggested that the cerium 4*f* electron moments may be itinerant in this compound. They suggested that cerium might behave quite differently from the localized 4*f* electrons associated with the other $RFe_2$ compounds. It is found experimentally that the net moment on the cerium site is $0.15\,\mu_B$, consisting mostly of the spin component and being polarized opposite to the iron moment of $1.2\,\mu_B$. The latter value is much smaller than that in the other $RFe_2$ compounds. The delocalization of both the cerium 4*f* and the iron 3*d* moments are because of the hybridization of both states (Eriksson *et al.* 1988). $CeFe_2$ is an example of an itinerant ferromagnetic system, where spin fluctuations are important for the physical properties. In the temperature variation of the resistivity of $CeFe_2$ there are basically two features. These are the much stronger $T^2$ dependence at low temperatures and the negative curvature at elevated temperatures in the magnetically ordered state (see below).

Figure 7 shows the resistivity variations of $RCo_2$ compounds (Gratz *et al.* 1995). The reason for having selected these compounds is to show the effect of spin-fluctuation scattering on resistivity (see *Spin Fluctuations*). Whereas $\rho_{mag}$ in $YCo_2$ is determined by the spin fluctuations in the cobalt sublattice only (see Fig. 1 and earlier comments), in $RCo_2$ compounds containing R atoms with an intrinsic moment, the magnetization is a result of the strong interplay between the two magnetic sublattices, and thus $\rho_{mag}$ depends on both. It leads to magnetic ordering at temperatures indicated by the arrows in Fig. 7. In the paramagnetic state (above $T_C$) there are spin fluctuations in the cobalt sublattice that cause the pronounced negative curvature in $\rho$ vs. $T$ (as in $YCo_2$, see Fig. 1). However, there is a temperature-independent spin-disorder scattering, $\rho_{spd}$, superimposed (owing to the disordered 4*f* moments). The onset of long-range magnetic order in the R sublattice below $T_C$ causes a suppression of the spin fluctuations in the cobalt 3*d* band, and an induced moment of the order of $1\,\mu_B$ per cobalt atom on the cobalt sites. Interestingly, this strong interaction of both sublattices causes the magnetic transition at $T_C$ to be of first order (normally second order) in the compounds with R = Dy, Ho, Er, and Tm. The sudden disappearance of the spin-fluctuation scattering below $T_C$ gives rise to the decrease in resistivity, within a few tenths of a degree, by approximately a factor six in the case of $ErCo_2$.

Below $T_C$, $\rho_{mag}$ depends on the dynamics of the localized moments only. This turns out to be much smaller than the spin-fluctuation scattering contribution to $\rho_{mag}$. The magnitude of the discontinuity in $\rho$ vs. $T$ depends on the temperature at which the magnetic transition takes place. The higher is $T_C$ the smaller is the discontinuity in $\rho$ vs. $T$. These

first-order transitions have a strong dependence on external parameters such as pressure or external magnetic fields. These transitions can also be driven into a second-order-type transition by a substitution of the magnetic R atoms by yttrium, e.g., $Er_{1-x}Y_x Co_2$ (Hauser *et al*. 1997). The resistivities of these $RCo_2$ compounds underline convincingly the sensitivity of the resistivity to spin-fluctuation scattering. The influence is more pronounced when compared to other dynamic measuring methods such as NMR or neutron scattering experiments. It has been argued that a reason for the dominant influence of spin-fluctuation scattering on the resistivity derives from the characteristic timescales of spin fluctuations and the transport phenomena (such as the electrical resistivity), which are of the same order of magnitude. A successful attempt to prove this argument, where inelastic neutron experiments and resistivity data for $YCo_2$ have been compared, seems to confirm this timescale argument (Gratz *et al*. 2000).

## 2. Conclusion

In this article we have selected compounds of relatively simple crystal structures in order to present the influences of the different scattering mechanisms on the temperature dependence of the resistivity, and to discuss what can be learned from resistivity measurements with respect to properties of a given material. The contribution of the phonon scattering to the resistivity is discussed using the Bloch–Grüneisen law. Furthermore, it is shown that the temperature-induced changes of the crystal structure are readily detected using resistivity as a probe. The influence of the spin-dependent scattering processes on the resistivity is shown on selected cubic Laves phases ($RFe_2$). A pronounced kink at $T_C$ or $T_N$ in $\rho$ vs. $T$ is an indication of well-localized magnetic moments. The effect of spin-fluctuation scattering has been demonstrated in the $RCo_2$ series. Finally, the resistivity of $YMn_2$ is shown as an example that, although this compound crystallizes in the cubic Laves phase, its resistivity behavior is difficult to explain in the scope of a classical (Boltzmann equation) concept.

# Intermetallics: Hall Effect

The basic theories and experiments on the Hall effect are first described, and then typical Hall effect results in *f*-electron intermetallic compounds are presented.

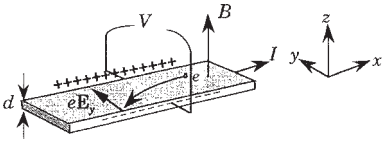

***Figure 1***
Experimental geometry for measurement of the Hall effect.

## *1. What is the Hall Effect?*

In isotropic metals and alloys, a resistive voltage develops only along the current direction ($x$) in a zero magnetic field. Under a magnetic field $\mathbf{B}$ applied normal ($z$) to the current direction (density $=\mathbf{j}$) (Fig. 1), there appears a transverse field:

$$\boldsymbol{E}_y = R_{\mathrm{H}}\mathbf{B} \times \mathbf{j} \tag{1}$$

which is known as the Hall effect, and $R_{\mathrm{H}}$ is defined as the Hall coefficient (Hurd 1972, 1980). Experimentally, $R_{\mathrm{H}}$ measured on a thin plate with a thickness of $d$ can be determined as:

$$R_{\mathrm{H}} = V_y d/IB \tag{2}$$

where $V_y$ is the transverse voltage, $I$ is the current, and $B$ is the magnetic field strength.

Empirically, the general expression for the Hall resistivity in magnetic materials is given as:

$$\rho_{\mathrm{H}} = R_{\mathrm{H0}}B + R_{\mathrm{S}}M \tag{3}$$

The origin of the first term is a Lorenz force $-e\mathbf{v}_{\mathrm{d}} \times \mathbf{B}$ experienced by the conduction electrons with a drift velocity of $\mathbf{v}_{\mathrm{d}}$, which is balanced by the force from the Hall field $e\mathbf{E}_y$ in a steady state:

$$-e\boldsymbol{v} \times \mathbf{B} = e\mathbf{E}_y \tag{4}$$

as shown in Fig. 1. $R_{\mathrm{H0}}$ is called the normal Hall coefficient. The second term in Eqn. (3) is the anomalous Hall resistivity, resulting from the asymmetric scattering of conduction electrons at magnetic ions, which often dominates in magnetic materials.

In the analysis of the Hall effect in magnetic intermetallics, special care should be paid to separate the various contributions to the Hall voltages. The temperature dependence of $R_{\mathrm{H}}$ in magnetic materials has often been ascribed wholly to the anomalous Hall effect. However, several other possibilities should be taken into account. One is the change in carrier number resulting from the Fermi surface reconstruction, if the system exhibits phase transitions. More importantly, the variation of the wave vector dependence of the conduction electron relaxation time $\tau(\mathbf{k})$ with temperatures (e.g., for scattering by phonons) changes from isotropic large angle scattering at high temperatures to smaller angle scattering at lower temperatures. This should not be ignored, because it leads to the temperature dependence of $R_{\mathrm{H0}}$. In fact, even in normal metals, an apparent temperature dependence of $R_{\mathrm{H0}}$ resulting from the temperature dependence of anisotropy in $\tau(\mathbf{k})$ was reported (Hurd 1972). Furthermore, the low-field/high-field transition in the cyclotron motion should be taken into account, especially in samples having a low residual resistivity.

## *2. Brief Summary of the Theories*

### *2.1 Normal Hall Effect*

In the free electron model, the current density can be written in terms of the carrier density $n$ as:

$$\mathbf{j} = ne\boldsymbol{v}_{\mathrm{d}} \tag{5}$$

Substituting Eqns. (4) and (5) into Eqn. (1), we obtain:

$$R_{\mathrm{H}} = 1/ne \tag{6}$$

Thus, the measurement of $R_{\mathrm{H}}$ allows us to determine the carrier density $n$. For simple metals at room temperature $R_{\mathrm{H}}$, calculated from the free electron density, agrees with experimental results. For instance, the experimental value of $R_{\mathrm{H}} = -3.4(\pm 0.1) \times 10^{-11}$ $\mathrm{m^3\,C^{-1}}$ in aluminum agrees well with the estimated value of $-3.45 \times 10^{-11}$ $\mathrm{m^3\ C^{-1}}$ from Eqn. (6) assuming three conduction electrons per ion. However, such an agreement is accidental except for the simple (alkaline) metals. In general, the Hall coefficient depends on the magnetic field direction. Even for metals with the cubic crystal structure, the Hall coefficient is field- and temperature-dependent, reflecting a non-spherical Fermi surface. All these behaviors are beyond the free electron model.

For cubic metals and low field condition, a general formula was given by Tsuji (1985) as:

$$R_{\mathrm{H}} = \left(\frac{12\pi^3}{e}\right)\frac{\int \tau(\mathbf{k})^2\mathbf{v}(\mathbf{k})^2\rho(\mathbf{k})^{-1}\mathrm{d}S}{\left(\int \tau(\mathbf{k})\mathbf{v}(\mathbf{k})\mathrm{d}S\right)2} \tag{7}$$

where $\tau(\mathbf{k})$, $\mathbf{v}(\mathbf{k})$ and $\rho(\mathbf{k})^{-1}$ are the relaxation time, velocity and mean local curvature of the Fermi surface at $\mathbf{k}$. This formula shows that, even for the cubic metals, the Hall coefficient can be temperature-dependent through the temperature dependence of $\tau(\mathbf{k})$. The sign of local mean curvature $\rho^{-1}(\mathbf{k})$ on the Fermi surface in the numerator determines the sign of the Hall coefficient through the Fermi surface integral in the numerator with weight factor $\tau(\mathbf{k})$.

The two-carrier model, the simplest possible approach to explain the temperature and field dependences, is derived from the Tsuji formula by dividing the Fermi surface integral into integrals over two

spherical Fermi spheres. In the model, we assume that the two Fermi spheres have different charges, $q_e$ ($=e<0$) and $q_h$ ($=|e|$), different carrier numbers $n_e$ and $n_h$, different effective masses $m_e$ and $m_h$ and different relaxation times $\tau_e$ and $\tau_h$. The two Fermi spheres carry the electrical current in parallel; i.e., the total conductivity is written as the sum of the contributions from the two spheres as:

$$\sigma_0 = \sigma_{0e} + \sigma_{0h} \tag{8a}$$

$$\sigma_{0\xi} = n_\xi q_\xi^2 \tau_\xi / m_\xi (\xi : \text{electron or hole}) \tag{8b}$$

In the low field condition ($\omega_c\tau \ll 1$), the Hall coefficient is written as:

$$R_H = [\sigma_e q_e \tau_e / m_e + \sigma_h q_h \tau_h / m_h]/\sigma_0^2 \tag{9}$$

Even in this simplest model, $R_H$ possibly varies with temperature, if $\tau_e$ and $\tau_h$ have different temperature dependences.

### 2.2 *Extraordinary Hall Effect*

#### *(a) Skew scattering and side jump mechanisms*

In magnetic materials, the second term in Eqn. (3), resulting from the magnetic scattering of conduction electrons, often dominates (Fert and Hamzic 1980, Berger and Bergmann 1980).

The origin of the anomalous Hall voltage can be described as follows. There remains a net unbalance between the scattering probabilities, from the same incident wave vector of $\mathbf{k}$, to the right (state $\mathbf{k}^r$) and to the left (state $\mathbf{k}^l$) with the $y$-component of different sign ($k_y^r = -k_y^l$):

$$W_{\boldsymbol{k}^r,\boldsymbol{k}} \neq W_{\boldsymbol{k}^l,\boldsymbol{k}} \tag{10}$$

For simplicity, we assume the magnetic field (magnetization) and the current directions as z- and x-axes, respectively. More generally, the breakdown of reversal symmetry in the transition probability $W_{\mathbf{k},\mathbf{k}'}$ (i.e., $W_{\mathbf{k},\mathbf{k}'} \neq W_{\mathbf{k}',\mathbf{k}}$) generates a current along the y-direction which is compensated by the anomalous Hall voltage along the y-direction.

More intuitively, an example to produce such an asymmetry in the scattering probability is shown in Fig. 2, where the asymmetry is caused by the coupling

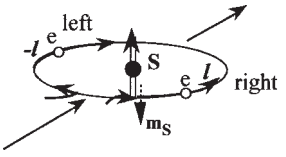

***Figure 2***
An example of conduction electron orbital motion leading to asymmetric scattering.

of an orbital motion (represented by the angular momentum $l$) of conduction electrons with an ion's spin $\mathbf{S}$. The pass along the left-hand half circle is preferred, since the energy is lower for $\mathbf{S}$//-$\mathbf{l}$. If the conduction electron spins ($\mathbf{s}$) are polarized as in 3*d*-ferromagnetic metals, even for the nonmagnetic scattering centers, the intrinsic spin–orbit interaction ($\mathbf{s}\cdot\mathbf{l}$) leads to the asymmetric scattering of conduction electrons (Hurd 1972).

The magnetic conductors are classified roughly into two categories, depending on whether the electrons responsible for magnetism are itinerant or localized. Several theories based on the itinerant magnetic electrons have been reported, and were successfully applied to 3*d*-magnetic systems (Hurd 1972). However, such theories are not suitable for rare-earth intermetallics with highly localized 4*f* electrons. Here we briefly summarize mechanisms that are more suitable for systems containing localized magnetic electrons.

The origin of the left–right asymmetric scattering, the orbital exchange interaction, is introduced (Kondo 1962) via the relation:

$$H_{O.Ex} \approx \xi(2 - g_J)\mathbf{l}\cdot\mathbf{J}, \tag{11}$$

where $g_J$ and $\mathbf{J}$ are the Landé g-factor and the total angular momentum of the localized electrons (ions), respectively. However, the orbital exchange term is apparently not enough to explain the experimental results in 4*f*-electron systems, since gadolinium-containing materials, where the orbital angular momentum is absent ($g_J = 2$), also show a large anomalous Hall effect. It is understood as a combined effect of the spin exchange scattering ($\sim\mathbf{s}\cdot\mathbf{J}$) and the spin–orbit scattering (due to the intrinsic spin–orbit coupling $\sim\mathbf{s}\cdot\mathbf{l}$) (Fert and Hamzic 1980). The combination of the two mechanisms (the orbital exchange and the spin–orbit coupled spin exchange scattering) well explains the experimental results, both for dilute rare-earth impurities in noble metals and for rare-earth intermetallic compounds, though several additional mechanisms have been proposed.

In the ferromagnetic state with a large magnetic scattering, the field dependence of $R_H$ mimics that of the magnetization, since the second term in Eqn. (3) prevails in $R_H$. Figure 3 shows how to decompose the normal and anomalous Hall components in the field-dependent Hall resistivity for ferromagnetic metal thin plates based on Eqn. (2). $\rho_H$ shows a tendency to saturate around a demagnetization field $B_d$ (the demagnetizing coefficient is $\sim 1$ for thin plates). The slope above $B_d$ gives the normal part of the Hall coefficient $R_{H0}$, while the intercept of the extrapolated line of the slope with the vertical axis gives $R_S M_S$.

The anomalous Hall term can be further decomposed into so-called skew-scattering and side jump mechanisms. Another possible mechanism (spin-effect, Fert *et al.* 1981), originating from the difference in the relaxation time between the split up- and

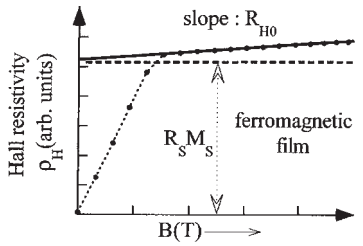

***Figure 3***
A typical example of Hall resistivity in a ferromagnetic thin plate.

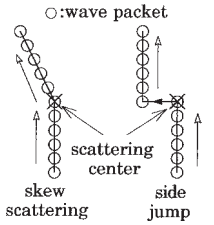

***Figure 4***
Schematic comparison of skew-scattering and side-jump scattering.

down-spin bands, can be neglected under ordinary conditions (at least at low fields). Note that the spin component could be basically viewed as arising from the two-carrier (up- and down-spin carriers) model with different relaxation times described above. The skew scattering mechanism can be understood within the classical picture as a deflection of the electron trajectory by an angle $\theta$ after the scattering through spin–orbit coupling. The side jump mechanism is basically a quantum effect, which can be viewed as a side step of the center of gravity of a wave packet, as shown in Fig. 4, as an analogy.

The difference in the two mechanisms is reflected in the dependence of each term on the resistivity $\rho$ (Hurd 1972): the anomalous Hall coefficient $R_S$ is the sum of the skew scattering term proportional to $\rho$ and the side-jump term proportional to $\rho^2$:

$$R_S = a\rho + b\rho^2 \tag{12}$$

The electron scattering on only static imperfections (like impurities) was initially considered as the origin of the anomalous Hall effect in measurements of the impurity concentration dependence of $R_H$, where the residual resistivity $\rho_0$ is employed in Eqn. (12).

Later on, it has been extended to the scattering by thermal spin disorder and/or by phonons, both experimentally and theoretically (Irkhin and Shavrov 1962, Kondorskii 1965). In most theories, the magnetic part of the resistivity $\rho_{mag}$ is assumed to be inserted in Eqn. (12), although it is not always easy to separate the nonmagnetic contribution from the total resistivity. In rare-earth intermetallic compounds, $\rho_{mag}$ is usually obtained by subtracting the resistivity $\rho_{ref}(T)$ of nonmagnetic reference compound from the total resistivity $\rho_{tot}(T)$ as:

$$\rho_{mag}(T) = \rho_{tot}(T) - \rho_{ref}(T) \tag{13}$$

It should be noted, however, that for the itinerant magnetic electrons model, the relation, $R_S \sim \rho_{tot}^2$, was theoretically reported for the thermal phonon or spin disorder scattering at elevated temperatures (Hurd 1972).

*(b) Kondo systems*

The skew scattering theory based on the Coqblin–Schrieffer model (1969) was first proposed by Fert (1973), and was successfully applied to explain the Hall effect in dilute lanthanum–cerium alloys. For cerium compounds, Coleman *et al.* (1985) have given an explanation of the large anomalous Hall constant in terms of skew scattering by impurities, based on the resonance-level model assuming a strong spin–orbit coupling in the two limits of $T \gg T_K$ and $T \ll T_K$. Later, Fert and Levy (1987) formulated the more generalized form, which describes experiments reasonably well in a wider temperature range from $T > T_K$ to $T \ll T_K$. The Hall coefficient from the intrinsic skew scattering was given by the following general expression:

$$R_S(T) = \gamma \chi_{red}(T) \rho_r(T) \tag{14}$$

where $\chi_{red}(T)$ $\{= 3k_B\chi/(g\mu_B)^2 j(j+1)\}$ is the reduced susceptibility, $\rho_r(T)$ is the resistivity due to the resonant scattering. The coefficient $\gamma$ takes different values $\gamma_1$ and $\gamma_2$ above and below $T_K$, related to the phase shifts $\delta_l$ for channel $l$:

$$\gamma_1 = (-5/7) g\mu_B k_B^{-1} \sin\delta_2 \cos\delta_2 \tag{15a}$$

for $T \gg T_K$, and

$$\gamma_2 = (-5\pi/21) g\mu_B k_B^{-1} \sin(2\delta_3 - \delta_2) \sin\delta_2 / \sin^2\delta_3 \tag{15b}$$

for $T \gg T_K$.

Fert and Levy (1987) have succeeded in reproducing the experimental temperature dependence of $R_H$ in typical heavy-Fermion compounds such as $CeAl_3$ and $CeCu_6$. Even for the coherent state, they found that Eqn. (14) accounts for the main features of the Hall effect.

For the coherent state, Kontani and Yamada (1994) first derived a formula for the anomalous Hall coefficient, based on the Fermi liquid theory. The anomalous part of the Hall coefficient is described as:

$$R_S = C\chi_{enh}\rho^2 \tag{16}$$

where the electrical resistivity follows $\rho = \rho_0 + AT^2$ and $\chi_{enh}$ is the enhancement factor proportional to the magnetic susceptibility (see *Electron Systems: Strong Correlations*).

## 3. Typical Experimental Results

Firstly, the most important factors for analyzing the temperature dependence of Hall coefficient in Kondo systems can be summarized as follows.

From the viewpoint of reliability of the analysis, $R_H(T)$, $\chi(T)$, and $\rho(T)$ should be measured on the same sample and with the same geometry, which reduces the errors due to unknown sources. For compounds with an anisotropic crystal structure, measurements on single crystals are essential. The magnetic contribution to the measured resistivity $\rho_{exp}(T)$ could be estimated by subtracting the resistivity $\rho_{ref}(T)$ of a proper reference compound (for example, a lanthanum analog for a cerium compound) as:

$$\rho_{mag}(T) = \rho_{exp}(T) - \rho_{ref}(T) \tag{17}$$

Using $\rho_{mag}(T)$ thus obtained, $R_H(T)$ is plotted against $\chi(T) \times \rho_{mag}(T)$ as shown in Fig. 5. The slopes in the two linear regions above $T_K$ and below $T_K$ give $\gamma_1$ and $\gamma_2$ in Eqns. (15a) and (15b).

### 3.1 Well-localized 4f Compounds

The series $RECu_6$ (RE: La, Pr, Nd, and Sm) was selected as a typical example for the well-localized system. Fig. 6 shows the temperature dependence of $R_H$ in $RECu_6$ for the light rare-earth elements (Ōnuki *et al.* 1989). At high temperatures, $R_H$ is only weakly temperature-dependent for all the compounds except $CeCu_6$. For all the compounds, $R_H$ is approaching $-5 \times 10^{-10}\,m^3\,C^{-1}$, which should be the normal part

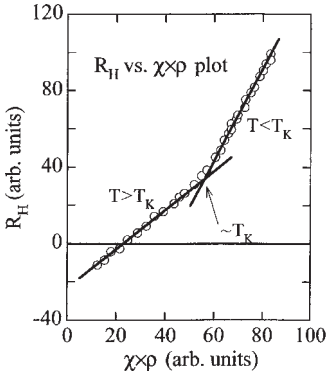

***Figure 5***
Schematic figure showing how to estimate $\gamma_1$ and $\gamma_2$ from the experimental $R_H$.

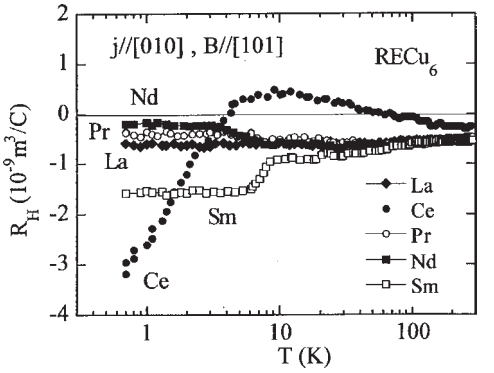

***Figure 6***
Temperature dependence of $R_H$ in $RECu_6$.

of the Hall coefficient. The negative sign of $R_H$ suggests that the relaxation time for the carriers with electron-like Fermi surface curvatures, positive $\rho^{-1}$ in Eqn. (7), is larger than that for the hole-like Fermi surface curvatures, since $RECu_6$ is a compensated metal with the same volume for both electron-like and hole-like Fermi surfaces.

$R_H$ for $NdCu_6$ and $SmCu_6$ shows a clear change at the corresponding Néel temperatures $T_N$ of 6 K and 9 K, respectively. At $T_N$, two possible contributions coexist; namely the change in the carrier concentration resulting from the AF super-zone gap formation, and the change in anisotropy in the relaxation time. For $SmCu_6$, taking into account the fact that the change in $R_H$ is steep, while that in $\rho$ is gradual, the two contributions compete in $\rho$ and cooperate in $R_H$.

The unique behavior in $CeCu_6$ results from the dominant Kondo scattering in this compound, which will be discussed below.

### 3.2 Cerium–Kondo Systems at Higher Temperatures ($Ce_xLa_{1-x}Cu_6$, $CeRu_2Si_2$, etc.)

Among the rare-earth intermetallic compounds, the works on the Hall effect were rather limited to the Kondo or heavy-Fermion compounds, mainly cerium and ytterbium compounds (Cattaneo 1985, Ōnuki *et al.* 1993). Here, we concentrate on the current understanding of the Hall effect in cerium compounds, based on typical examples in correlation with the reported theories.

To start with, the Hall coefficient of $Ce_xLa_{1-x}Cu_6$, which has been the most systematically investigated, is best suited for comparison with the skew scattering theory. Figure 7 shows the comparison of the temperature dependences of $R_H$ in the experiment with Eqn. (14) for selected values of cerium concentration. Here, the magnetic contribution to the resistivity, $\rho_m(T)$, has been estimated by subtracting the resistivity $\rho_{nm}(T)$ of a $LaCu_6$ sample from the

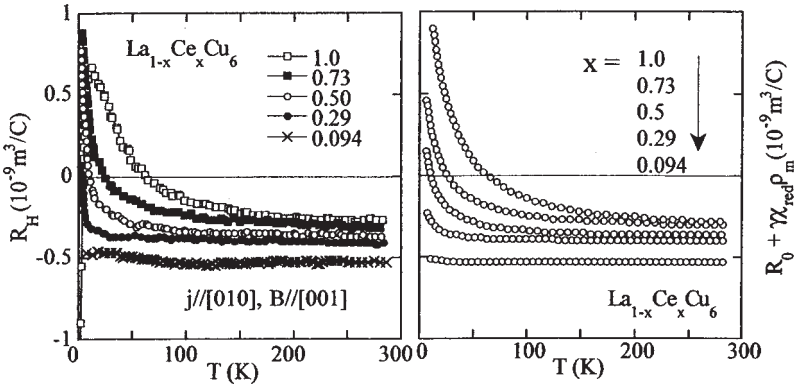

***Figure 7***
Comparison of $R_H$ in the experiment with Eqn. (14) for $La_{1-x}Ce_xCu_6$.

experimental one: $\rho_{exp}(T)$; $\rho_m(T) = \rho_{exp}(T) - \rho_{nm}(T)$. $\chi_{red} = \chi/C$ is estimated by using the experimental value of $\chi$. It should be noted that the experimental curves could be fitted by almost the same value of the phase shift $\delta_2 \approx -0.02$ for all cerium concentrations. The agreement is quite good over a wide temperature range. Even for pure $CeCu_6$, the agreement is satisfactory above $\sim 20$ K, below which the development of the coherent state naturally leads to a different conduction electron state. However, it is not easy to separate the intrinsic skew scattering contribution only from this figure, since a large anisotropy in $R_H$ at low temperatures could be expected.

For the coherent state, the scaling relation Eqn. (16) has been tested in selected heavy-Fermion systems. The results for $CeCu_6$ and $CeRu_2Si_2$ are shown in Fig. 8, where the linearity is reasonably good for the lowest temperatures (Ōnuki *et al.* 1993).

For $CeRu_2Si_2$, there has been a controversy over the difference in the anisotropy between the anomalous Hall coefficient and the magnetic susceptibility: the anisotropy in $R_H$ is small in contrast to the large anisotropy in $\chi$, reflecting the crystalline electric field (CEF) of the 4*f* levels. This fact opens the question of whether the temperature dependence of $R_H$ is caused by the skew scattering contribution to the anomalous Hall effect or not. Kontani *et al.* have explained the difference in the anisotropy as being due to the different contribution from the higher excited CEF levels to $\chi$ and $R_H$ (Kontani *et al.* 1997). However, in order to fully understand the heavy-Fermion state, more systematic investigations on high-quality single crystals are necessary.

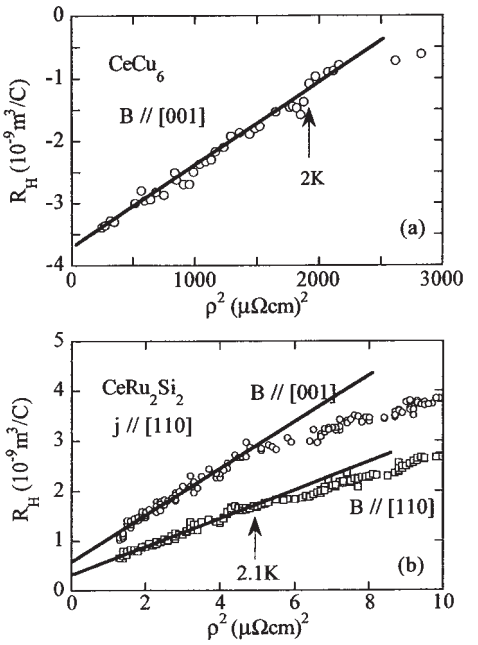

***Figure 8***
$R_H$ versus $\rho^2$ plots for $CeCu_6$ and $CeRu_2Si_2$ at low temperatures.

### *3.3 Uranium Intermetallic Compounds (UNiGa, UCoAl, $UPd_3$)*

UNiGa is one of the typical compounds whose Hall effect has been successfully utilized to solve important issues (Kobayashi *et al.* 1996). At low temperatures, uranium moments order ferromagnetically within the basal plane sheets with a strong uniaxial anisotropy along the c-axis. An antiferromagnetic (AF) structure, characterized by c-axis stacking of the type ($\uparrow\uparrow\downarrow\uparrow\downarrow\downarrow$), is stabilized.

A magnetic field applied along the c-axis induces a first-order type metamagnetic transition leading to a ferromagnetic (F) stacking, accompanied by a large resistance change across the metamagnetic transition

(Sechovsky *et al.* 1991). Spin-dependent scattering was initially thought to be the origin of the large magnetoresistance, since it bears a geometrical resemblance to the giant magnetoresistance (GMR) in artificial magnetic superlattices.

Another plausible explanation of the large magnetoresistance is based on the Fermi surface reconstruction due to the disappearance of the AF super-zone gap. This was initially rejected from results of specific heat measurements (Sechovsky *et al.* 1993), where no clear change in C/T was observed across the metamagnetic transition.

The measurement of Hall effect has been used as a powerful tool to judge the origin of the large magnetoresistance (Kobayashi *et al.* 1996). Figure 9 shows the field dependence of $R_H$ across the metamagnetic transition at 4.2 K, along with the magnetization and magnetoresistance measured on the same sample in the same geometry. Fortunately, $R_S$ is practically field-independent at low and high fields, except close to the metamagnetic transition, since both M and $\rho$ are almost constant due to the strong uniaxial anisotropy. Therefore, the normal Hall coefficient $R_{H0}$ below and above the metamagnetic transition can be determined from the slopes in the two regions. $R_{H0}$ changes from $-2.9 \times 10^{-9}\,m^3\,C^{-1}$ in the AF state to $-1.7 \times 10^{-9}\,m^3\,C^{-1}$ in the F state, which gives evidence of a Fermi surface change across the metamagnetic transition. Based on this fact, the specific heat was remeasured, and a clear change of the $\gamma$ value was found from $43\,mJ\,K^{-2}\,mol^{-1}$ below to $48\,mJ\,K^{-2}\,mol^{-1}$ above the metamagnetic transition. This corroborates the scenario of the Fermi surface reconstruction across the metamagnetic transition.

Another important issue on this material is the itinerancy of 5*f* electrons. The temperature dependence of $R_H$ for UNiGa is shown in Fig. 10, along with those of $\rho(T)$ and $M(T)$.

It is meaningful to compare this result with those obtained on $UPd_3$. The latter compound was confirmed to be a typical 5*f*-localized system, based on an inelastic neutron scattering experiment. The temperature dependences of $R_H$ for $B \| [0001]$ and [1010] are shown in Fig. 11 (Ōnuki *et al.* 1993). One prominent feature of these figures is the large difference in the temperature-dependent part of $R_H$ between the two compounds. That in UNiGa is about two orders of magnitude larger than that in $UPd_3$. This fact strongly suggests that the 5*f* electrons responsible for the magnetism are itinerant in UNiGa, while they are localized in $UPd_3$.

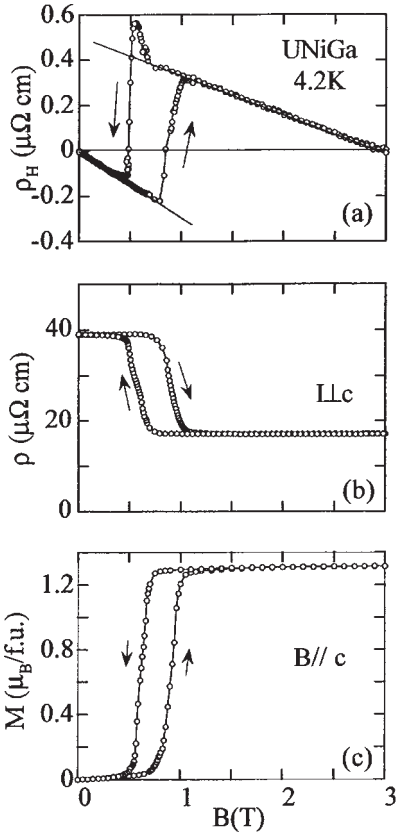

***Figure 9***
Field dependence of $\rho_H$, $\rho$, and M in UNiGa at 4.2 K.

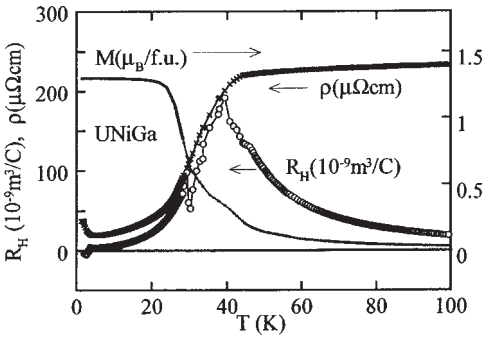

***Figure 10***
Temperature dependence of $\rho$, $R_H$ and M in UNiGa.

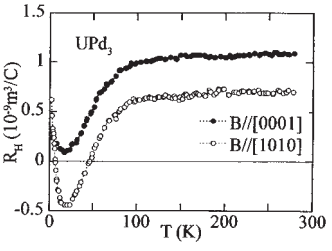

***Figure 11***
Temperature dependence of $R_H$ in $UPd_3$.

In the paramagnetic state, $R_H$ for UNiGa varies linearly as $\rho M$, as expected from Eqn. (14), while in the ferromagnetically aligned state at low temperatures, $R_S/\rho$ is linear, passing through zero as a function of $\rho$ (Fig. 12). Namely, in the high field state, the side jump scattering in Eqn. (12) dominates, resembling 3*d* ferromagnetic materials with a strong electron scattering. It should be also noted that such good linear relations were found experimentally by using the total resistivity, as was theoretically obtained for the itinerant magnetic system (Irkhin and Shavrov 1962), in many uranium compounds (without subtracting the nonmagnetic component).

In contrast, no simple correlation was found between $R_H$, $\chi$, and $\rho$ for $UPd_3$, as shown in Fig. 13,

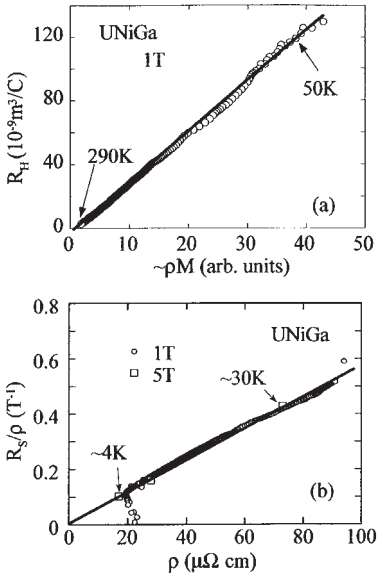

***Figure 12***
(a) $R_H$ versus $\rho M$ plot and (b) $R_S/\rho$ versus $\rho$ plot for UNiGa.

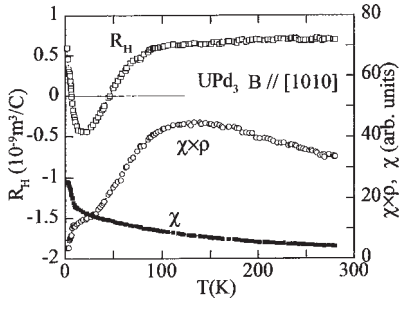

***Figure 13***
Temperature dependences of $R_H$, $\chi$, $\chi\rho$ in $UPd_3$.

which can be understood if the contribution from the temperature-dependent anisotropic relaxation time masks a small skew scattering contribution. This fact is another evidence of the localized character of the 5*f* electrons (at least there is only very little hybridization) in this compound.

Another example of 5*f*-itinerant compounds is UCoAl (Sato *et al.* 1998), which is a rare example exhibiting a metamagnetic transition from the paramagnetic ground state. The mechanism of the metamagnetic transition in typical 3*d* metamagnets, such as $YCo_2$ and $LuCo_2$, is well understood in terms of itinerant-electron metamagnetism resulting from the high 3*d*-band density of states near the Fermi level (Goto *et al.* 1994). A close resemblance of UCoAl to the 3*d*-itinerant metamagnets has been invoked, based on intensive studies of the effect of alloying and pressure on the metamagnetic transition. Figure 14 shows the temperature dependence of $R_H$ for two different values of the magnetic field. The inset shows $M/B$ measured on a same sample. The temperature dependences of the two properties resemble each other, which becomes more apparent in the $R_H$ vs. $\chi\rho$ plot in Fig. 15. In the wide temperature range above 60 K, $R_H$ is linear against $\chi\rho$, as expected for the skew

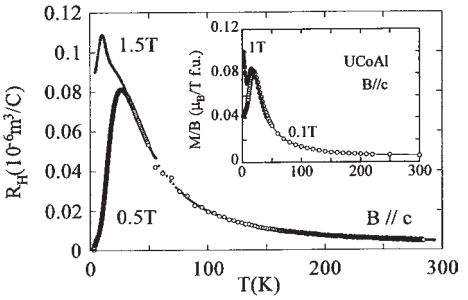

***Figure 14***
Temperature dependence of $R_H$ in UCoAl.

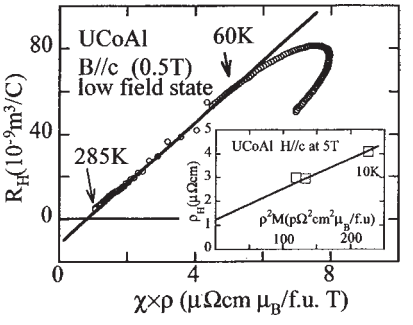

***Figure 15***
$R_H$ versus $\chi\rho$ plot for UCoAl. The inset shows $\rho_H$ versus $\rho^2 M$ plot at high fields.

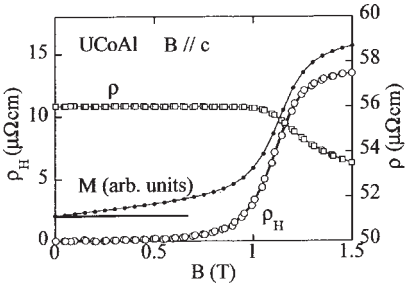

***Figure 16***
Field dependence of $\rho$, $\rho_H$, and $M$ in UCoAl at 4.2 K.

scattering mechanism. This fact, as well as the large magnitude of $R_H$, suggests the 5*f* electrons to be itinerant.

The field dependence at low temperatures in Fig. 14 reflects the metamagnetic transition. Figure 16 shows the field dependence of resistance, Hall resistivity and magnetization for UCoAl on the same sample and under the same conditions. We note an apparent resemblance between the Hall resistivity and the magnetization curves. Note that in the field-induced ferromagnetic state, $\rho_H$ varies as $\rho^2$ (the inset of Fig. 15). Across the metamagnetic transition field, the transverse magnetoresistance shows a clear decrease with increasing field, while an increase in the resistivity has been reported for the longitudinal geometry. This can be understood to be a so-called anisotropic magnetoresistance resulting from the anisotropy in the spin–orbit coupling, which is common in 3*d*-ferromagnetic metals and alloys. This fact also suggests that UCoAl is in a 5*f*-band split ferromagnetic state above the metamagnetic transition field. The change in the density of states due to the band splitting was further manifested in the field dependence of specific heat as a decrease of C/T (Matsuda *et al*. 1999).

## 4. Concluding Remarks

The Hall effect in intermetallics is not always analyzed straightforwardly. However, depending on the system, it has the potential to give important information on the electronic structure, which can hardly be extracted by other experimental techniques. In order to accomplish this, a proper analysis including the separation of different contributions, e.g., either normal or anomalous, is essential.

# Invar Materials: Phenomena

In the search for a cheaper length standard than the meter made of Pt–Ir, the Swiss physicist Charles Guillaume in 1897 discovered "Invar," a ferromagnetic (FM) f.c.c. alloy of 65 at.% iron and 35 at.% nickel with small and almost temperature-independent—"invariant"—thermal expansion. After discovering "Elinvar," a FM f.c.c. Fe–Ni–Cr alloy with constant elastic behavior, Guillaume was awarded the Nobel Price for physics in 1920, not the least because of the technical importance of his findings. The understanding of Invar remained a problem (Wassermann 1990, Wittenauer 1997) before *ab initio* calculations (Entel *et al.* 1993) gave basic insights into the relations between lattice structure, atomic volume, and magnetic properties, and brought to light "anti-Invar" and how it relates to martensite, the long-known structural f.c.c.–b.c.c. transformation of iron and iron-rich alloys (Wassermann *et al.* 1999).

## 1. Basic Physical Properties and Definitions

Invar- and often also Elinvar-like behavior is found in transition metal alloy systems with different lattice structures (see Table 1), most with iron as a component. Figure 1 shows schematically the most typical features. The temperature dependence of the thermal expansion coefficient $\alpha$ (Fig. 1(a)) in the FM ordered range $T < T_C$ (where $T_C$ is the Curie temperature) of Invar is reduced relative to a nonmagnetic reference, for which $\alpha(T)$ is given by the classical Grüneisen theory. Analogous behavior is found in antiferromagnetic (AF) Invar alloys such as $Fe_{40}Mn_{60}$ in the range $T < T_N$ (where $T_N$ is the Néel temperature). Figure 1(b) shows that relative to the Grüneisen reference the volume in a FM or an AF Invar alloy in the range $T \leqslant T_{C,N}$ is enhanced. This spontaneous volume magnetostriction, $\omega_s$, has a maximum value at zero temperature, $\omega_{s0} = (\Delta V/V)_{T=0}$, corresponding to the area between the data and the reference curve in Fig. 1(a). Figure 1(c) shows that the shear modulus, $G$, starts to soften at $T_C$ and then displays the temperature-independent Elinvar behavior. Figure 1(d) shows that the bulk modulus, $B(T)$, softens much above $T_C$ in FM Invar alloys, different from that observed in AF Invar alloys (Wassermann 1990).

For $e/a < 8.5$ (the number of valence electrons per atom) in f.c.c. iron-based systems, there is also *anti-Invar* behavior (Acet *et al.* 1994), the opposite of Invar. Anti-Invar behavior describes the increase of the volume and the enhancement of the thermal expansion relative to a reference in the high-temperature *paramagnetic* range. The relative volume increase, $\Delta V/V$, can be determined quantitatively by plotting $\alpha T_m = f(T/T_m)$, where $T_m$ is the melting temperature. For "normal" metals and alloys without magnetovolume anomalies such a plot results in an almost universal expansion curve, giving the average lattice curve $\alpha_{lat} T_m(T)$, which can be used as a general Grüneisen-like reference for $\alpha(T)$ of Invar

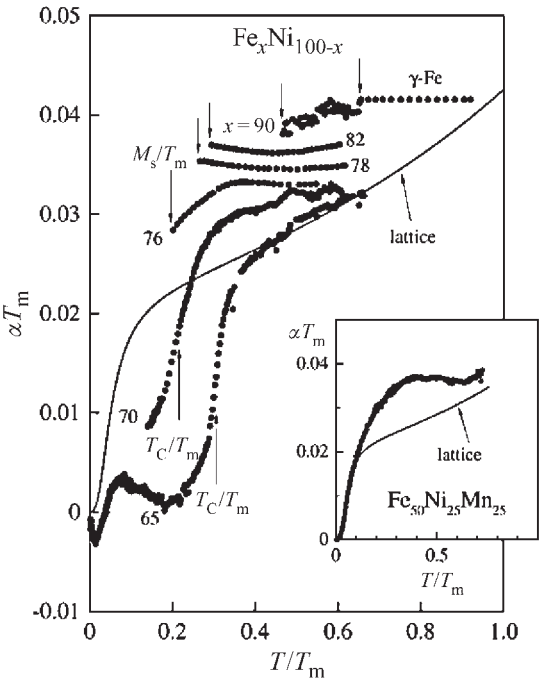

***Figure 2***
Thermal expansion coefficient $\alpha$ multiplied by the melting temperature $T_m$ vs. $T/T_m$ for f.c.c. Fe–Ni alloys and f.c.c. $\gamma$-iron. The upward pointing arrows indicate the Curie temperatures $T_c$. The curves for $70 \leqslant x \leqslant 100$ are measured down to their corresponding martensite start temperatures $M_s$. The solid curve is the nonmagnetic Grüneisen-like lattice reference. Inset: $\alpha T_m(T/T_m)$ for $Fe_{50}Ni_{25}Mn_{25}$ anti-Invar, f.c.c. stable to 0 K.

and anti-Invar alloys. A plot of $\alpha T_m = f(T/T_m)$ for $Fe_xNi_{100-x}$ alloys and elemental iron in the f.c.c. stability range shown in Fig. 2 reveals the continuous transition from FM Invar behavior in $Fe_{65}Ni_{35}$ ($e/a = 8.7$) to anti-Invar behavior in iron-rich samples and f.c.c. iron. In $Fe_{70}Ni_{30}$ ($e/a = 8.6$) both effects are observed, i.e., Invar behavior for $T < T_C/T_m$ and anti-Invar behavior for $T > T_C/T_m$. For $x > 75$ ($e/a < 8.5$) one encounters only anti-Invar behavior, for which an example is given in the inset of Fig. 2, showing $\alpha(T)$ of $Fe_{50}Ni_{25}Mn_{25}$, a paramagnetic alloy with f.c.c. stability to 0 k. With decreasing temperature the anti-Invar behavior terminates at the martensite start temperature, $M_s$, where the f.c.c.–b.c.c. transition takes place.

Figure 3 shows absolute values of the relative volume increase, $|\Delta V/V|$, vs. the composition ($e/a$) caused by the FM and AF Invar effects and the anti-Invar effect in different f.c.c. alloys. The volume increases shown occur *in addition* to the $\sim 7.5\%$ increase any metal or alloy experiences in the range $0 \leqslant T \leqslant T_m$ because of the "normal" thermal expansion due to anharmonic lattice potential (Grüneisen behavior). FM Invar behavior occurs only for $e/a > 8.5$, while for $e/a < 8.5$ one finds either anti-Invar behavior at high temperatures and AF Invar behavior at low temperatures, or anti-Invar behavior at high temperatures and martensite at low temperatures, if the f.c.c. stability is limited.

## 2. *Microscopic Understanding*

The present understanding of Invar and anti-Invar behavior stems from ground state properties as determined in *ab initio* calculations (Entel *et al.* 1993, Herper *et al.* 1999). A simplified picture is given in Fig. 4, showing for Invar and anti-Invar the volume dependence of the total energy $E(V)$ (Figs. 4(a) and (b)) and the magnetic moments (Figs. 4(c) and (d)). $V_0$ denotes the equilibrium and $V_c$ the critical volume, where the equilibrium state becomes energetically unfavorable. In anti-Invar (Fig. 4(a)) the ground state at $V_0$ is a low-spin (LS) state with a small magnetic moment (Fig. 4(c)) relative to the FM high-spin (HS) state at larger volumes, causing an enhanced anharmonicity of the lattice towards *larger* volumes $V > V_c$ in $E(V)$. Invar (Fig. 4(b)) is just the opposite, because the ground state at $V_0$ is a FM HS state and the enhanced anharmonicity in $E(V)$ is towards *smaller* volumes $V < V_c$, caused by the LS state.

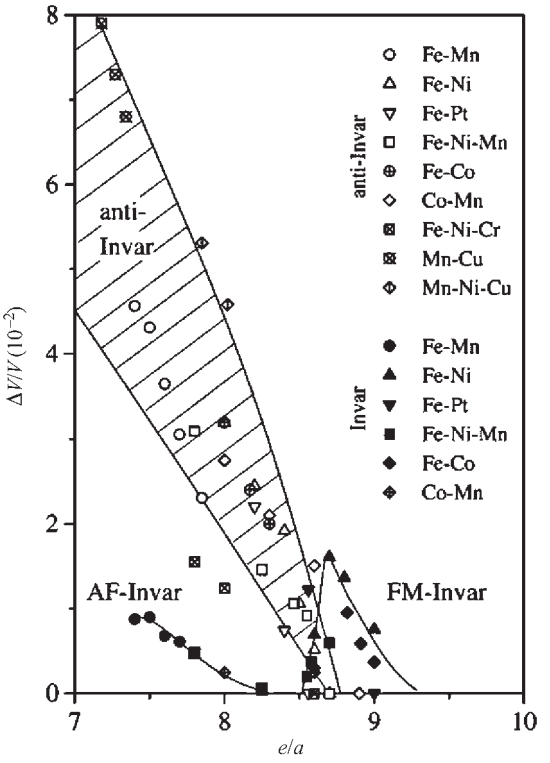

***Figure 3***
Relative volume enhancement $|\Delta V/V|$ through FM Invar, AF Invar, and anti-Invar effect vs. composition in electrons per atom ($e/a$) for different f.c.c. alloy systems.

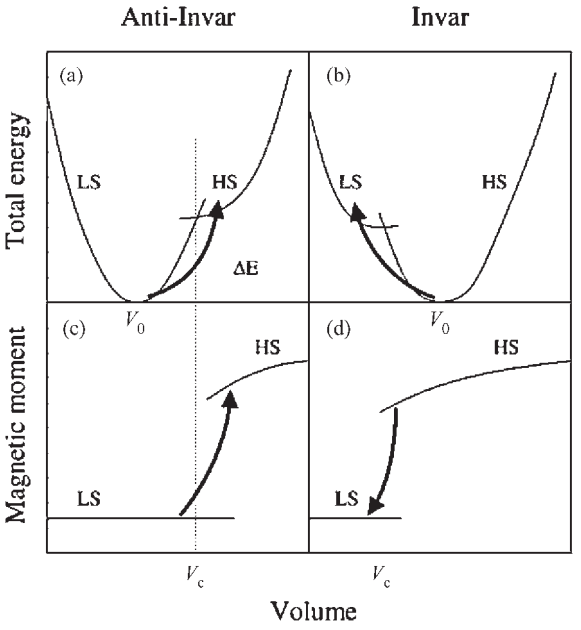

***Figure 4***
Schematic representation of volume dependence of (a, b) the total energy and (c, d) the magnetic moment of Invar and anti-Invar. $V_0$, equilibrium volume; $V_c$, critical volume for the transition from the LS to the HS state. Arrows indicate the direction of response of the system to increasing temperature.

The presence of these moment–volume instabilities in Fe–Ni and Fe–Pt Invar alloys has been demonstrated experimentally in Mössbauer experiments at 4.2 K, showing HS to LS transitions to occur when the lattice constant is reduced by high pressure (Abd-Elmeguid and Micklitz 1989). The *ab initio* calculations also corroborate the systematic behavior shown in Fig. 3. With increasing $e/a$ anti-Invar behavior progressively transforms to FM Invar behavior as $\Delta E$, the energetic difference between the HS and the LS states, decreases, goes through zero (so that LS and HS states are degenerate) near $e/a \sim 8.3$, and then increases again with the HS state becoming lower in energy.

Concerning the behavior at finite temperatures, the key point is that $\Delta E$ is of the order of milli-Rydbergs (1 mRy $\sim$ 150 K), so that transitions from the ground state to the energetically elevated state are possible by raising the temperature. Thus, as indicated with the arrows in Fig. 4, in anti-Invar LS–HS and in Invar HS–LS transitions occur, and the magnetic moment increases (Fig. 4(c)) or decreases (Fig. 4(d)), respectively. This is confirmed by high-temperature neutron investigations on the paramagnetic spin fluctuations of $Fe_xNi_{100-x}$ alloys within the f.c.c. stability range (Acet *et al.* 1997). Figure 5 shows the results in a plot of the average magnetic moment, $\mu$, vs. the temperature for compositions between $x = 65$ Invar (dashed curve) and pure $\gamma$-iron. With increasing iron concentration the slope of the $\mu(T)$ curves changes sign, in accordance with a change from a HS–LS transition for $Fe_{65}Ni_{35}$ Invar to a LS–HS transition in $Fe_{90}Ni_{10}$ anti-Invar or $Fe_{77}Ni_{13}Mn_7C_3$, an anti-Invar material with f.c.c. stability to 0 K. The high-temperature spin fluctuations in Fe–Ni alloys and in f.c.c. iron are always FM, although at low temperatures AF correlations occur, even AF long-range order in f.c.c. iron for $T_N < 70$ K. There is evidence from first principles calculations (van Schilfgaarde *et al.* 1999) that noncollinear magnetic moments and AF short-range order cause additional lattice softening and negative anharmonicity in Fe–Ni Invar.

Deeper insight into the microscopic background is gained from calculations resolving the properties of the d electrons in the vicinity of the Fermi energy $E_F$ (Entel *et al.* 1993) with respect to their orbital symmetry ($t_{2g}$, $e_g$) and their antibonding (AB), nonbonding (NB), or bonding (B) character. The respective electronic density of states (DOS) curves in the LS and HS state are shown schematically in Fig. 6. The

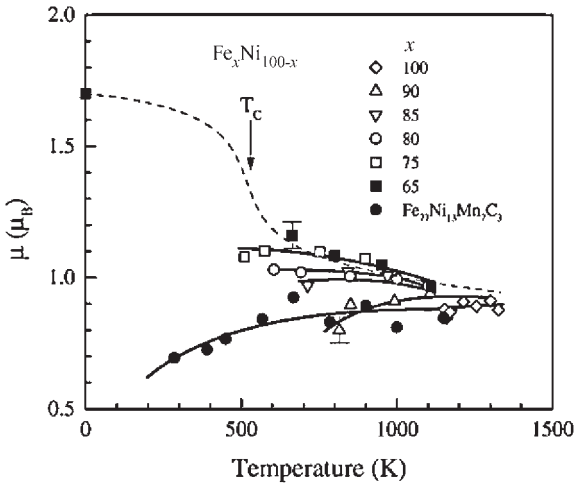

***Figure 5***
Average magnetic moment vs. temperature for $Fe_xNi_{100-x}$ alloys with different $x$ as indicated and pure $\gamma$-iron, all within the range of the stability of the f.c.c. structure. The dashed line is $\mu(T)$ for $Fe_{65}Ni_{35}$ Invar with f.c.c. stability to 0 K. The solid curve and the filled circles are for $Fe_{77}Ni_{13}Mn_7C_3$ anti-Invar f.c.c. stable to 0 K.

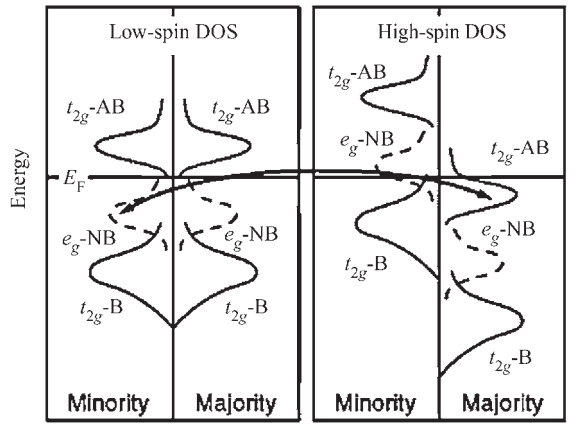

***Figure 6***
Schematic representation of the spin split DOS for a system with moment–volume instability. DOS in the LS state (left) and in the HS state (right). The arrow marks the electronic transitions near the Fermi energy $E_F$ from the AB $t_{2g}$ majority-spin states to NB $e_g$ minority-spin states (arrow from right to left) corresponding to a HS–LS transition in Invar, and in the reverse direction for a LS–HS transition in anti-Invar with increasing temperature.

$t_{2g}$ orbitals have a maximum charge density in the [110] direction and thus in an f.c.c. lattice form strong dd$\sigma$ bonds with nearest neighbors. The $t_{2g}$ DOS is therefore split and shows an energetically high-lying peak with AB character and an energetically low-lying one with B character. The $e_g$ orbitals have maximum charge densities in the [100] direction and in an f.c.c. lattice form dd$\pi$ bonds with the next nearest neighbors. They are NB and found between the two $t_{2g}$ peaks in the f.c.c. DOS. The position of the Fermi energy, $E_F$, relative to these levels, which depends on the electron concentration, the atomic volume, and the temperature, determines which type of transition occurs between these levels, to lead to Invar, anti-Invar, or to a martensitic transformation.

The arrow in Fig. 6 indicates the possible excitations with increasing temperature. For anti-Invar with a LS ground state the arrow reads from left to right, because there is a charge transfer from NB minority-spin $e_g$ orbitals to AB majority-spin $t_{2g}$ orbitals. These excitations lead to a band splitting and finally the HS state with a large volume caused by the AB character of the $t_{2g}$ majority-spin states. In Invar the arrow in Fig. 6 reads from right to left, because the HS state is the ground state and the charge transfer is from AB $t_{2g}$ majority-spin states to NB $e_g$ minority-spin states when the temperature is increased. This reduces the band splitting, corresponding to a HS to LS transition.

In summary, more than 100 years after the finding by Guillaume, through to the $t_{2g}$–$e_g$ scenario, the microscopic background of Invar, Elinvar, and anti-Invar and also the relationship to the martensite in iron-based systems is basically understood. However, the true solution of the Invar problem will be found when a first principles calculation reproduces correctly the archetypical property of Invar, i.e., the anomalous temperature dependence of the thermal expansion coefficient. To reach this goal a substantial amount of research is still necessary.

## Itinerant Electron Systems: Magnetism (Ferromagnetism)

The development of the electron band model (Bloch 1929) paved the way for an understanding of the magnetism of ''itinerant'' electrons. The first attempts to understand the metallic state were based on the free electron gas model and Pauli (1927) showed that the quenching of the spin can be explained if it is assumed that all the electrons in open shells (conduction electrons) are at least partially free. The Pauli exclusion principle requires that two electrons have to be different in at least one quantum number. For free electrons the only relevant quantum numbers are the spin and the electron momentum $k$. Since any state with quantum number $k$ can accommodate two electrons, these electrons must have opposite spin so that all spins appear to be compensated. For the susceptibility of the noninteracting (no exchange) gas of free electrons Pauli developed his well-known expression:

$$\chi_P = 2\mu_B^2 N(\varepsilon_F) \tag{1}$$

which relates the paramagnetism of the free electrons to the density of states at the Fermi energy $N(\varepsilon_F)$. Formally this relation resembles the result for the specific heat of the free electron gas which also depends on the density of states at the Fermi energy.

These ideas about the metallic state described as an electron gas were further developed by Mott (1935) and Slater (1936a, 1936b), who introduced more realistic models for the bandstructure and finally by Stoner (1936, 1938), who succeeded to formulate a phenomenological ''molecular field'' model (analogous to the Weiss model) by employing the electronic bandstructure instead of the discrete angular momentum levels. This model of itinerant electron magnetism accounts for noninteger magnetic moments in terms of a band filling of the narrow $d$ band and by taking into account the interaction of the $s$ and $d$ electrons of the valence band. Within the framework of the Stoner model, the susceptibility of the interacting (including exchange) gas of free electrons becomes enhanced by the exchange interaction and reads:

$$\chi_S = \frac{2\mu_B^2 N(\varepsilon_F)}{1 - IN(\varepsilon_F)} \tag{2}$$

The quantity $I$ in Eqn. (2) is the Stoner exchange factor, which is a slowly varying atomic quantity through the periodic table. The denominator allows the formulation of a criterion for the spontaneous onset of magnetism. If, in the nonmagnetic state the denominator is negative, the resulting negative susceptibility means that the paramagnetic state is not at a total energy minimum but at a maximum, so that any magnetic state must have a lower total energy. This is the famous Stoner criterion which is usually formulated such, that magnetism occurs if the inequality holds:

$$IN(\varepsilon_F) \geqslant 1 \tag{3}$$

An attempt to clarify the role of the exchange interaction in metals was made by performing Hartree–Fock calculations for the free electron gas in comparison to tight binding calculations for the valence electrons (see review by Wohlfarth (1953)).

A crucial step towards the understanding and practicability of quantum mechanical calculations of the metallic state was done by Slater (1951). He suggested that the exchange interaction could be approximated by an averaged potential over the occupied states of a homogenous electron gas, which is no longer a nonlocal quantity but depends only on the local electron density at the point $r$:

$$v_s(r) = -3e^2\left(\frac{3}{8\pi}\right)^{1/3}\rho(r)^{1/3} \tag{4}$$

A significant improvement to the Slater exchange occurred with the introduction of the X$\alpha$ method where the Slater exchange potential $v_s(r)$ is multiplied by a factor $\alpha$, which is determined from the requirement that the total energy of an isolated atom calculated from the X$\alpha$-potential equals the respective Hartree–Fock value (Schwarz 1972).

The next major step towards an understanding of the electronic structure of solids and subsequently of their magnetism was the density functional formalism introduced by Hohenberg and Kohn (1964). They showed that the ground state energy can be expressed in terms of a universal functional of the electron density (for details on this subject area see *Density Functional Theory: Magnetism*). The variation of the energy with respect to the electron density leads to effective one-electron Schrödinger type equations (Kohn and Sham 1965). In these equations the exchange-correlation potential $v_{xc}(r)$ enters additively to the Coulomb part, allowing straightforward use of independent interpolation formulae to approximate

***Table 1***
Exchange splitting $\Delta E$ and Stoner factor $I$ for closed packed cobalt for various models of the LSDA for exchange and correlation.

| | exp[a] | $X\alpha$[b] | LA[c] | HL[d] | vBH[e] |
|---|---|---|---|---|---|
| $\Delta E$ (eV) | 1.05 | 2.05 | 1.23 | 1.40 | 1.49 |
| $I$ (eV/$\mu_B$) | 0.65 | 1.21 | 0.72 | 0.93 | 0.96 |

$v_{xc}(r)$. This treatment is called the "local spin density approximation" (LSDA) for exchange and correlation (Hedin and Lundquist 1971, von Barth and Hedin 1972, Parr and Yang 1989).

Table 1 compares the values for $\Delta E$ and $I$ for h.c.p. (f.c.c.) cobalt for some commonly used models of the LSDA. Table 1 shows that most of the usual models yield too large a band splitting and Stoner factor. This shortcoming is due to an incomplete description of correlation effects. Only in case (c), where a special treatment is used to improve the correlation, do the calculated values come closer to the experimental estimates. Despite the large scattering found for $\Delta E$ and $I$ the calculated magnetic moments are all between 1.55 and 1.7 $\mu_B$ (exp: 1.62 $\mu_B$). The data given in Table 1 are taken from: (a) best value from experiments (h.c.p. cobalt) given by Wohlfarth (1980), (b) $X\alpha$ result for f.c.c. cobalt given by Wakoh and Yamashita (1970), (c) to obtain an improved description of the correlation effects Oles and Stollhoff (1986) introduced their local approach (LA) (f.c.c. cobalt), and (d) and (e) are values taken from Mohn and Schwarz (1993) for h.c.p. cobalt employing the Hedin–Lundquist (HL) and the von Barth–Hedin (vBH) exchange potential.

Parallel to the development of bandstructure theory there was a search for "simple" toy models to explain solid state magnetism. The most prominent of these models was introduced by Hubbard (1963), who tried to describe transition metal oxides with their narrow $d$ bands and their strong correlation. These models resemble the main features of electrons in a solid which are the bonding to a certain site and the Coulomb repulsion of electrons at the same site.

With these tools at hand it became possible to calculate the ground state properties with high reliability and also to understand the complex mechanisms occurring in solids. Among the remaining problems the most crucial one was the temperature dependence of solid state magnetism. While for the localized moment models the finite temperature effects became reasonably clear at a very early stage, this development took some time for metals.

For the free electron gas the temperature dependence of the susceptibility was calculated from the finite temperature properties of the Fermi–Dirac distribution (Sommerfeld expansion). Stoner applied the same ideas to introduce finite temperatures into the itinerant electron model. Unfortunately, the respective Curie temperatures $T_c$ came out too large by a factor of 4–8 and the inverse susceptibility above $T_c$ showed a $T^2$ rather than a linear $T$ dependence (as observed experimentally). After years of persistent struggle to salvage the finite temperature Stoner model, it finally became clear that the single particle excitations are not (or only to a small amount) responsible for the finite temperature behavior of metallic magnetism.

These results suggest that two extreme limits must be considered:

(i) the localized limit for which the magnetic moments and their fluctuations are localized in space (delocalized in $k$ space), with their amplitudes being large and fixed.

(ii) the itinerant (or weak ferromagnetic) limit for which the moments and their fluctuations are localized in $k$ space (delocalized in real space), with their amplitudes being temperature dependent.

A Curie–Weiss law is observed in both cases but its physical origin and the corresponding value of the Curie constant is different.

To solve these inconsistencies, Moriya and Kawabata (1973) tried to include thermally induced collective excitations of the spins (as they were already known for localized spins) in order to formulate an unified picture of magnetism (for a review see Moriya 1985). A similar approach was introduced by Murata and Doniach (1972), who introduced local and random classical fluctuations of the spin density (spin fluctuations) which should be excited thermally. Both of the latter two models become equivalent at high temperatures and lead to a Curie–Weiss law. Although the Murata–Doniach approach runs into trouble at $T = 0\,K$ (the classical fluctuations violate of the third law of thermodynamics), it has successfully been applied to calculate $T_c$ from data derived from de Haas–van Alphen measurements (Lonzarich and Taillefer 1985) and to formulate a simple model for $T_c$ of metallic solids (Mohn and Wohlfarth 1986) which gives much better results than the Stoner model.

## *1. Models for Delocalized Moments*

The magnetism of the delocalized (itinerant) band electrons represents an extreme limit of solid state magnetism. For these electrons the angular quantum number is no longer a sufficient description of their quantum state since their properties are described by a new quantum number, the electron momentum $k$. Together with the symmetry breaking due to the crystal field, it is also this quantum number which is responsible for the quenching of the angular momentum. Each electronic state, which is now represented by a certain value of $k$, is occupied with electrons which differ pairwise in all their other quantum

numbers so that the total angular momenta are always close to zero. In this situation the discrete energy levels, which were characterized by their magnetic quantum number $m_J$ and integer occupation numbers, which appeared in the Weiss model, have now to be replaced by quasi-continuous energy levels. These are characterized by the respective $k$ vector and a no longer integer occupation number given by the density of states. Since the electron states are given by plane waves (Bloch states) they extend over the whole crystal. A possible magnetic moment created by these electrons is no longer localized at a certain atomic site but appears to be smeared out (delocalized) over the whole crystal. In the limit of the free electron gas the electron density is constant in real space, so that a magnetic moment (which would better be described by the spin density) is also constant everywhere in space.

The magnetic behavior of the delocalized electrons can be described by transforming the real-space properties of the localized moments into $k$ space. The delocalized electrons are localized in $k$ space, the intra-atomic exchange interaction (localized in real space), which was responsible for the formation of a localized moment, is now an interatomic-like exchange interaction localized in $k$ space. Also the energetic localization of the atomic-like energy states is now broadened to a band state and appears to be energetically delocalized.

This extreme point of view is of course only valid for a quasi-free electron description of metallic solids. If a metal can be described by considering a quasi-free electron behavior only, its paramagnetic susceptibility should be given by the Pauli susceptibility (Eqn. (1)). However, even for simple metals like the alkalines the Pauli values are too low compared to experimental values. The reason for this discrepancy is the relatively high electron density in solids (even in simple metals such as sodium) which leads to a non-negligible exchange interaction (c.f. Eqn. (4)). In extreme cases like f.c.c. palladium, the Pauli susceptibility is too low by a factor of 9–10. Although $d$ electron systems like palladium (but also iron, cobalt, and nickel) are far from showing a ''free electron-like'' behavior, since the $d$ electron band width is much smaller than that of the $s$ band, their magnetism can be described along similar lines. This is due to the fact that for a fermion system all excitations (either thermally or due to an external field) occur in a narrow energy range around the Fermi surface so that only the properties at the Fermi energy are relevant.

### *1.1 The Stoner Model of Itinerant Electron Magnetism*

Stoner (1936, 1938) formulated his model of itinerant electron magnetism which can be seen as a transcription of the Weiss model for metallic solids. Stoner replaced the local ''free atom-like'' energy levels in the Weiss model, which are characterized by their respective magnetic quantum number, by the electronic bandstructure. Due to the crystal field interaction in solids the angular momentum appears to be quenched (angular quantum numbers are no longer relevant), so that only the $k$ vector and the spin of the valence electrons remains in describing the state of the electrons. The model is based on the following three postulates: (i) the carriers of magnetism are the electrons in the $d$ band, (ii) effects of exchange and correlation are treated within a molecular field term, and (iii) it must conform to Fermi statistics.

It is assumed that for an applied magnetic field, which is the molecular field (eventually including an external field $H_{ex}$) the Fermi energy of the paramagnetic state is shifted to new values $\varepsilon_f^+$ for spin-up and $\varepsilon_f^-$ for spin-down which leads to new occupation numbers $n^+$ and $n^-$ (Fig. 1, left panel). This picture is identical to the actual shifting of the two spin-dependent bands by the spin splitting $\Delta E$ (Fig. 1, right panel).

Since the Fermi energy is the energy of the highest occupied state it is equal to the chemical potential $\mu$; and consequently the new Fermi energies, caused by the field, can be seen as chemical potentials for spin-up $(+)$ and spin-down $(-)$ as $\mu^+$ and $\mu^-$. The Stoner equations can now be formulated:

$$n^{\pm} = \int_0^{\infty} N(\varepsilon) \frac{1}{\exp\left(\dfrac{\varepsilon}{k_B T} - \eta^{\pm}\right) + 1} \, d\varepsilon \qquad (5)$$

$$k_B T \eta^{\pm} = k_B T \eta \pm \frac{IM}{2} \pm \mu_B H_{ex} \quad \text{with} \quad \eta = \frac{\mu}{K_B T}$$

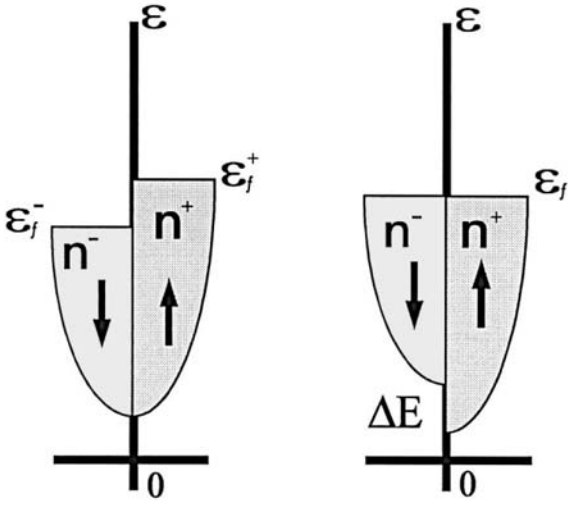

***Figure 1***
Magnetic splitting of the spin resolved density of states as assumed in the Stoner model of itinerant magnetism.

The number of spin-up and spin-down electrons $n^{\pm}$ is given by the integral over all occupied states, where for $T = 0\,\mathrm{K}$ the upper limit can be taken as the Fermi energy $\varepsilon_\mathrm{F}$. In its original formulation, Stoner assumed that the spin-up and spin-down bandstructure were equal so that the density of states $N(\varepsilon)$ are the same for both spin directions. This treatment is referred to as the rigid band picture, which assumes that during the transition from a nonmagnetic to a ferromagnetic state the spin-up and spin-down bands do not change their shape and that they only become shifted energetically by the spin splitting $\Delta E$ (c.f. Table 1) given by:

$$\Delta E = IM = I(n^+ - n^-) \tag{6}$$

In Eqns. (5) and (6), the quantity $I$ is the Stoner exchange factor and $M$ is the magnetic moment. From the Stoner equations the susceptibility can be calculated which becomes:

$$\chi = \frac{M}{H} = \frac{2\mu_\mathrm{B}^2 \int_0^\infty N(\varepsilon)\left|\frac{\mathrm{d}f}{\mathrm{d}\varepsilon}\right|\mathrm{d}\varepsilon}{1 - I\int_0^\infty N(\varepsilon)\left|\frac{\mathrm{d}f}{\mathrm{d}\varepsilon}\right|\mathrm{d}\varepsilon} \tag{7}$$

where $\mathrm{d}f/\mathrm{d}\varepsilon$ is the energy derivative of the Fermi–Dirac distribution. Equation (7) is the most general form of the Stoner susceptibility which for $T = 0\,\mathrm{K}$ reduces to:

$$\chi = \frac{2\mu_\mathrm{B}^2 N(\varepsilon_\mathrm{F})}{1 - IN(\varepsilon_\mathrm{F})} = 2\mu_\mathrm{B}^2 N(\varepsilon_\mathrm{F}) S \tag{8}$$

which is the Pauli susceptibility $2\mu_B^2 N(\varepsilon_\mathrm{F})$ enhanced by the exchange interaction via a factor $S$ (Stoner enhancement factor). If the term $IN(\varepsilon_\mathrm{F})$ becomes larger than 1, $\chi$ becomes negative, which means that the interacting electron gas is unstable against the formation of a magnetic moment (spontaneous magnetic order). This gives rise to the formulation of the famous Stoner criterion for the onset of magnetism which happens if:

$$IN(\varepsilon_\mathrm{F}) \geqslant 1 \tag{9}$$

Since the Stoner exchange factor $I$ is an atom specific constant, a possible transition to a magnetic state depends only on the density of states at the Fermi energy $N(\varepsilon_\mathrm{F})$. This in turn means that bands are needed which are narrow enough to create a large density of states. This is not only the explanation why band magnetism occurs only in the 3*d* transition metals (Cr, Mn, Fe, Co, and Ni) and the 5*f*-actinides starting with curium. The band width of the 4*d* and 5*d* series is already too large, which implies that a certain degree of *localization* is necessary.

If a system fulfills the Stoner criterion and thus has a magnetic ground state, Eqn. (7) also allows to calculate the Curie temperature by requiring that $T_\mathrm{c}$ is given by the temperature for which the denominator of Eqn. (7) becomes zero:

$$I\int_0^\infty N(\varepsilon)\left|\frac{\mathrm{d}f}{\mathrm{d}\varepsilon}\right|\mathrm{d}\varepsilon = 1 \tag{10}$$

Eqn. (10) is a temperature dependent Stoner criterion. Due to the convolution with the function $\mathrm{d}f/\mathrm{d}\varepsilon$, the effective density of states becomes progressively smaller when the temperature rises until the relation given above is fulfilled. Once this happens, the Stoner theory does no longer see any magnetic moment so that the paramagnetic state (the state above $T_\mathrm{c}$) is the nonmagnetic state. This is a new mechanism compared to the Weiss model, where the paramagnetic state was given by complete disorder of the local moments, or to the Heisenberg model within the mean field approximation, where the thermal agitation leads to a breakdown of the interaction aligning neighboring spins. Unfortunately the Curie temperatures calculated within the Stoner model are too high by a factor of 4–8 (Gunnarsson 1976). The thermal excitation mechanism is called single-particle excitations or simply Stoner excitations. At $T = 0\,\mathrm{K}$ all states below the Fermi energy are occupied and all states above are empty. With rising temperature the softening of the Fermi–Dirac distribution creates holes below the ($T = 0\,\mathrm{K}$) Fermi energy and creates occupied states above.

This is the typical case of an electron-hole excitation or exciton, however, only excitations which are connected with a spin flip are able to reduce the bulk magnetic moment. The energy scale on which these single particle excitations occur is set by the $T = 0\,\mathrm{K}$ Fermi energy via the effective Fermi degeneracy temperature $T_\mathrm{F}$:

$$T_\mathrm{F}^{-2} = \left|\frac{\pi^2 k_\mathrm{B}^2}{6}\left[\frac{N(\varepsilon_\mathrm{F})''}{N(\varepsilon_\mathrm{F})} - \left(\frac{N(\varepsilon_\mathrm{F})'}{N(\varepsilon_\mathrm{F})}\right)^2\right]\right| \tag{11}$$

which depends on the local structure of the density of states at the Fermi energy via its first and second energy derivative (Sommerfeld expansion). For most systems this temperature is 5000 K to 10000 K so that $T_\mathrm{c}$ within the Stoner model hardly ever reaches a reasonable order of magnitude. With the definition of $T_\mathrm{F}$ (which is basically the expansion of the integrand of Eqn. (10)), $T_\mathrm{c}$ can be written as:

$$T_\mathrm{c}^2 = T_\mathrm{F}^2(IN(\varepsilon_\mathrm{F}) - 1) \tag{12}$$

It is easy to see that $T_\mathrm{c}$ only becomes considerably smaller than $T_\mathrm{F}$ if $IN(\varepsilon_\mathrm{F})$ is only slightly larger than one, which is the condition for the very weak itinerant electron magnetism (Edwards and Wohlfarth 1968).

Systems under this class are supposed to have a very low saturation magnetization and also a very low $T_\mathrm{c}$. The progress in metallurgy and solid state

chemistry during the 1960s, mostly due to the search for BCS-superconductors, led to the discovery of a few candidates like $ZrZn_2$, $Sc_3In$, and $Ni_3Al$. Although their behavior below $T_c$ can be described within the theory of weak itinerant ferromagnets, for $T > T_c$ all three systems show a Curie–Weiss behavior which is not consistent with the Stoner model.

Within the Stoner model the finite temperature behavior of the susceptibility and the magnetic moment are described by the equation for the magnetic isotherms of weakly itinerant systems:

$$\left(\frac{M(H,T)}{M(0,0)}\right)^3 - \frac{M(H,T)}{M(0,0)}\left(1 - \frac{T^2}{T_c^2}\right) = \frac{2\chi_0 H}{M(0,0)} \qquad (13)$$

which represents the linear Arrott plots found also experimentally. Explicitly the temperature dependence of the magnetic moment is given by:

$$\frac{M}{M_0} = \left(1 - \frac{T^2}{T_c^2}\right)^{1/2} \qquad (14)$$

which for $T \to T_c$ shows the expected mean field behavior with a critical exponent $\beta = \frac{1}{2}$.

Eqn. (13) is equivalent to the Landau expansion of the free energy of a ferromagnet which reads:

$$F(M) = \frac{A}{2}M^2 + \frac{B}{4}M^4 - MH \qquad (15)$$

The respective values of the coefficients $A$ and $B$ can easily be determined and become:

$$A = -\frac{1}{2\chi_0}\left(1 - \frac{T^2}{T_c^2}\right) \quad \text{and} \quad B = \frac{1}{2x_0 M_0^2} \qquad (16)$$

where $\chi_0$ and $M_0$ are the susceptibility and magnetic moment at the equilibrium, respectively.

The temperature dependence of the susceptibility is a subject on its own. The functional dependence above $T_c$ can easily be calculated from Eqn. (13) if one considers, that for $T > T_c$ the magnetic moment $M(0, T)$ vanishes. The respective result is:

$$\chi = 2\chi_0\left(\frac{T^2}{T_c^2} - 1\right)^{-1} \text{ for } T > T_c \qquad (17)$$

which allows to calculate the Curie constant $C$ defined as:

$$C = \frac{\mathrm{d}(\chi^{-1})}{\mathrm{d}T} = \frac{T}{\chi_0 T_c^2} \qquad (18)$$

which for the Stoner model varies linear in $T$ rather than being a "constant."

For temperatures below $T_c$ one has to consider the additional temperature dependence of the magnetic moment, so that the susceptibility becomes:

$$\chi = \chi_0\left(1 - \frac{T^2}{T_c^2}\right)^{-1} \text{ for } T \leqslant T_c \qquad (19)$$

The reason for the surprising result that the susceptibility changes by a factor of two is not an artifact of the Stoner model, but is a general feature. The reason for it lies in the fact that the susceptibility simply measures the amount of magnetic moment produced by an applied field. The result means that it is twice as easy to create the same moment from a nonmagnetic spin system than from a magnetic spin system, where the applied field has to work against an already magnetized ensemble. In both temperature ranges, however, the inverse susceptibility does not show a Curie–Weiss law, but always a $T^2$ behavior.

Although the Stoner model gives a very good description of the $T = 0\,\mathrm{K}$ ground state properties, its finite temperature behavior fails completely. The electron-hole excitations considered are not able to yield reasonable values for $T_c$ and also lead to the wrong power law for the $\chi$ versus $T$ dependence.

### *1.2 The Hubbard Model*

Parallel to the development of bandstructure theory there was a search for "simple" toy models to explain solid state magnetism. The Hubbard model combines electron hopping between neighboring sites and the Coulomb repulsion of electrons at the same site. These features are combined within the Hubbard Hamiltonian (Hubbard 1963), which in its simplest form reads:

$$H = \sum_{ij\sigma} t_{ij} c_{i\sigma}^{+} c_{j\sigma} + U \sum_i n_{i\uparrow} n_{i\downarrow} \qquad (20)$$

The electron hopping is controlled by the parameter $t_{ij}$, $U$ models the Coulomb interaction. $c_{i\sigma}^{+}$, $c_{i\sigma}$ are the fermion creation and annihilation operators for an electron with spin $\sigma$ on site $i$ and $n_{i\sigma} = c_{i\sigma}^{+} c_{i\sigma}$ is the related ladder operator counting the occupation on site $i$. These fermion operators obey the following anticommutator rules:

$$[c_{i\sigma}^{+},\ c_{j\sigma'}] = \partial_{ij}\partial_{\sigma\sigma'}\ [c_{i\sigma}^{+},\ c_{j\sigma'}^{+}] = [c_{i\sigma},\ c_{j\sigma'}] = 0 \qquad (21)$$

Depending on the sign of $U$ the Hubbard Hamiltonian describes various phases, i.e., (i) $U > 0$ (repulsive) paramagnetic metallic, ferromagnetic metallic, and antiferromagnetic insulating; and (ii) $U < 0$ (attractive) normal Fermi liquid, superconducting, charge density wave (insulator), and normal Bose liquid (insulator).

$U$ is, however, not the only parameter. There exists also the strength of the electron hopping $t_{ij}$ and the temperature $T$. Further "hidden" variables are the dimensionality of the system and the structure of

the crystal lattice. Since the band filling (thus the number of electrons) plays an important role also the electron density $n = n_\uparrow + n_\downarrow$ can be regarded as a parameter of the Hubbard Hamiltonian. Since the Pauli principle avoids that two electrons with like spin occupy the same lattice site then $n_\sigma \leqslant 1$ for $\sigma = \uparrow, \downarrow$ and thus $n \leqslant 2$. The special case $n = 1$ describes the half-filled band (antiferromagnetism).

A straightforward solution can be found in the unperturbed case $U = 0$. The solution is found by the Fourier transform of the respective operator. In the time dependent form

$$i\hbar \dot{c}_{i\sigma} = -\sum_j t_{ij} c_{j\sigma} \Rightarrow c_{i\sigma} = \frac{1}{\sqrt{N}} \sum_{\mathbf{k}} e^{i\mathbf{k}\mathbf{R}_i} c_{\vec{k}\,\sigma} \quad (22)$$

$$i\hbar \dot{c}_{\mathbf{k}\sigma}(t) = \varepsilon^0_{\mathbf{k}} c_{\mathbf{k}\sigma}(t) \Rightarrow c_{\mathbf{k}\sigma}(t) = e^{-\frac{i}{\hbar}\varepsilon^0_{\mathbf{k}} t} c_{\mathbf{k}\sigma}(0) \quad (23)$$

which as a solution describes a single electronic band in the tight binding limit:

$$\varepsilon^0_{\mathbf{k}} = \varepsilon_0 - \sum_{j \neq i} t_{ij} e^{i\mathbf{k}(\mathbf{R}_i - \mathbf{R}_j)} \quad (24)$$

For a $2d$ square lattice $\varepsilon^0_k = -2t(\cos(k_x a) + \cos(k_y a))$ leading to a bandwidth $W = 4t$.

In a similar way one treats the case for $U \neq 0$ in the Hartree–Fock approximation where the Hubbard interaction $n_{i\uparrow} n_{i\downarrow}$ is replaced by $\bar{n}_{i\uparrow} n_{i\downarrow} + n_{i\uparrow} \bar{n}_{i\downarrow} - \bar{n}_{i\uparrow} \bar{n}_{i\downarrow}$. The entities $\bar{n}_{i\sigma}$ are thermodynamical averages which have to be determined self-consistently. The physical interpretation of the Hartree–Fock approximation is that fluctuations in the double occupancy $n_{i\uparrow} n_{i\downarrow}$ are suppressed. The respective time-dependent Schrödinger equations reads:

$$\left( i\hbar \frac{\mathrm{d}}{\mathrm{d}t} - \varepsilon_0 - U\bar{n}_{i-\sigma} \right) c_{i\sigma} = -\sum_j t_{ij} c_{j\sigma} \quad (25)$$

The solutions are two bands split by the Hubbard interaction $U$:

$$\varepsilon^{\uparrow}_{\mathbf{k}} = \varepsilon^0_{\mathbf{k}} + \tfrac{1}{2}U(\bar{n} + m),\ \varepsilon^{\downarrow}_{\mathbf{k}} = \varepsilon^0_{\mathbf{k}} + \tfrac{1}{2}U(\bar{n} - m) \quad (26)$$

$$\text{with} \quad \bar{n}_\uparrow = \tfrac{1}{2}(\bar{n} + m),\ \bar{n}_\downarrow = \tfrac{1}{2}(\bar{n} - m) \quad (27)$$

The respective band splitting is thus given by $\Delta E = Um = \varepsilon^{\uparrow}_{\mathbf{k}} - \varepsilon^{\downarrow}_{\mathbf{k}}$, which can directly be compared to the result obtained from the Stoner model (Eqn. (6)). In complete analogy to the Stoner model one also arrives at a criterion for magnetic ground state which is fulfilled if $UN(\varepsilon_\mathrm{F}) \geqslant 1$ (c.f. Eqn. (9)).

It is found that within the Hartree–Fock approximation the Hubbard model and the Stoner model become equivalent. The suppression of fluctuations in the double occupancy leads to an effective mean field treatment where $Um$ represents the resulting self-consistent molecular field.

The missing physics is again the orientational disorder. This is well described by the Heisenberg model but hard to see for itinerant electrons where in the Hartree–Fock approximation the paramagnetic state becomes the nonmagnetic state. However, what is required for the paramagnetic state is that the average over the magnetic moments vanishes:

$$\left\langle \sum_i m_i \right\rangle = \left\langle \sum_i (n_{i\uparrow} - n_{i\downarrow}) \right\rangle \quad (28)$$

but the individual moment at site $i$ remains, so that $m_i = n_{i\uparrow} - n_{i\downarrow} \neq 0$ for times $\tau$ such that

$$\frac{\hbar}{W} \leqslant \tau \leqslant \frac{\hbar}{k_\mathrm{B} T}$$

### *1.3 Spin Fluctuations*

From the preceding discussion it becomes clear that also in itinerant systems collective excitations of the spin system govern the finite-temperature properties. In the mid-1970s the first self-consistent spin polarized bandstructure calculations of the ground state of transition metals were performed using the LSDA to treat exchange and correlation effects. These calculations yielded satisfactory values for the magnetic moment, the exchange splitting, the cohesive energy, and a magnetic ground state which could be explained within the Stoner model. However, any attempt to explain the finite temperature behavior from these results failed. In the light of the previous discussion this failure is nowadays no longer surprising. Although these calculations contain all the many-body interactions via the density functional formalism, they still lack the ability to describe an excitation spectrum beyond the single particle picture. It has become clear (see review Shimizu 1981), that the problem is caused by imposing the translational symmetry of the spin density, an assumption which becomes violated by the collective excitations for $T > 0\,\mathrm{K}$. This breakdown of the conventional band picture has led to three main directions to go beyond it.

(i) In the Murata and Doniach (1972) approach the properties of the magnetic systems are described via a Landau–Ginzburg expansion of the free energy. The effect of spin fluctuations is formulated via randomly fluctuating local magnetic moments which couple to the bulk magnetization. Although these local moments $m(r)$ are vectors, the averaging process using Gaussian statistics leads to scalar quantities $\langle m(r)^2 \rangle$, which simply renormalize the original Landau expansion for a ferromagnet (Eqn. (15)). This scheme was successfully applied by Lonzarich and Taillefer (1985) to ferromagnetic and nearly ferromagnetic metals.

(ii) In the disordered local moment approach, the magnetic moments on individual atoms are allowed

to have random orientations in the sense described by Herring (1952a, 1952b) and later by Hubbard (1979a, 1979b) and Hasegawa (1980). Pindor *et al.* (1983) implemented this model in a self-consistent Korringa–Kohn–Rostoker (KKR) Coherent-Potential-Approximation (CPA) calculation to simulate the magnetic properties of the transition metals at finite temperature. Within this formalism Staunton *et al.* (1984) calculated the temperature dependent spin density and the wave vector-dependent susceptibility $\chi(q)$. With this model $T_c$ values of 1260 K and 225 K for iron and nickel were obtained, which should be compared to experimental values of 1043 K and 630 K, respectively. The discrepancy between theoretical and experimental values could be due to the assumption that directional disorder is complete above $T_c$, so that effects of short range order are neglected which could be important as suggested by Prange and Korenman (1979a, 1979b) and Capellmann (1979). However, what these CPA calculations have clearly shown is that the density of states (and thus all related macroscopic quantities) remain virtually unchanged up to temperatures well above the Curie point.

(iii) Later Nolting *et al.* (1995) proposed a new approach where the LSDA ground state bandstructure is fitted to a tight-binding model which enters a Hubbard Hamiltonian. The idea of this treatment is to start from the best quantum mechanical ground state available and to use it as a basis for a many particle treatment within the Hubbard model, which also allows correction for the too small correlation in the usual LSDA schemes. The calculated $T_c$ values for Fe, Co, and Ni are in excellent agreement with experimental values. What makes this approach even more promising is the fact that it explains the experimental photo-electron spectra which could not be related to the bare LSDA bandstructure results.

### *1.4 Fluctuations of the Magnetic Moment*

The idea of the introduction of fluctuations is to account for the shortcoming of the Stoner model, which does not allow for any tilting of the spins. In addition, these fluctuating moments which are induced by temperature should give rise to a Curie–Weiss behavior of the susceptibility. Such a fluctuation is shown in Fig. 2.

For the gas of free electrons the eigenfunctions are plane waves and the charge and spin density are constant in space. A local fluctuation (here it is only a parallel component) can be seen as a perturbation of the ground state spin density with a finite lifetime well below the characteristic time for electron hopping. It can also be assumed that the spatial extension of the fluctuation is larger than the range of interaction in the system, which means that fluctuations are treated in the limit of long wavelength.

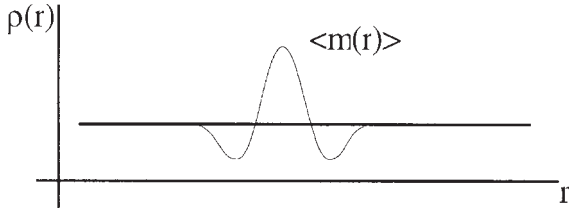

***Figure 2***
Schematic depiction of a local, longitudinal fluctuation of the spin density $\rho(r)$ (thick horizonal line) of the electron gas.

In the framework of the Landau theory of phase transitions the bulk magnetic moment $M$ was introduced as the order parameter for the free energy (Eqn. (15)). With this choice it was assumed that any vector properties of $M$ were irrelevant for the results, since time reversal symmetry requires that only even powers of $M$ enter the free energy. Introducing local fluctuations of the magnetic moment one has to recognize the vector properties of both the magnetic moment $M$ and its fluctuation $m(r)$. Consequently one has to distinguish fluctuations which are parallel and which are perpendicular to the direction of $M$. In the fluctuation treatment one replaces the order parameter $M$ in Eqn. (15) by a new quantity which, in addition, contains the fluctuating magnetic moment:

$$M^{2n} \rightarrow \langle (M + \sum m_i)^{2n} \rangle \tag{29}$$

The bracket $\langle \cdots \rangle$ denotes the Gaussian average and the index of $m$ represents the three components of the fluctuation in the local coordinate system of $M$. Unambiguously it can be assumed that $M$ points into the $z$ direction, which (for an isotropic system) leads to two components of the fluctuation which are perpendicular to $M$, namely $m_x$ and $m_y$, and one parallel component, $m_z$. To simplify the legibility the obvious $r$ dependence of $m(r)$ is omitted. As an example the square of the order parameter is given in:

$$\langle (M + \sum m_i)^{2n} \rangle = \langle M^2 + 2M \sum m_i + \sum \sum m_i m_j \rangle$$
$$M^2 + 2\langle m_\perp^2 \rangle + \langle m_{||}^2 \rangle \tag{30}$$

When averaged the mixed term vanishes because $m_i$ always appears with an odd power. From the term $m_i m_j$, for the same reason, only the diagonal elements remain. In the resulting relation the subscripts were replaced by symbols denoting the perpendicular components $m_x$ and $m_y \Rightarrow m_\perp$ and the parallel component $m_z \Rightarrow m_\parallel$.

One now replaces the order parameter $M^{2n}$ in the free energy expression (Eqn. (15)) by the respective new order parameter $\langle (M + \sum m_i)^{2n} \rangle$ and obtains

the "dynamical" form for the free energy $F$:

$$F = \frac{A}{2}(M^2 + 2\langle m_\perp^2 \rangle + \langle m_{||}^2 \rangle) + \frac{B}{4}(M^4 + M^2(6\langle m_\parallel^2 \rangle + 4\langle m_\perp^2 \rangle) + 8\langle m_\parallel^2 \rangle^2 + 3\langle m_\perp^2 \rangle^2 + 4\langle m_\parallel^2 \rangle \langle m_\perp^2 \rangle) \quad (31)$$

The original static form of $F$ has just been extended by the fluctuations. For $T = 0\,\mathrm{K}$, the fluctuations vanish and Eqn. (31) reduces to Eqn. (15). Since the fluctuations only renormalize the original Landau coefficients, the physical meaning and definition of both $A$ and $B$ are the same as before. What can be seen immediately is that even when the bulk magnetization $M$ vanishes, the fluctuations are present at all temperatures since they represent thermally induced local magnetic moments so that the paramagnetic state (for $T > T_c$) is no longer the nonmagnetic state as in the Stoner model.

This expression for the free energy can now be used to derive important properties of the fluctuating moments. Since $T_c$ is given by the temperature where the susceptibility diverges under the condition that the bulk magnetic moment $M$ vanishes, one can calculate the amplitude of the fluctuations at $T = T_c$:

$$\frac{\partial^2 F}{\partial M^2} = \chi^{-1} = A + \frac{B}{2}(10\langle m^2 \rangle) = 0 \quad \text{for} \quad T = T_c \quad (32)$$

In Eqn. (32) the subscripts for the parallel and perpendicular component disappear, since when $M$ vanishes a distinction between directions parallel and perpendicular to $M$ no longer has any meaning. Using Eqn. (16) the "Moriya formula" is recovered:

$$\langle m^2 \rangle = \frac{M_0^2}{5} \text{ at } T = T_c \quad (33)$$

which demonstrates that the mean square amplitude of the fluctuation at $T_c$ is a ground state property.

Based on these results and inspired by the work of Lonzarich and Taillefer (1985), Mohn and Wohlfarth (1986) derived a simple model for the Curie temperature in weakly itinerant systems which reads:

$$T_c \propto T_{SF} = \frac{M_0^2}{10\chi_0 k_B} \quad (34)$$

Here $T_{SF}$ is the Curie temperature caused by the spin fluctuations. Eqn. (34) describes the long wavelength limit ($q \to 0$) for weakly itinerant magnets and is thus an approximation which is based on the assumption of an effective cut-off for the collective excitations which should be fairly constant. In the present literature this approach in known as the Mohn–Wohlfarth model and has triggered considerable interest in the application of spin fluctuation theory. Although the approach can be expected to break down for strong ferromagnets (Qi *et al.* 1994) it can still be used to describe the relative change of $T_c$ (Jaswal 1993), e.g., for different concentrations in an alloy system.

From the dynamical form of the free energy (Eqn. (31)) it is straightforward to calculate the specific heat and its discontinuity at $T_c$ (Mohn and Hilscher 1989a). The specific heat becomes linear in temperature and that the discontinuity at $T_c$ is reduced by a factor of four with respect to the Stoner result, which is due to the fact that the paramagnetic state (above $T_c$) is no longer the nonmagnetic state:

$$\Delta c_m = \frac{M_0^2}{4\chi_0 T_c} \quad (35)$$

As for the specific heat, spin fluctuations also have a major impact on the magnetomechanical properties and it has been shown that their presence not only reduces the spontaneous magnetostriction with respect to the Stoner model in the desired way, but also leads to a different (linear) pressure dependence of $T_c$ (Mohn *et al.* 1987):

$$\frac{T_c(P)}{T_c(P=0)} = \left(1 - \frac{P}{P_c}\right) \quad (36)$$

where $P_c$ is the critical pressure for the disappearance of magnetism.

In addition, the temperature dependence of the bulk magnetization differs from the Stoner result (Eqn. (14)) and reads:

$$\frac{M}{M_0} = \left(1 - \frac{T}{T_c}\right)^{1/2} \quad (37)$$

For low temperatures the reduction of the magnetic moment is stronger than in the Stoner model. The reason is the same as for the comparison of the Weiss and Heisenberg models, i.e., the collective modes described by the spin fluctuations can readily be excited at low temperature, where the Stoner excitations are still very small.

About at the same time Entel and Schröter (1988, 1989), Mohn *et al.* (1989b), and Wagner (1989) showed how bandstructure results derived from the "fixed spin moment" (FSM) method (Schwarz and Mohn 1984) can be implemented into the spin fluctuation theory. An explicit expression for the fluctuating magnetic moment can be derived from a Landau–Ginzburg expansion for the free energy, which also contains a gradient term to describe the local variation of the fluctuations:

$$H = \frac{1}{V}\int \mathrm{d}r[E(M + m(r))] + \frac{K}{2}\sum_{ij}(\nabla_j m_i)^2 \quad (38)$$

$E(M + m(r))$ is the dynamical form of the free energy as given by Eqn. (31). In addition, a quadratic gradient term is added containing a new coefficient $K$,

which measures the strength of the spin fluctuations. It should be noted that $K$ is analogous to the spin wave stiffness constant which appears in the Heisenberg model.

To calculate the free energy the partition function must be evaluated by integrating over all fluctuation variables. Since this integration cannot be carried out analytically for the assumed Hamiltonian one approximates the result by using the Peierls–Feynman (Peierls 1936, Feynman 1955) inequality which represents an effective mean-field treatment:

$$F \leqslant F_0 + \langle H - H_0 \rangle_0 \tag{39}$$

For the trial Hamiltonian the lowest order translationally invariant quadratic form in the fluctuations $m(r)$ is chosen:

$$H_0 = \frac{1}{V}\sum_{i=1}^{3} \int \mathrm{d}^3 r \int \mathrm{d}^3 r' \Omega_i(r - r') m_i(r) m_i(r') \tag{40}$$

where $\Omega_i(r-r')$ is used as a variational parameter to determine the optimal solution. It should be noted that the form used in Eqn. (40) resembles the Heisenberg–Hamiltonian, where the localized spins on the lattice sites $i$ and $j$ are replaced by fluctuating moments located on positions $r$ and $r'$. For the temperature dependence of the fluctuating moment:

$$\langle m_i^2 \rangle = \frac{k_\mathrm{B} T}{2} \frac{V}{8\pi^3} \int_0^{k_\mathrm{c}} \frac{4\pi k^2}{\frac{C}{2}k^2 + \frac{\partial \phi}{\partial \langle m_i^2 \rangle}} \, \mathrm{d}k \tag{41}$$

The function $\varphi$ is that part of the energy functional which depends on the fluctuations:

$$\phi = \frac{1}{V} \int \mathrm{d}^3 r \langle E(M + m(r)) - E(M) \rangle \tag{42}$$

In Eqn. (41) there appear two unknown parameters: the "spin wave stiffness" $K$ and the cut-off wave vector $k_\mathrm{c}$. The latter quantity must be introduced, since the Ornstein–Zernicke correlation function, which appears in the integrand, leads to a divergence if the integration is carried out to $k \to \infty$. A physical justification for the introduction of this cut-off may be found in the strong damping of the spin fluctuations by the single particle excitations for $k$ vectors larger than a critical value. From the zero-temperature properties of the derivative of in $\varphi$ the integrand of Eqn. (41) the spin wave stiffness constant $K$ by $\xi^2/\chi_0$ where $\xi$ is the correlation length and $\chi_0$ is the susceptibility can be replaced. Since $\partial\varphi/\partial\langle m_i^2 \rangle$ must vanish at $T = T_\mathrm{c}$, integration at $T_\mathrm{c}$ obtains a result similar to the Mohn–Wohlfarth model:

$$T_\mathrm{c} = \frac{M_0^2}{10\chi_0 k_\mathrm{B}} \frac{4\pi^2 \xi^2}{V k_\mathrm{c}} \tag{43}$$

In addition to Eqn. (34), here also the finite wavelength dependencies of the fluctuations are included which should lead to a wider applicability.

## 2. Examples

Historically it is assumed that the 3*d* transition metals are the prototypical representatives of itinerant electron magnets. They have noninteger magnetic moments and thus cannot be explained on the basis of any local moment model. However, the ideal "Stoner system" would rather be free electron like. This is somehow realized in the simple metals, which, due to the large bandwidth of the *s* electrons, are unfortunately all nonmagnetic. The key magnetic properties of the magnetic 3*d* transition metals are given in Table 2.

Phenomenologically one distinguishes between two classes of itinerant electron magnetic systems named weak- and strong ferromagnets. Their major properties are described as follows:

(i) Weak itinerant ferromagnets: majority carrier (spin up electrons) bands are not completely filled; minority bands often empty, unsaturated magnetic moments, large susceptibility, strong pressure dependence of the magnetic moment and the Curie temperature (alloys of iron with metals and metalloids with less than half-filled valence bands such as Fe–V, Fe–Cr, Y–Fe, Zr–Fe, etc. b.c.c. Fe).

(ii) Strong itinerant ferromagnets: majority carrier bands completely filled; minority bands partially filled, saturated magnetic moments, small susceptibility, small (often vanishing) pressure dependence of the magnetic moment and the Curie temperature (alloys of iron, cobalt, and nickel with metals and metalloids with more than half-filled valence band such as Fe–Co, Fe–Ni, Ni–Co, Ni–Cu, Ni–Zn, etc., h.c.p. Co, f.c.c. Ni, and f.c.c. Fe).

An example for the first group of weak itinerant electron magnets is given in Fig. 3, where the spin resolved density of states (DOS) of b.c.c. iron is shown. For the spin-polarized case (full line) the Fermi energy $\varepsilon_\mathrm{F}$ intersects the majority band just before the upper edge of the *d* band. For the minority band $\varepsilon_\mathrm{F}$ is located in a minimum of the DOS, a

position which is highly favorable in energy. Thus b.c.c. iron is an example for a system with an unsaturated magnetic moment. The dotted line shows the DOS for the hypothetical nonmagnetic state (majority and minority DOS are equal). The Fermi energy $\varepsilon_F$ lies in a region of rather large DOS, which is a prerequisite to fulfill the condition given by the Stoner criterion (Eqn. (12)). An example for the strong itinerant case is found in Fig. 4 for h.c.p. cobalt. The additional valence electron saturates the majority band, so that $\varepsilon_F$ lies above the spin up *d* band. This is the typical result for this class of itinerant ferromagnets, the resulting low DOS at $\varepsilon_F$ causes the small susceptibility observed. For both b.c.c. iron and h.c.p. cobalt, it can be observed that the shape of the majority and minority DOS is almost equal. For these monoatomic solids spin polarization

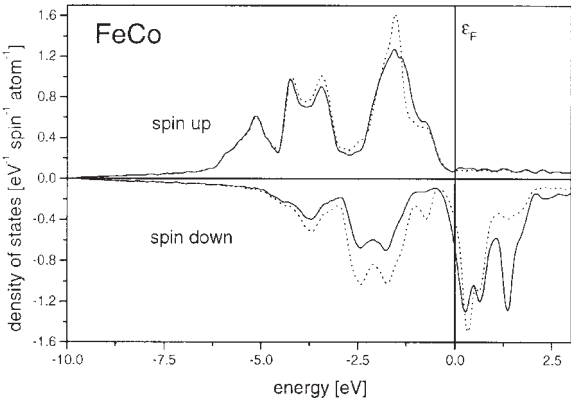

***Figure 5***

only produces a mutual shift between the spin up and spin down bands (see Fig. 1) an effect which is known as the rigid band picture. The resulting spin splitting can, for example, be measured from the energy difference of the respective DOS peaks in the middle of the *d* bands. The respective value for $\Delta E$ is 1.49 eV, which according to Eqn. (6) yields a Stoner exchange factor, *I*, of 0.98 eV.

In the case of magnetic alloys the rigid band picture breaks down. As an example the DOS for FeCo (in the CsCl structure) is shown in Fig. 5.

From the completely filled majority band it is obvious that FeCo is a strong ferromagnet. Due to the interaction with the neighboring cobalt atoms, the magnetic moment of iron is increased to 2.6 $\mu_B$ making iron a strong ferromagnet (in contrast to b.c.c. iron). The moment per cobalt atom is 1.7 $\mu_B$ which is only a minor increase compared to h.c.p. cobalt which already shows strong ferromagnetism. The density of states also nicely shows the influence of the spin splitting on the binding mechanism. For the majority spin both the iron and the cobalt *d* band are very much alike. For both constituents the spin up *d* band is filled and between the two atomic species a so-called *common band* is formed. In the minority band strong differences in the height of the iron and cobalt DOS are visible. Below $\varepsilon_F$ the cobalt DOS is larger than the iron DOS and vice versa above $\varepsilon_F$. This behavior is needed to accommodate the additional electron of cobalt. In general this kind of spin dependent interaction has been described as *covalent magnetism* (Williams *et al.* 1982).

As a general feature it must be mentioned that pure itinerant electron magnetism hardly ever occurs. The most prominent candidates for this extreme model are $ZrZn_2$ and $Ni_3Al$, both having very small magnetic moments and very large susceptibilities leading to small $T_c$ values. In most other magnetic transition

metal alloys the narrow 3*d* band leads to a certain degree of localization, which has to be taken into account. Examples for this latter behavior are most Mn compounds in particular the Mn containing Heusler alloys whose finite temperature magnetic properties have successfully be described on the basis of a Heisenberg model (Kübler *et al*. 1983).

## Josephson Junctions: High-$T_c$

With the advent of ceramic superconductors, attempts were very quickly made to translate the techniques known from classical superconducting electronics to this new class of materials. In classical superconductivity, Josephson junctions are generally fabricated in a multilayer technology, incorporating at least two superconducting layers (niobium or NbN) and between them either insulating layers for tunnel junctions ($Al_2O_3$, MgO, AlN, etc.) or normal conducting layers for proximity effect devices or combinations thereof for special junction types, e.g., SINIS junctions. For high-$T_c$ devices this concept turned out to be very difficult with the materials preparation techniques available at that time and with the very short coherence length of the high-$T_c$ superconductors (HTSs). It was recognized very early that grain boundaries in HTSs behave like Josephson junctions. Much research was done on how to prepare grain boundaries in HTSs in a controlled manner and to elucidate the relationship between grain boundary structure and critical current density, $j_c$, for the supercurrent. This led to the experimental verification of the prediction for a d-wave symmetry of the wave functions describing the superconducting state in a HTS. The results also made clear that grain boundary junctions are unlikely to create the necessary reproducibility needed for superconducting electronic devices. Nevertheless, as a research tool or for devices with a very small number of junctions like SQUIDs, the grain boundary junctions are very valuable.

Subsequently a new junction type has been demonstrated, which makes use of the high critical current densities in the *ab*-planes of the HTS and the epitaxial growth of homologous perovskite materials onto a ramp, cut into the superconductor under a flat angle. Even though the fabrication process is more complicated, the reproducibility and controllability of these junctions is much better than that of grain boundary junctions. Circuits of some tens of junctions can be realized with reasonable chance of success. In various forms, this junction type is the standard in research laboratories and industry for circuits with about 10 junctions or more.

The $I_cR_n$ product of HTS Josephson junctions strongly influences the switching speed and maximum frequency in digital circuits and oscillators and the modulation voltage for SQUIDs. Whereas at low temperatures $I_cR_n$ products of 30 mV or more were originally expected for YBaCuO Josephson junctions, the maximum values reached are about 9 mV. Most junctions, however, only show an $I_cR_n$ product of a few hundred microvolts at their operation temperature. It is clear that interfaces between electrode and barriers of the Josephson junctions play an important role. It has been shown that band bending effects at these interfaces probably play an important role in decreasing their transparency. There are strong indications that calcium doping near the interface might decrease the band bending.

### *1. Grain Boundary Junctions*

The first HTS Josephson junctions were based on the naturally occurring grain boundaries in sintered bulk materials or in polycrystalline films prepared by the two-step method. It was possible to demonstrate the Josephson effect and SQUID operation with these junctions, but a controlled preparation was impossible. After the epitaxial growth of YBCO on $SrTiO_3$ was demonstrated, Dimos *et al.* (1990) used this technique to prepare the first controlled grain boundaries on a $SrTiO_3$ bicrystal: two crystals of $SrTiO_3$ with different orientation of the crystal axes are glued together, so that an artificial grain boundary is created.

YBCO films epitaxially grown on top of the bicrystal have the same orientation as the substrate and form a grain boundary with the same angle as the bicrystal at the bicrystal interface (see Fig. 1(a)). By changing the angle of the bicrystal, grain boundaries in the YBCO films with different angles can be created. In this way more complicated grain boundary structures can also be created such as tri-ray and multiple parallel structures.

The electrical transport through such a grain boundary shows Josephson behavior, which can be described by an RSJ model with some capacitive loading. The normal resistance and the critical current density of the grain boundary junction depend on the grain boundary angle (see Fig. 1(b)).

Whereas the electrical transport can be described by simple models, the magnetic field dependence of the critical current density is complicated and shows only a vague resemblance to the Fraunhofer pattern found for classical Josephson junctions. This behavior was for long attributed to inhomogeneities in the grain boundary. Subsequent work has shown instead that the magnetic field dependence can be explained by a d-wave symmetry of the wave function describing the state of the superconductor.

The local structure of the grain boundary leads to locally back-flowing currents and thus to a mixture of positive and negative current densities along the junction. Simulations assuming d-wave symmetry yield good agreement with measured results for the magnetic field dependence. In contrast to the well-known flux lines containing $\Phi_0 = h/2e$, flux lines

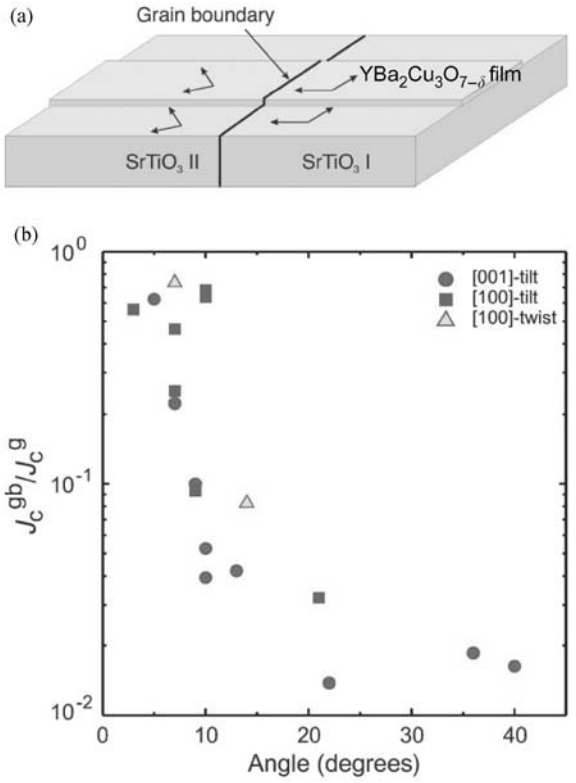

***Figure 1***

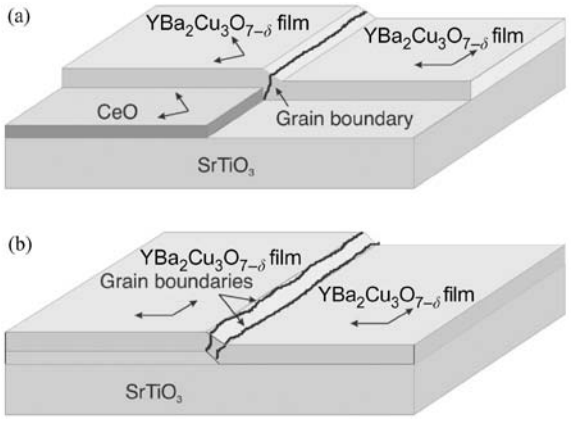

***Figure 3***
(a) Seed layer and (b) step edge Josephson junctions.

containing $\Phi_0/2$ can spontaneously occur at interfaces. Tsuei and Kirtley (2000) predicted the d-wave symmetry and showed experimentally using a tricrystal grain boundary ring structure (see Fig. 2) that the predicted flux lines with half-integer flux quanta exist.

In this geometry two of the three junctions are normal Josephson junctions, the third is a Josephson $\pi$-junction, in which an additional phase shift of $\pi$ occurs owing to the symmetry of the d-wave function:

$$J = J_0 \sin\varphi (\text{normal Josephson junction})$$

$$J = J_0 \sin\varphi + \pi = -J_0 \sin\varphi (\text{Josephson } \pi\text{-junction})$$

The Josephson $\pi$-junction is unique to HTSs. It can simplify the design of superconducting electronics circuits and it opens opportunities for new applications, e.g., qubits for quantum computing.

In addition to the bicrystal method, a number of other methods exist for creating artificial grain boundaries. The two principal ones are seed layer junctions and step edge junctions (Fig. 3). Seed layer junctions make use of the fact that some oxide layers grow on top of each other epitaxially, but rotated in their crystal axes by a certain angle owing to a mismatch of the lattice parameters. The complicated grain boundary structures result in poor Josephson behavior and bad reproducibility. Step edge junctions in contrast can yield junctions of high quality, although this technique is also not very reproducible.

For fabrication one has to prepare a step on a substrate surface, which is either done by etching away part of the substrate or by locally adding (homo)epitaxially a layer on top of the substrate. Step height and angle are critical. Deposition of a thin film of a HTS on top results in the formation of grain boundaries at the top and the bottom edge of the step. A step edge Josephson junction thus consists of two series-connected closely coupled Josephson junctions. In general some roughening owing to the etching or lithographic process occurs along the step resulting in complicated grain boundary structures along the edge. For a small number of Josephson junctions next to each other as needed in SQUID applications, these junctions are quite similar in general. High-quality step edge junctions have successfully been fabricated and incorporated in SQUID structures.

## 2. *Josephson Junctions with Artificial Barriers*

Two advantages of classical planar Josephson junctions are the ability to fabricate it anywhere on a substrate and to change its transport properties in a controlled way, e.g., engineer the composition of the barrier down to the atomic level by thin-film deposition techniques. For high-$T_c$ Josephson junctions one would also like to adjust the barrier transparency and its height and fabricate the junction in places where it would be needed from circuit design requirements and not vice versa. In this sense planar high-$T_c$ Josephson junctions would be ideal. Not only is the circuit design and layout well known from classical superconductivity, but also barrier material and barrier thickness could be varied or even complex barrier structures realized.

### 2.1 *Planar Junctions*

HTSs are strongly anisotropic with significantly higher critical current densities in the Cu–O *ab*-planes than for transport along the *c*-axis. The quasi two-dimensional behavior leads to the possibility of building junctions by layer-by-layer engineering, choosing layer compositions that enable epitaxial growth on one side that modify the transport properties from superconducting to normal conducting or insulating behavior over a length scale of one or very few perovskite building blocks on the other side.

Such work requires extreme growth control of the materials and is practically only possible in oxide-MBE machines or pulsed laser deposition systems with similar controls. Bozovic and Eckstein (1997) have done pioneering work especially by applying MBE to the growth of bismuth compounds and to the modification of transport properties in the *c*-axis direction (see Fig. 4). Even though the critical current densities are still quite low, MBE seems to be the way towards a reproducible fabrication of large numbers of high-$T_c$ Josephson junctions.

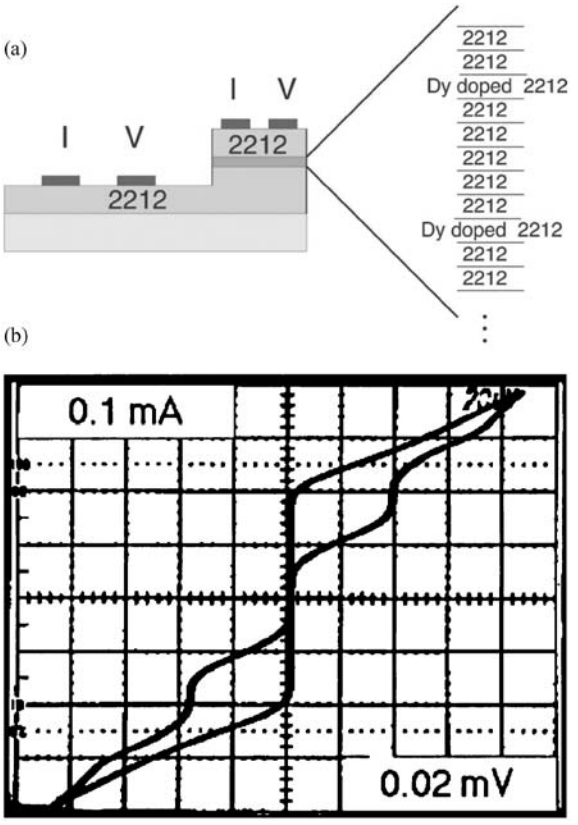

***Figure 4***
Layer-by-layer engineering of bismuth compounds for HTS Josephson junctions: (a) cross-section through a sandwich; (b) *I–V* characteristics of the resulting Josephson junction.

The fabrication of planar Josephson junctions has been tried in a number of ways. Attempts to isolate natural tunnel junctions from bismuth compounds (transport in the *c*-axis direction) have been successful. These junctions show interesting characteristics, but have only little practical impact. Attempts to make use of the *c*-axis coupling in YBaCuO or to grow sandwich structures on *a*-axis-oriented YBaCuO results in irreproducible Josephson junction behavior, with very unrealistic decay length for the transport through the structures. Sandwich junctions on 103-oriented YBaCuO have shown some success, these junctions showing reproducibility comparable to other high-$T_c$ Josephson junctions.

### 2.2 *Ramp-type Josephson Junctions*

Ramp-type Josephson junctions form the basis for most applications in which 10 or more junctions are needed. They are based on the idea that the barrier

for Josephson operation should separate the CuO planes capable of carrying high current densities and transporting the supercurrents to the barrier. A schematic cross-section is depicted in Fig. 5(a). The most critical step is the cut through the base sandwich under a flat angle without destroying the surface of the ramp for subsequent epitaxial growth of the barrier and counter-electrode. Depending on the type of

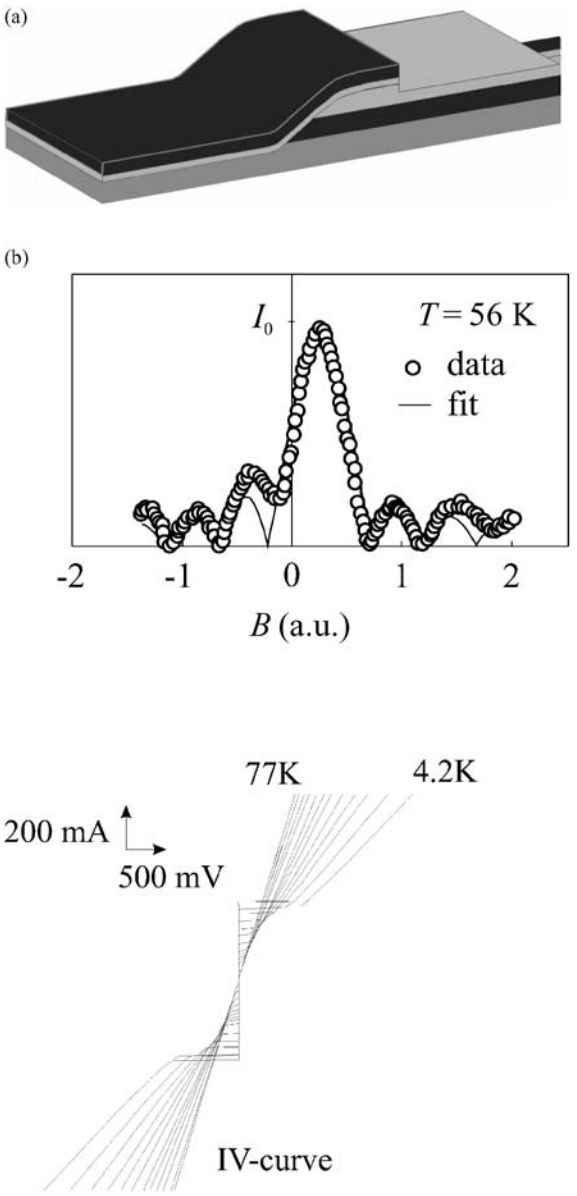

***Figure 5***
(a) Schematic and (b) magnetic field dependence and $I$–$V$ characteristics of a typical ramp-type junction.

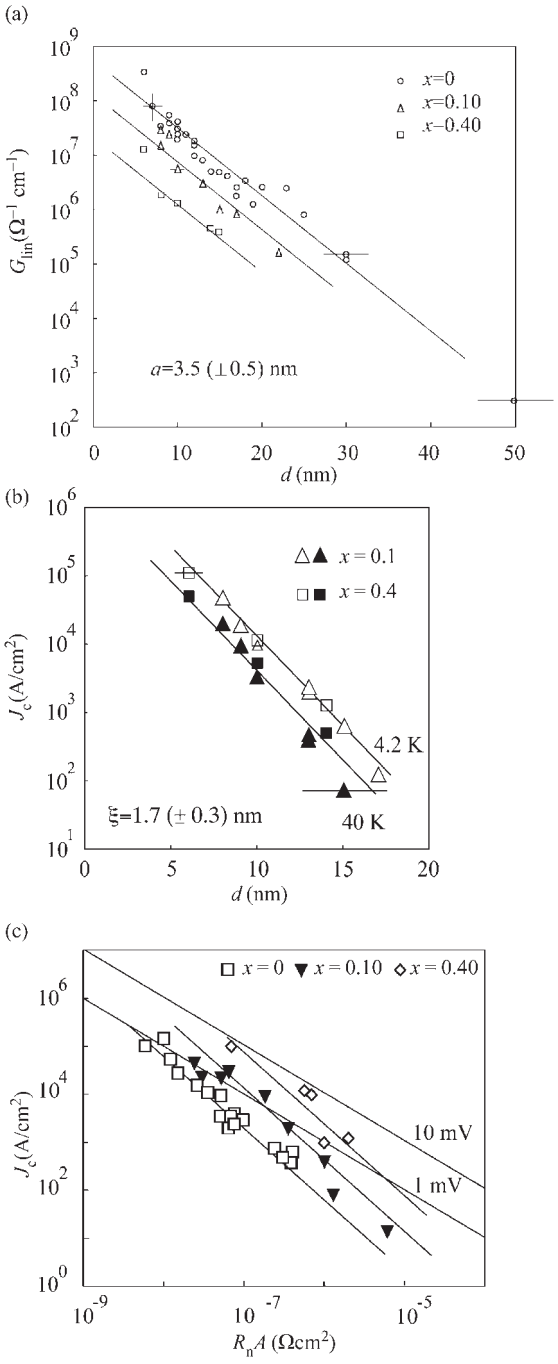

***Figure 6***
Dependence of (a) normal state conductance and (b) critical current density on the barrier thickness for gallium-doped PrBaCuO for different doping levels. (c) Relationship between critical current density and specific resistance with lines of constant $I_cR_n$ product.

barrier and thickness, the critical current density and the normal resistance of the junction can be adjusted.

The most promising barrier for operation at 77 K is cobalt-doped YBaCuO. Also "interface engineered" junctions have received a lot of attention because of their slightly better reproducibility. For operation at temperatures below 50 K, e.g., for digital applications, PrBaCuO barriers are very attractive. With this barrier material the critical current density and the normal resistance can be adjusted independently (see Fig. 6(a))—the critical current density via the thickness of the barrier and the normal resistance via the amount of gallium doping, which enhances the specific resistance with increasing gallium content.

### 2.3 *High-$T_c$–Low-$T_c$ Junctions*

In an effort to combine high-$T_c$ and low-$T_c$ junctions on the same chip, high critical current density transitions between high-$T_c$ and low-$T_c$ superconductors have been developed in the form of ramp-type junctions with YBaCuO base electrode, gold barrier, and niobium counter-electrode. These junctions show excellent Josephson characteristics (see Figs. 7(a) and (b)) with little parameter spread. In addition, these junctions can be prepared on ramps with an orientation in different crystallographic directions, thus yielding junctions with 0- to $\pi$-junction characteristics. Such junctions combine the reproducibility of the low-$T_c$ junctions with the high $I_cR_n$ product and the unique d-wave characteristics of HTSs.

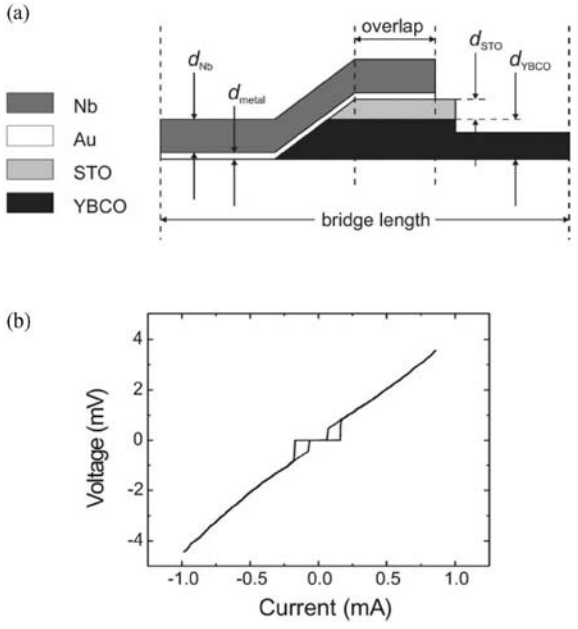

***Figure 7***
YBaCuO/Au/Nb ramp-type junction: (a) cross-section; (b) *I–V* characteristics.

### 2.4 *Electron Beam and Ion Beam Josephson Junctions*

Oxygen-deficient or structurally damaged regions of HTSs have a lower $T_c$ or become normally conducting or even insulating. Such damage can be introduced locally by high-energy bombardment with electrons or with ions. In this way a Josephson junction can be "written" into a thin film of YBaCuO. The resulting junctions show good nonhysteretic Josephson behavior. For electron beam writing, electron microscopes with an acceleration voltage of about 400 keV are needed; for ion beam writing, focused ion beam (FIB) etchers are applied with an acceleration voltage of about 30 keV. Quite high radiation doses are needed to prepare the barrier, so that the writing speed is quite low. In addition, the junction parameters cannot easily be modified. Nevertheless, electron beam and FIB writing is attractive for the prototyping of simple superconducting circuits but cannot be considered as a production-type technique.

## 3. *Conclusion*

The availability of reliable and reproducible high-$T_c$ Josephson junctions depends strongly on advances in materials research in the area of perovskites and the refined control of the deposition of these materials, both for composition and structure. The techniques for the preparation of high-$T_c$ Josephson junctions are sufficient for small electronics circuits with about 10–50 Josephson junctions. For applications with a larger number of junctions, the knowledge of fabrication and understanding of these materials has to be improved significantly in order to reach the required reproducibility.

# Josephson Junctions: Low-$T_c$

In the field of superconducting electronics, Josephson junctions with electrodes made of niobium thin films ($T_c = 9.0$–$9.3$ K) or niobium nitride (NbN) thin films ($T_c = 14$–$17$ K) play an important role. For example, Josephson junctions with niobium thin films as electrodes and very thin aluminum oxide layers as barriers ($Nb/AlO_x/Nb$ junctions) are widely used for implementing practical superconducting devices, e.g., superconducting quantum interference devices (SQUIDs) for biomedical applications (see *SQUIDs: Biomedical Applications*), superconductor–insulator–superconductor (SIS) mixers for radio astronomy, and Josephson junction devices for voltage standards (see *Josephson Voltage Standard*). Also, $Nb/AlO_x/Nb$ junctions are used for demonstrating the performance of various digital and analog circuits that are operated based on Josephson effects. This is because $Nb/AlO_x/Nb$ junctions are extremely stable with respect to thermal cycling and storage in air, have high-quality tunneling characteristics, and can be fabricated with good run-to-run reproducibility. Josephson junctions with NbN thin films as electrodes are used for fabricating superconducting devices with unique performance, e.g., an SIS mixer having low noise temperatures at a frequency range over 700 GHz and an analog-to-digital converter operated at 10 K.

This article describes the fabrication, electrical characteristics, and stability of $Nb/AlO_x/Nb$ junctions and NbN Josephson junctions.

## 1. $Nb/AlO_x/Nb$ Junctions

### 1.1 Fabrication

The first successful fabrication of $Nb/AlO_x/Nb$ junctions was reported by Gurvitch *et al.* (1983), followed by a large number of reports on the characterization of junctions and the development of technologies for fabricating junctions with high yield, high uniformity, and high reproducibility. The adoption of aluminum as a barrier material for Josephson junctions with niobium electrodes was motivated by the fact that aluminum shows a suitable wettability on fresh surfaces of niobium. Because of the affinity of aluminum to niobium, an aluminum layer deposited on a niobium base electrode well covers the surface of the electrode even when the thickness of the overlayer is very small ($< 10$ nm). This enables the formation of a uniform and pinhole-free tunnel barrier by thermally oxidizing an aluminum layer on a niobium electrode, resulting in the fabrication of a high-quality junction. However, there exist several causes that induce deterioration of junction characteristics. For example, Huggins and Gurvitch (1985) emphasized that heat sinking of the substrate to a water-cooled table during the junction preparation is crucial for obtaining a high yield of high-quality samples. Experimental results suggest that without heat sinking of the substrate, diffusion of oxygen atoms in the barrier into the electrodes occurs by elevation of the substrate temperature during the deposition of the counter electrodes. Kuroda and Yuda (1988) have claimed that relaxation of stress in sputter-deposited niobium films with etching of the films causes deformation of the electrodes, resulting in large leakage currents in junctions.

Fabrication of $Nb/AlO_x/Nb$ junctions is generally carried out in a sputtering system with a stainless steel chamber (or chambers), a water-cooled substrate holder (or holders), sputtering targets of niobium and aluminum, and a vacuum pump (or pumps)

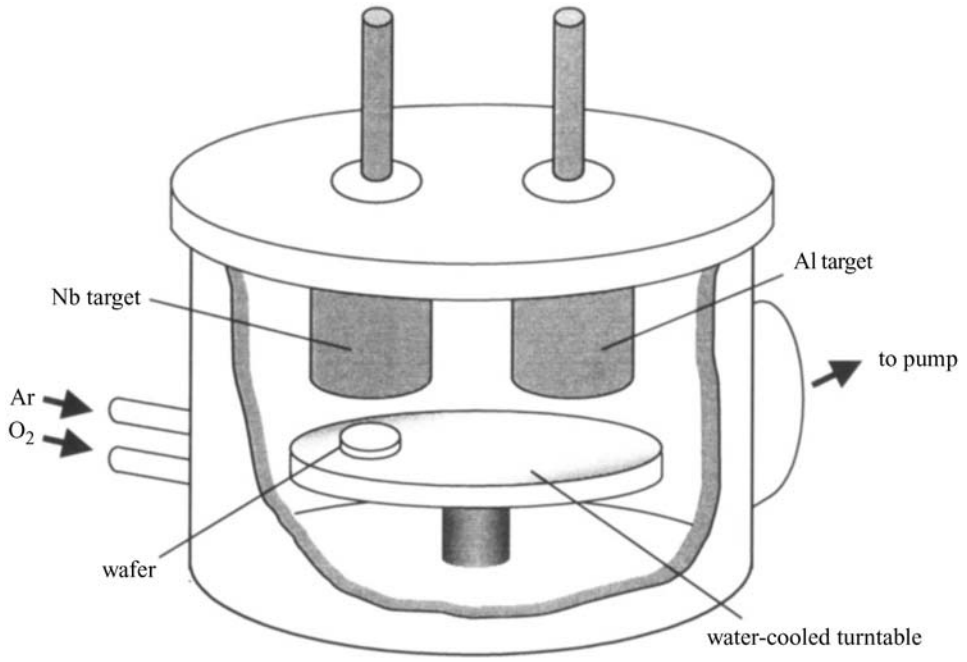

***Figure 1***
Schematic of a sputtering system used for fabricating Nb/$AlO_x$/Nb junctions.

(see Fig. 1). A wafer (usually a single crystal of silicon) with a mirror polished surface is set on the substrate holder (the turntable in Fig. 1) with a good thermal contact. After filling the chamber with research-purity argon up to a pressure of 1–2 Pa, a niobium film (100–200 nm) is deposited on the wafer by sputtering the niobium target. A very thin aluminum layer (5–10 nm) is then deposited on top of the niobium film by sputtering the aluminum target. The formation of a tunnel barrier is achieved by oxidizing the aluminum layer in a static atmosphere of pure oxygen. The pressure of oxygen gas and oxidation time are set so as to obtain a targeted critical current density, $J_c$, for the junctions (Miller *et al*. 1993). After finishing the formation of a tunnel barrier, a niobium film (100–200 nm) for the counter electrodes of the junctions is deposited in an argon atmosphere, resulting in the formation of a junction sandwich on the wafer (Fig. 2(a)).

Definition of individual junctions from the junction sandwich is performed using photolithography and etching techniques. After taking the wafer out of the sputtering system, the wafer is covered with a photoresist pattern that defines the base electrodes of the junctions. Multilayers unprotected by the photoresist pattern are then removed by wet etching or dry etching (Fig. 2(b)). The definition of individual junctions is performed by trimming the counter niobium film in a reactive gas using another photoresist pattern as a mask (Fig. 2(c)). Next, an insulation film (usually a sputtered $SiO_2$ film) is deposited onto the sample to protect the exposed surface of the base electrodes (Fig. 2(d)). Via holes for making contacts to junctions are then fabricated by locally etching the insulation film in a reactive gas (Fig. 2(e)). Finally, wiring electrodes are fabricated by depositing a niobium film on the sample and trimming with a reactive gas (Fig. 2(f)).

The process used for fabricating Nb/$AlO_x$/Nb junctions is called a ''whole-wafer'' process because a junction sandwich is formed on the whole surface of a wafer prior to the lithographic processes. The advantage of the ''whole-wafer'' process is that all wet processes are excluded from the formation of the junction sandwich, enabling fabrication of junctions with good run-to-run reproducibility. The concept of the ''whole-wafer'' process was first demonstrated by Kroger *et al*. (1981) in the fabrication of Nb/Si:H/Nb junctions.

### *1.2 Electrical Characteristics*

Measurement of current–voltage (*I–V*) characteristics for Nb/$AlO_x$/Nb junctions is, in general, carried out while immersing the sample in liquid helium since all devices fabricated using Nb/$AlO_x$/Nb junctions are operated at liquid helium temperature (4.2 K), with a

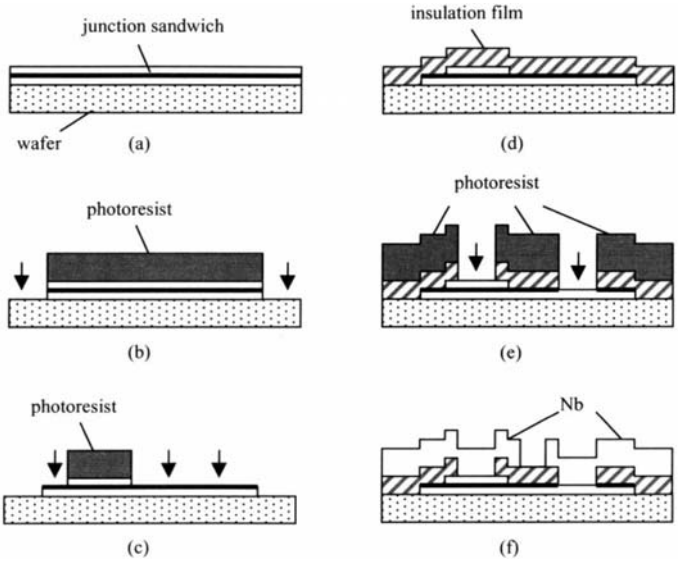

***Figure 2***
Fabrication process of a $Nb/AlO_x/Nb$ junction.

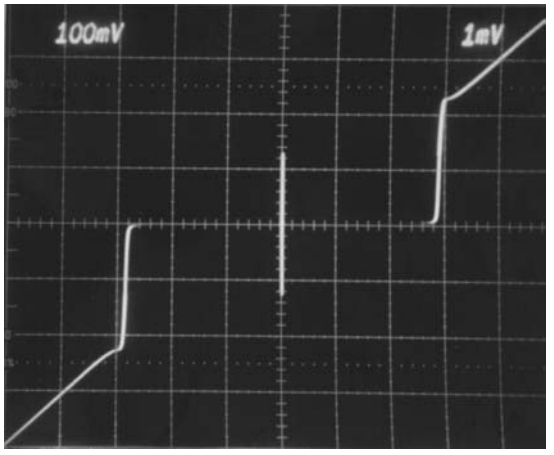

***Figure 3***
*I–V* characteristic for a $Nb/AlO_x/Nb$ junction at 4.2 K (vertical axis: 1 mA per division; horizontal axis: 1 mV per division).

few exceptions. During the measurement of *I–V* characteristics, the sample is surrounded with $\mu$-metal or niobium cans to minimize the influence of external magnetic fields, e.g., the terrestrial magnetic field. An *I–V* characteristic measured for a $Nb/AlO_x/Nb$ junction at 4.2 K is shown in Fig. 3. Like this example, at 4.2 K $Nb/AlO_x/Nb$ junctions typically show high-quality tunneling characteristics with a well-defined gap and very small subgap leakage currents.

The gap voltage, $V_g$, which is defined as the voltage at which the slope of the *I–V* curve becomes a maximum, is 2.9 mV for the junction in Fig. 3, very close to the theoretical value (3.0 mV) calculated for a Josephson tunnel junction with niobium base and counter electrodes. This means that the superconducting properties in the base and counterelectrodes of the junction are as good as that for bulk niobium. The relative amplitude of leakage currents for a Josephson tunnel junction can be evaluated by a ratio of a static resistance measured below $V_g$ (typically at a voltage near half of $V_g$) and a static resistance measured above $V_g$ (typically at a voltage more than twice $V_g$).

The former is called the subgap resistance, $R_{sg}$ and the latter the normal resistance, $R_n$. $Nb/AlO_x/Nb$ junctions typically have $R_{sg}/R_n$ values exceeding 10 unless their critical current density is extremely high. The specific capacitance, $C_s$, i.e., a capacitance per unit area, for a Josephson tunnel junction is an important parameter in the design of SQUIDs, SIS mixers, etc. $C_s$ values for $Nb/AlO_x/Nb$ junctions have been estimated from measurement of Fiske modes for junctions (van der Zant *et al.* 1994) and measurement of resonant voltages for SQUIDs (Maezawa *et al.* 1995).

### *1.3 Stability*

The stability of $Nb/AlO_x/Nb$ junctions against thermal cycling, aging at room temperature, and annealing at an elevated temperature has been examined. In

one study (Gates *et al.* 1984) 400 Nb/$AlO_x$/Nb junctions were cycled 4880 times between room temperature and 6 K, resulting in no failures due to shorts and no change in the average critical currents. The same junctions were then aged in a nitrogen atmosphere at room temperature for two months, resulting in no change in the average critical currents. Finally, the junctions were annealed at 100 °C for 2 h in a helium atmosphere, again resulting in no change in the average critical currents. A finite change (reduction) in the critical currents was observed after the junctions had been annealed at 150 °C.

## 2. *NbN Josephson Junctions*

### *2.1 Fabrication*

Fabrication of Josephson junctions with NbN films as base and counter electrodes was first reported by Shinoki *et al.* (1981). Reactively sputter-deposited NbN films were used as electrodes and amorphous silicon (a-Si) films that had been produced by glow discharge decomposition of silane (5% $SiH_4$ and 95% argon) as tunnel barriers. The NbN/a-Si/NbN junctions showed good tunneling characteristics with small subgap leakage currents. However, their gap voltages remained at 4.2 mV, much lower than the theoretical gap voltage (>6 mV) for a Josephson tunnel junction with NbN base and counter electrodes. Improvement of the gap voltage for NbN junctions was made by Shoji *et al.* (1985) by introducing very thin MgO films (<1 nm) as tunnel barriers and a "whole-wafer" process to the junction fabrication. MgO is employed as a barrier material for NbN junctions since it has the same structure (B1: f.c.c., NaCl type) as NbN and a lattice parameter close to that of NbN. Wang *et al.* (1997) reported NbN junctions with reactively sputter-deposited aluminum nitride (AlN) barriers had gap voltages as large as those for NbN/MgO/NbN junctions. AlN also has B1 structure and a lattice parameter close to that of NbN.

### *2.2 Electrical Characteristics*

An *I–V* characteristic measured for a NbN/MgO/NbN junction at 4.2 K is shown in Fig. 4. Like this example, NbN/MgO/NbN junctions typically show good *I–V* characteristics at 4.2 K with gap voltages greater than 5 mV and small subgap leakage currents. This is the same as for the case of NbN/AlN/NbN junctions. The $V_g$ values for NbN/MgO/NbN and NbN/AlN/NbN junctions are roughly twice those for Nb/$AlO_x$/Nb junctions, but are still smaller than the theoretical $V_g$ value for all-NbN junctions. The reduction of experimental $V_g$ values from the theoretical value mainly arises from lower superconducting energy gaps in counter electrodes than in base electrodes. The relative

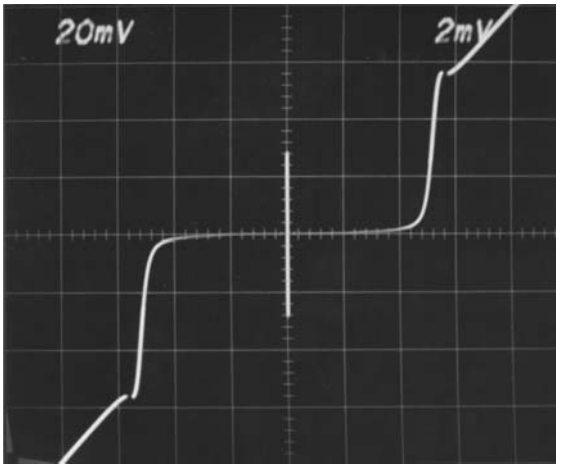

***Figure 4***
*I–V* characteristic for a NbN/MgO/NbN junction at 4.2 K (vertical axis: 0.2 mA per division; horizontal axis: 2 mV per division).

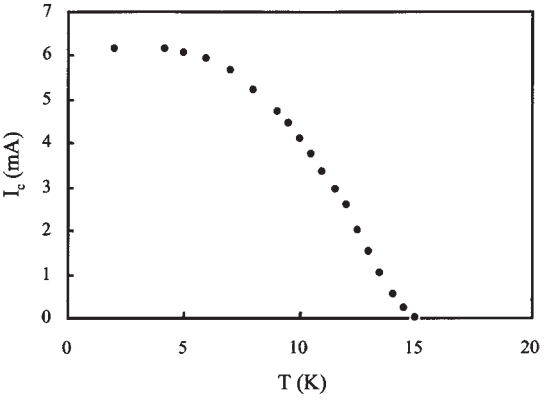

***Figure 5***
Temperature dependence of critical current for a NbN/MgO/NbN junction.

amplitude of leakage currents for NbN/MgO/NbN and NbN/AlN/NbN junctions depends strongly on their critical current density. For example, NbN/MgO/NbN junctions with $J_c < 1\,kAcm^{-2}$ typically have $R_{sg}/R_n > 10$, while junctions with $J_c > 1\,kA\,cm^{-2}$ have $R_{sg}/R_n < 10$. A theoretical explanation for the reduction of $R_{sg}/R_n$ values with increase in critical current density has not been given. $C_s$ values for NbN/MgO/NbN and NbN/AlN/NbN junctions have been estimated from measurement of Fiske modes (Shoji *et al.* 1985) and measurement of resonant voltages for SQUIDs (Wang *et al.* 1997), respectively.

Critical currents for a NbN/MgO/NbN junction measured at 2 K and higher temperatures are plotted in Fig. 5. As can be seen, owing to high superconducting

critical temperature (14–17 K) in NbN electrodes, critical currents of NbN Josephson junctions at 10 K are more than 60% of those at 4.2 K. This has stimulated development of Josephson devices that are operated at 10 K with a compact closed-cycle refrigeration system.

### *2.3 Stability*

As is the case for $Nb/AlO_x/Nb$ junctions, Josephson junctions having NbN electrodes show extremely high stability with respect to thermal cycling and storage in air. Furthermore, because NbN is less chemically active, Josephson junctions with NbN electrodes can withstand a higher processing temperature than those with niobium electrodes.

## *3. Summary*

Fabrication of high-quality Josephson junctions with sputter-deposited niobium films or reactively sputter-deposited NbN films as electrodes has been achieved by the use of barrier materials fit to the electrodes and the introduction of a ''whole-wafer'' process. In the case of Josephson junctions with niobium electrodes, aluminum is employed as a barrier material since it shows suitable wetting on a fresh surface of niobium. Because of the affinity of aluminum to niobium, an aluminum layer deposited on a niobium electrode covers the surface of the electrode well, resulting in the formation of a uniform and pinhole-free tunnel barrier by thermal oxidation of the aluminum layer. The introduction of a ''whole-wafer'' process enables junctions to be fabricated with good run-to-run reproducibility. In the case of Josephson junctions with NbN electrodes, high-quality tunneling characteristics with gap voltages greater than 5 mV and small subgap leakage currents have been achieved by the use of very thin MgO or AlN films as tunnel barriers. Both materials have the same structure as NbN and lattice parameters close to that of NbN, which must be the origin of the improved junction characteristics.

# Josephson Voltage Standard

The electronic system of a macroscopic superconductor is characterized by the formation of electron pairs, so-called Cooper pairs (Bardeen *et al.* 1947), which carry d.c. currents without these being dissipated. The Cooper pair system of two separated superconductors can be described by two independent single macroscopic order parameters $\psi_{1,2} = |\psi_{1,2}|\exp(i\varphi_{1,2})$, the time evolution of which is expressed by the Schrödinger equation $\partial\psi_{1,2}/\partial t = (-i/\hbar)E_{1,2}\psi_{1,2}$. $E_{1,2}$ are the energies of the Cooper pair systems and $|\psi_{1,2}| = (n_{1,2})^{1/2}$ denotes the Cooper pair densities $n_{1,2}$. In 1962 Josephson described the phenomenon of Cooper pair transport between two weakly coupled superconductors by two equations:

$$I_J = I_c \sin\varphi \text{ and } V(t) = (\hbar/2e)\mathrm{d}\varphi/\mathrm{d}t$$

The first Josephson equation denotes the superconducting d.c. Cooper pair current across the barrier dependent on the phase difference $\varphi_2 - \varphi_1 = \varphi$ of the order parameters of the two weakly coupled superconductors: a Josephson junction. $I_c$ is the maximum possible supercurrent. The second equation shows that the voltage across a Josephson junction is proportional to the time derivative of the phase difference (see *Josephson Junctions: Low-$T_c$*, *Josephson Junctions: High-$T_c$*). If the Josephson junction is biased by a constant voltage, $V(t)$ in the second Josephson equation is replaced by the constant value $V$. Integrating

the equation and introducing the result $\varphi = \varphi_0 + (2e/\hbar)Vt$ into the current equation, one obtains $I = I_c \sin(\omega t + \varphi_0)$, which describes an alternating supercurrent with frequency $f = \omega/2\pi = 2e/V$. The Josephson junction is a high-frequency oscillator that converts a frequency into a voltage: $V = (h/2e)f = \varphi_0 f$.

The parameter $\varphi_0$ denotes the flux quantum. The d.c. voltage across a Josephson junction is the rate of flux quanta transferred across the junction. If the Josephson oscillator is phase locked to an external microwave oscillator with a well-known frequency, $f_e$, constant voltage steps appear at $V_n = n\varphi_0 f_e$ ($n = 1, 2, 3 \ldots$) in the nonlinear d.c. characteristic of the junction (Shapiro 1963). For the $n$th harmonic the current range, $\Delta I_n$, over which the junction oscillator is phase locked to the external oscillator is described by $\Delta I_n = 2I_c |J_n(2eV_{rf}/\hbar\omega_e|$, where $V_{rf}$ is the radio-frequency (RF) voltage amplitude across the junction. The precision of the voltage steps is determined only by the uncertainty of $f_e$, which can be kept smaller than $10^{-11}$ by means of modern frequency standards like atomic cesium clocks. This makes the voltage steps ideal reference voltages for standard voltage measurements. The maximum step voltage (e.g., $V_1 \approx 145\,\mu V$ for $f_e = 70\,GHz$) is limited by the energy gap voltage of the superconducting electrodes (e.g., 2.5 mV for niobium).

In contrast to the ideal Josephson contact described above, a real junction is a parallel connection of the external current source $I(t) = I_0 + I_1 \sin \omega_e t$, the junction normal-state resistance $R_n$, the junction capacitance $C$, and the ideal Josephson inductance $I = I_c \sin \varphi$. If the currents are distributed homogeneously across the junction area $A$, this circuit is described by

$$I_0 + I_1 \sin \omega_e t = I_e \sin \varphi + V(t)/R_n + C dV(t)/dt$$

(Stewart 1968, McCumber 1969, Kautz 1981). With $V(t) = (\hbar/2e)d\varphi/dt$, $i_0 = I_0/I_c$, $i_1 = I_1/I_c$, $\Omega = \hbar\omega_e/2eI_cR_n$, $t' = \hbar t/2eI_cR_n$, and $\beta = 2eI_cR_n^1C/\hbar$, one obtains a dimensionless differential equation for a damped driven oscillator:

$$\beta d^2\varphi/dt^2 + d\varphi/dt + \sin \varphi = i_0 + i_1 \sin(\Omega t')$$

where $\beta^{1/2}$ is the quality factor for the LC Josephson resonator and characterizes the damping of the Josephson oscillator.

Large values of $R_n$ and $C$ lead to low junction damping and thus to a hysteresis in the d.c. characteristic. Particularly, superconductor–insulator–superconductor (SIS) tunnel junctions provide very low damping and a strong hysteresis in the d.c. characteristic (Fig. 1(a)). Moreover, in this case, the quasiparticle branch of the d.c. characteristic more or less follows the voltage axis at nearly zero current for voltages smaller than the gap voltage. Therefore, the constant voltage steps may cross the voltage axis with the effect that reference voltages are generated without any current flowing across the junctions (Fig. 1(b)). The zero current steps generally are multivalued: up to about seven defined voltage steps per junction for $f_e = 70\,GHz$. Other junction types made of superconductor–normal metal–superconductor (SNS) sandwiches or superconductor–insulator–normal metal–insulator–superconductor (SINIS) sandwiches (Maezawa and Shoji 1997, Sugiyama *et al.* 1997, Kupriyanov *et al.* 1999) show much higher damping and thus no hysteresis in the d.c. characteristic (Fig. 1(c)).

There is only one reference voltage step at a certain bias current (Fig. 1(d)), which makes the reference voltage single valued but also results in an arbitrarily lower maximum output reference voltage per single junction at a given frequency. Typical junction data are given in Table 1.

## *1. Conventional SIS Voltage Standard*

Figure 1 shows that a single Josephson junction generates reference voltages not much higher than about 1 mV. Early voltage standards on the basis of a single junction, together with a conventional voltage divider, provided an output voltage of 1 V with an uncertainty of about $5 \times 10^{-8}$ V (Kose 1974). The accuracy of these instruments was finally limited by the complex calibration procedure for the voltage divider. Further improvement could therefore be achieved only by an increase in the Josephson reference voltage from a few millivolts to values of 1 V or more by means of large series arrays of Josephson junctions. To realize such a series array voltage standard, the use of underdamped SIS tunnel junctions has been suggested (Levinsen *et al.* 1977), because for zero current steps it would not be necessary to have a small junction parameter spread. In the zero current mode a parasitic series resistance would not create errors and the maximum output reference voltage of about 1 mV per junction in the case of niobium electrodes would limit the junction number to a technologically acceptable value (about 1000 junctions for 1 V). In addition, a large number of quantized voltages between zero and the maximum output voltage for convenient nonlinearity or voltage ratio measurements can be adjusted.

To operate successfully such a series array of underdamped tunnel junctions, two problems must be solved.

(i) The single junction is a nonlinear, underdamped oscillator that has to be coupled to the external oscillator without creating chaos (for an overview see Kautz 1996). To reach the goal of a stable phase lock with the external oscillator, the resonance frequency of the Josephson oscillator, $\omega_p = (2eI_c/\hbar C)^{1/2}$, should be kept lower than the frequency of the external drive, $\omega_e$. Moreover, the

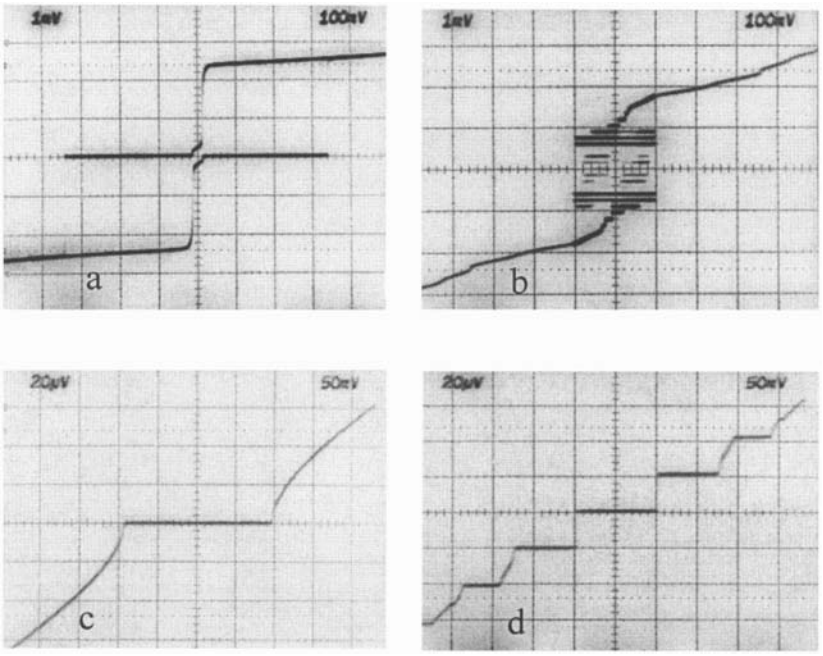

***Figure 1***
d.c. characteristic of (a) Nb–$Al_2O_3$–Nb tunnel junction (vertical: 1 mV per division; horizontal: 0.125 mA per division); (b) Nb–$Al_2O_3$–Nb tunnel junction under 70 GHz microwave radiation (vertical: 1 mV per division; horizontal: 0.125 mA per division); (c) Nb–PdAu–Nb junction (vertical: 20 μV per division; horizontal: 0.4 mA per division); (d) Nb–PdAu–Nb junction under 10 GHz microwave radiation (vertical: 20 μV per division; horizontal: 0.4 mA per division).

***Table 1***
Typical junction parameters for SIS, SNS, and SINIS junctions.

| Parameter | SIS | SNS | SINIS |
|---|---|---|---|
| $\beta_c$ | $10^5$ | $\rightarrow 0$ | 1 |
| $I_cR_n$ | 1 mV | 20 μV | 100 μV |
| $\omega_e/2\pi$ | 70 GHz | 10 GHz | 70 GHz |
| $R_n$ | 100 Ω | 0.003 Ω | 0.1 mΩ |
| $(\omega_eC)^{-1}$ | 0.06 Ω | $\rightarrow \infty$ | 0.06 Ω |
| $A$ | 20 μm × 50 μm | 2 μm × 2 μm | 20 μm × 50 μm |

distribution of the phase difference across the junction area should be homogeneous. These restrictions lead to a limitation of the critical current and thus to a finite current width of the step. With an external drive frequency of $f_e = 70$ GHz, a sufficient step width and a stable phase lock are obtained for critical currents of about 150 μA and junction areas of about 20 μm × 50 μm in the case of Nb–$Al_2O_3$–Nb junctions.

(ii) As the stable phase lock of the junctions to the external microwave is also dependent on the incident microwave power, the array must be integrated into a microwave circuit that homogeneously distributes the microwave power to all junctions (Niemeyer *et al.* 1984, 1985). The series array is therefore arranged as a part of a periodic low-impedance (5 Ω) superconducting microstripline. In the case of the SIS junction array, the RF currents are mainly capacitive and the impedance mismatch between the stripline impedance and $R_n$ is large. This prevents an effective RF power dissipation in a single junction of the array. As only a very small fraction of the RF power is transferred to the single junction, the distribution of the power along the stripline is homogeneous enough to integrate up to about 3500 junctions into a continuous stripline. For larger arrays the stripline configuration is divided into four or eight parallel microwave paths that are terminated by matched loads and separated by d.c. blocks from the RF distribution network (cf. Fig. 2).

This RF design has proved so effective that it can be applied to circuits with up to $2 \times 10^4$ junctions and output voltages of more than 10 V (Hamilton *et al.*

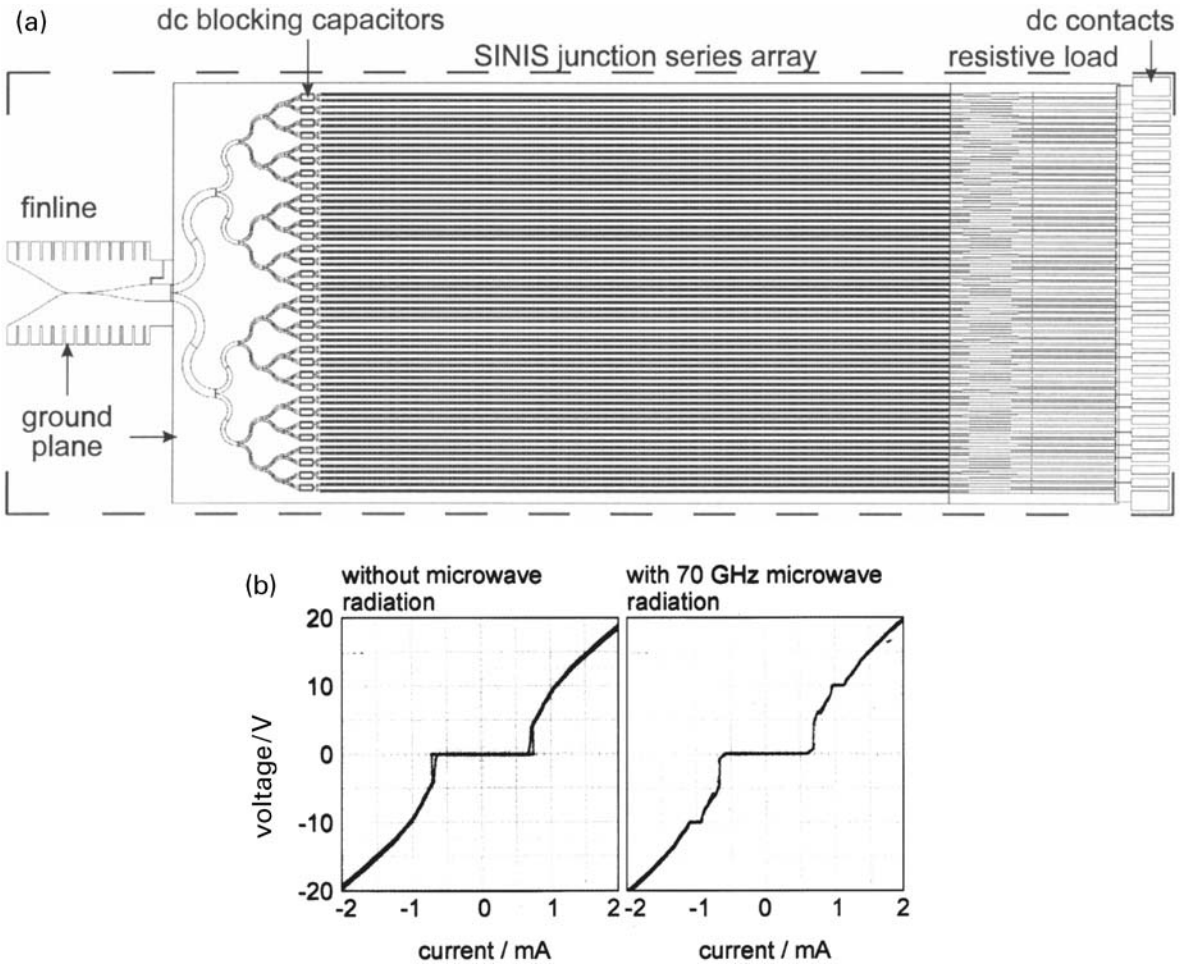

***Figure 2***
(a) Design of a 10 V SINIS array with 69 120 Nb–$Al_2O_3$–Al–$Al_2$–$Al_2O_3$–Nb junctions. Chip size: 28 mm × 10.5 mm. (b) d.c. characteristic of the array without and with 70 GHz microwave radiation.

1989). Further increases in the circuit reliability can be achieved by the wafer technology on the basis of Nb–$Al_2O_3$–Nb (Gurvitch *et al*. 1983, Niemeyer *et al*. 1989, Müller *et al*. 1997).

Since 1990 the Josephson constant, $K_{J90}\,\eta\,2e/h$, has been officially defined as a practical unit to the value of 483597.9 $GHzV^{-1}$ for the reproduction of the unit of volts. This value was chosen as close as possible to the SI value but is not identical to it because an instrument as precise as a Josephson series array voltage standard does not exist. Only direct comparisons between Josephson voltage standards may allow one to define their practical precision, which normally is limited by the room temperature zero instrument and the drift of the thermal e.m.f. differences in the voltage leads. Key comparisons of the PTB standard with that of the BIPM reveal uncertainties of $5 \times 10^{-11}$ related to 10 V.

## 2. *Programmable Voltage Standards*

In the case of the conventional SIS voltage standard, the use of zero-current voltage steps implies a difficult stability problem: as the reference voltages completely overlap the system does not automatically return to the adjusted voltage if the phase lock is lost owing to an external disturbance. Readjustment of the standard is time consuming and thus prevents rapid programmable selection of certain reference voltages. Especially, the synthesis of a.c. voltages for D/A conversion with fundamental precision seems to be

impossible. Therefore, using highly damped junctions (cf. Fig. 1(c) and (d)) in series arrays to avoid the reference voltage being multivalued has been suggested (Hamilton *et al.* 1995). If such an array is biased on a constant voltage step, it will remain at the adjusted value even if the phase lock is lost for a short moment. Besides zero voltage, an individual junction contributes an exactly defined number of constant voltage steps to the total reference voltage: in modern designs the steps are $\pm V_1$. In this case, an array of $N$ junctions provides only one reference voltage: $NV_1$. To adjust rapidly any voltage between zero and $NV_1$, new circuit designs have been suggested, which are described below.

### 2.1 *Binary Arrays*

For the rapid selection of d.c. reference voltages it has been suggested to divide an array of highly damped Josephson junctions into a series of binary sections that allow the reference voltage to be defined by combining a certain fraction of the binary sections in such a way that the desired reference voltage is obtained (Benz *et al.* 1997). Binary divided SNS arrays of 32768 Nb–PdAu–Nb junctions have been successfully operated at 16 GHz and generate RF-induced reference voltages of 1 V. As the junction capacitance approaches zero (Table 1), the RF currents are resistive. The array is part of a coplanar stripline configuration of eight parallel lines, with a line impedance of about 50 Ω, so that a large impedance mismatch between junctions and stripline allows homogeneous microwave coupling to all junctions.

The small product of $I_cR_n$ of 10–40 μV is tolerable for voltage standards with relatively low drive frequencies and maximum output voltages not larger than 1 V. But it would be advantageous to increase $I_cR_n$ to values that would make possible drive frequencies of 70 GHz and thus a reduction of the junction number for a given maximum output voltage.

Large products of $I_cR_n$ are obtained in series arrays of Nb–$Al_2O_3$–Al–$Al_2O_3$–Nb SINIS junction (Schulze *et al.* 1998). Here the transparency of the junction barriers can be adjusted over a wide range by the fabrication parameters. This allows SINIS arrays to be operated over a frequency range of at least 10–100 GHz. Typical junction parameters are listed in Table 1. An 8192-junction array divided into binary subarrays is, therefore, large enough to reach a maximum output voltage of 1 V. Moreover, the microwave supply to the conventional voltage standard can be used for this type of programmable voltage standard. Direct comparisons of the 1 V output voltages of SIS and SINIS arrays show no deviation within a standard uncertainty of $1.6 \times 10^{-10}$ (Behr *et al.* 1999). Rapid calibration of Zener references has been realized with a standard deviation of less than 10 nV. With a two-array system fully automated calibrations of the ratio of a 1 Ω/10 Ω resistive voltage divider have been performed with an uncertainty of five parts in $10^9$ (Behr *et al.* 2000). A 7492-junction SINIS array has been used to determine the fast reverse d.c. to d.c. transfer difference of a multijunction thermal converter (Funck *et al.* 2000).

The SINIS arrays are integrated into a low-impedance microstripline comparable to that for the SIS arrays. However, in contrast to the SIS junctions, an arbitrary part of dissipative RF current here flows over the junction resistance because $R_n$ is comparable to the stripline impedance. This impedance matching allows RF power from the individual junction oscillator to be transferred to the stripline to an amount large enough for the phase locking of adjacent junctions. If the junction number is large enough, the array will act as a coherent microwave oscillator whose output power is added to the RF power of the external oscillator that is locked to the first junctions in the array (Schulze *et al.* 1999). It is, therefore, possible to generate constant voltage steps in very long arrays, although the attenuation of the stripline is rather high (about 0.05 dB per stripline period or 1 dB $mm^{-1}$).

As a result of the microwave contribution from the active stripline, the microwave power required to generate a certain reference voltage is about 10 times smaller than that needed to reach comparable output voltages by means of a conventional SIS array with much fewer junctions. The coherent operation of the SINIS array makes it possible to generate maximum reference voltages of 10 V with a 69120-junction array under 70 GHz radiation with an RF power of less than 1 mW at the circuit antenna (Fig. 2) (Schulze *et al.* 2000, Kohlmann *et al.* 2000).

The binary arrays described reach a minimum switching time between different reference voltages of about 1 μs. This makes them ideal programmable d.c. quantum voltmeters. However, while array sections are switched from the step voltage to zero voltage, undefined voltage states of the transients between the voltage steps contribute to the reference voltage. This makes it difficult to achieve an accuracy sufficient for synthesizing fast a.c. voltages.

### 2.2 *Digital-to-Analog Converter*

To overcome the difficulties with the switching transients in the case of binary arrays, it has been suggested using an RF pulse drive instead of a sinusoidal microwave drive, which allows the reference voltage to be adjusted by controlling the repetition rate of the drive over a wide range (Benz and Hamilton 1996, Benz *et al.* 1998). By the restriction to single polarity pulses the system generates unipolar waveforms only. A unipolar 23.4 MHz sine wave with a peak-to-peak amplitude of 4.3 mV with an error of five parts in $10^8$ has been verified in experiments (Benz *et al.* 1998). Bipolar waveforms can be synthesized by biasing of

an array of overdamped junctions with a signal composed of a conventional sinusoidal drive and a two-level broadband digital code. This allows a controlled sequence of negative and positive pulses to be generated. Reference voltages between $-NV_1$ and $+NV_1$ are obtained by time averaging of periodic sequences of pulses with an appropriate number and polarity (Benz *et al*. 1999). A synthesis of a sine wave with an amplitude of $\pm 18$ mV at 5 kHz has been verified. All pulse-driven D/A converters need a perfect broadband transmission line without dispersion for fast signal propagation. In practice this is very difficult to achieve for large arrays with an output voltage amplitude of 1 V or more.

In principle, the use of rapid single-flux quantum (RSFQ) voltage multipliers would overcome the difficulties with the broadband transmission lines of the pulse-driven systems (Semenov 1993, Semenov *et al*. 1997, Sasaki *et al*. 1999). These complex digital circuits amplify the voltage with integer gain by multiplication of SFQ pulses. An RSFQ D/A converter contains a certain number of voltage multipliers in series connection that are independently controlled by the generation of a train of pulses with a repetition rate proportional to the input code. With a 2500-junction circuit an output voltage of 5 mV has been verified. Higher voltages can basically be achieved by hybrid integration of such circuits.

## Kerr Microscopy

Kerr microscopy allows the imaging of magnetic domains and magnetization processes in an optical polarization microscope. The method is based on the magnetooptical Kerr effect, i.e., the rotation of plane polarized light in dependence of the magnetization direction on reflection from a nontransparent sample.

In this article some fundamentals and possibilities of Kerr microscopy will be presented. Examples of domain images obtained by the method from a variety of materials can be found in *Magnets, Soft and Hard: Domains*. For a comparison with other imaging techniques (see *Magnetic Materials: Transmission Electron Microscopy* and *Magnetic Force Microscopy*). A comprehensive review on domain imaging with emphasis on Kerr microscopy is given by Hubert and Schäfer (1998) where also an extended bibliography can be found.

### *1. Kerr Microscope*

Domain observations with a lateral resolution down to the limit of optical microscopy (about 300 nm) are possible in a conventional polarizing microscope (Fig. 1). The domain contrast is optimized by the rotation of an analyzer and compensator. The aperture diaphragm, controlling the illumination, has to be adjustable so that the angle and plane of incidence can be chosen, allowing optimization of the Kerr sensitivity to in- or out-of-plane magnetization configurations (see Sect. 2). The application of fields up to 1 T is possible using an electromagnet with proper pole-tip geometry. The often weak domain contrasts require image processing for enhancement (see Sect. 3).

### *2. Kerr Effect and Contrast*

For the Kerr effect the magnetooptical interaction between light and magnetization $\boldsymbol{m}$ is phenomenologically described by a dielectric law

$$\boldsymbol{D} = \varepsilon(\boldsymbol{E} + i\boldsymbol{Q}\boldsymbol{m} \times \boldsymbol{E}) \qquad (1)$$

in which a displacement vector $\boldsymbol{D}$, representing the magnetooptically generated light amplitude, is connected to the electric vector $\boldsymbol{E}$ of the illuminating plane light wave ($\varepsilon$ is the dielectric constant and $Q$ is a complex material constant). Accordingly, the Kerr effect is linear in magnetization.

The cross-product in Eqn. (1) reveals the gyroelectric nature of the Kerr effect. Its symmetry can be derived by using the concept of a Lorentz force ($\boldsymbol{m} \times \boldsymbol{E}$) acting on light-agitated electrons (Fig. 2(a)). The Lorentz motion $v_{\mathrm{Lor}}$ (parallel to $\boldsymbol{D}$) creates a

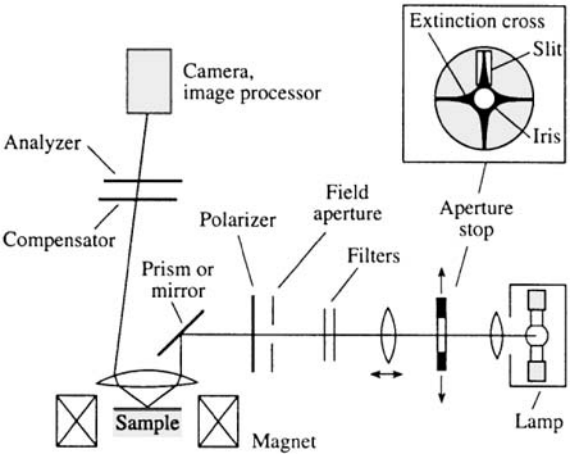

***Figure 1***
The essential components of a Kerr microscope. The inset shows the diffraction plane of the microscope where the illumination diaphragm can be viewed and adjusted. To obtain best contrast conditions the illumination should be restricted to the zone of maximum extinction that is cross-shaped at crossed polarizers due to depolarization effects. For perpendicular incidence an aperture iris has to be centered, while for oblique incidence an off-centered slit aperture is preferred.

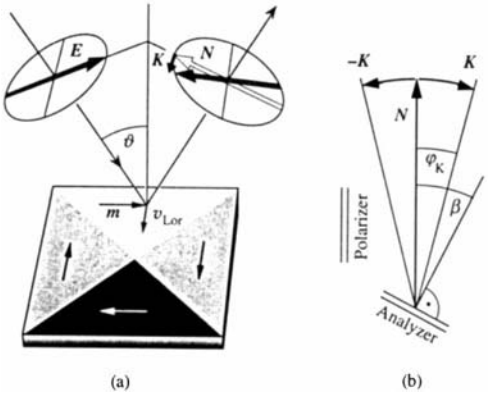

***Figure 2***
(a) Schematic diagram of the (longitudinal) Kerr effect. The interaction of the incident light $\boldsymbol{E}$-vector with the magnetization $\boldsymbol{m}$ generates the "Lorentz velocity" $v_{\mathrm{Lor}}$. The regularly reflected amplitude $\boldsymbol{N}$ is modified by the magnetization-dependent amplitude $\boldsymbol{K}$, leading to a rotation of the $\boldsymbol{E}$-vector in reflection by a small angle $\varphi_{\mathrm{K}}$; (b) the analyzer should be set at the angle $\beta > \varphi_{\mathrm{K}}$ to achieve optimum contrast conditions.

magnetic contribution ***K*** (Kerr amplitude) to the reflected amplitude, which is polarized perpendicular to the regularly reflected amplitude ***N***. By interference of ***K*** and ***N*** the resulting vector is rotated by the (small) angle $\varphi_K = K/N$. For two domains with opposite magnetization the Kerr amplitudes differ in sign. A domain contrast is obtained by extinguishing the light of one domain by the proper setting of the analyzer (Fig. 2(b)). If ***K*** and ***N*** differ in phase, the rotation is connected with some ellipticity. In this case the ellipticity of the darker domains should be removed by a phase-shifting compensator (such as a rotatable quarter-wave plate) to improve the contrast.

For every magnetization configuration the light incidence has to be properly chosen to generate a Lorentz motion that results in a detectable rotation. It turns out that the Kerr rotation is proportional to the magnetization component parallel to the reflected light beam. This rule immediately shows that domains magnetized parallel to the surface require oblique illumination with the plane of incidence parallel to the magnetization axis for maximum contrast (*longitudinal* Kerr effect), while the contrast of perpendicularly magnetized domains becomes strongest at perpendicular incidence ($\varphi = 0$, *polar* Kerr effect). The separation of polar and in-plane magnetization components is possible by different microscope settings as demonstrated in Fig. 3.

Important for good domain visibility is the size of the usable signal and this also determines the signal-to-noise ratio in video systems. The relative signal $S$, i.e., the difference between the intensities of bright and dark domains, is derived (Hubert and Schäfer 1998) as

$$S \approx 4\beta KN \tag{2}$$

Three important properties should be noted: (i) the Kerr signal is a linear function of the Kerr amplitude $K$ and therefore of the respective magnetization components according to Eqn. (1); (ii) the (often weak) Kerr signal can be enhanced by increasing the analyzer angle $\beta$ beyond $\varphi_K$, allowing an increase in the signal-to-noise ratio and adjusting the sensitivity of the detector; and (iii) the ''visibility'' of domains is determined by the Kerr *amplitude* and not by the Kerr rotation.

Although $K$ depends on material constants, it can be enhanced in materials where the incoming light is not completely absorbed by magnetooptical interaction but ''uselessly'' reflected to some extent. Antireflection coatings increase the absorbed intensity (based on interference effects), proportionally raising $K$ and thus the useful signal (Fig. 4). Effective dielectric coatings are ZnS for metals and $MgF_2$ for oxides. As the Kerr effect is generally weak, this gain should not be relinquished even if digital image processing is applied.

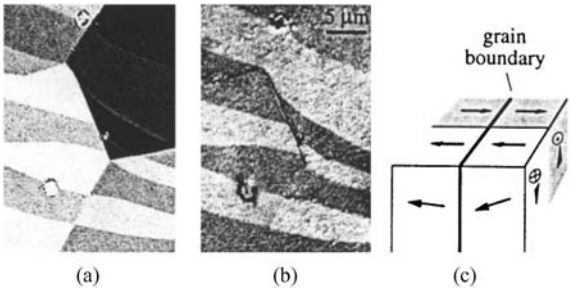

***Figure 3***
Domains in a coarse-grained NdFeB crystal in which the magnetization axes of the different grains are misaligned relative to the surface as sketched in (c); (a) the magnetization components perpendicular to the surface (polar components) can be imaged separately at perpendicular incidence. At oblique incidence polar and in-plane components show up simultaneously. When the illumination direction is rotated by 180°, the polar Kerr effect does not change sign, whereas the longitudinal effect does. By forming the image difference the polar contrast disappears, leaving just in-plane contrast as shown in (b).

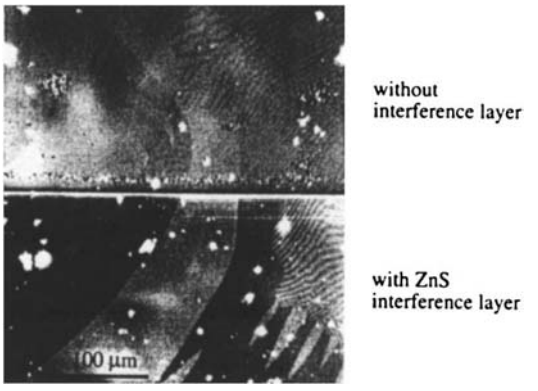

***Figure 4***
Effect of a dielectric antireflection coating on the Kerr contrast, demonstrated for an amorphous ribbon with and without a ZnS interference layer.

## *3. Contrast Enhancement by Image Processing*

A significant enhancement of magnetic contrast is possible by video microscopy and digital image processing. The standard procedure (Fig. 5) starts with a digitized image of the magnetically saturated state, where in an external a.c. or d.c. magnetic field all domains are eliminated. This background (reference) image is subtracted from a state containing domain information, so that in the difference image a

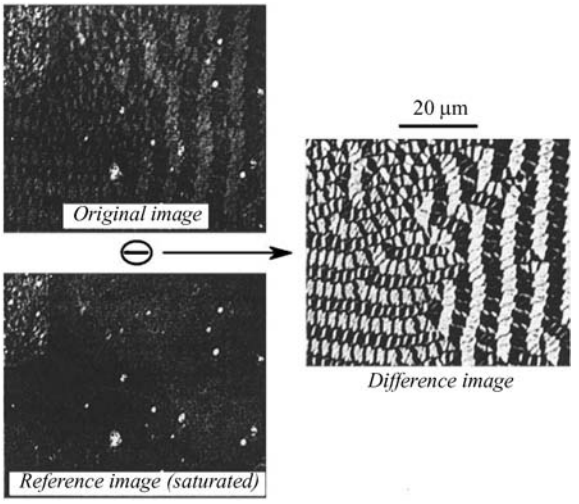

*Figure 5*

The moving domain walls become visible by a black and white contrast in the dynamically averaged difference image (b).

clear micrograph of the domain pattern is obtained which can be digitally enhanced, free of topographic structures.

The difference technique opens further experimental possibilities. For example, in Fig. 6 a domain image (Fig. 6(a)) is subtracted from an image where changes in the pattern are induced by a magnetic field. In the difference image (Fig. 6(b)) only those areas where the changes occur show a contrast. Such observations give hints as to the local variation of coercivity or to the amplitude of domain wall motion.

## 4. Quantitative Kerr Microscopy

Due to its linearity and direct sensitivity to $\boldsymbol{m}$, the Kerr effect can be used for quantitative determination

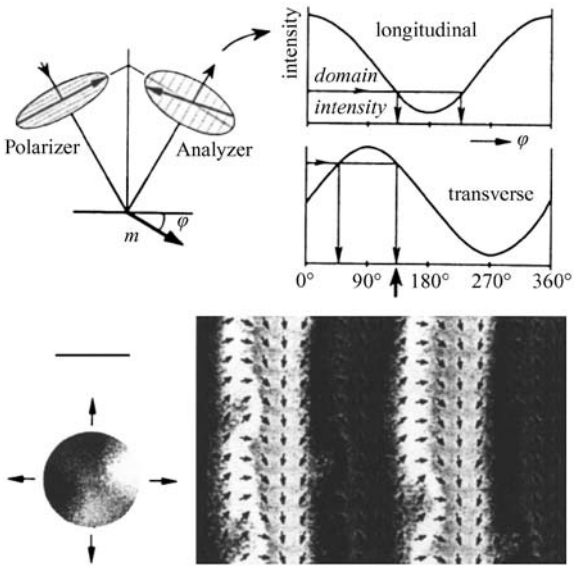

*Figure 7*
Quantitative Kerr microscopy: by imaging a domain pattern under two complementary Kerr sensitivities and comparing its intensities with the corresponding calibration functions, the magnetization vector field can be quantitatively measured. The example shows domains on an amorphous ribbon. A vector plot and color code can be used for presentation.

of the magnetization direction (Rave *et al*. 1987). The Kerr intensity has a sinusoidal dependence on the direction of the magnetization vector (Fig. 7). This sensitivity function is obtained by measuring the intensity of well-defined domains or saturated states. The intensity of unknown domains can then be compared with the calibration function and so the angle of $\boldsymbol{m}$ in the surface can be measured. The problem is that due to the sinusoidal dependence there are two possible angles for a given domain intensity. To resolve this ambiguity, the domain pattern of interest has to be imaged twice under different sensitivity conditions that should be shifted by 90° (e.g., by choosing two orthogonal planes of incidence). The method can only be applied to soft magnetic materials for which no polar magnetization components are present at the surface.

## 5. Depth-selective Microscopy

The magnetic information depth of the Kerr effect is about 20 nm in metals. A quantification of this depth sensitivity has to consider the *phase* of the magnetooptic amplitude (Träger *et al*. 1992). The total magnetooptical signal can be seen as a superposition of contributions from different depths,

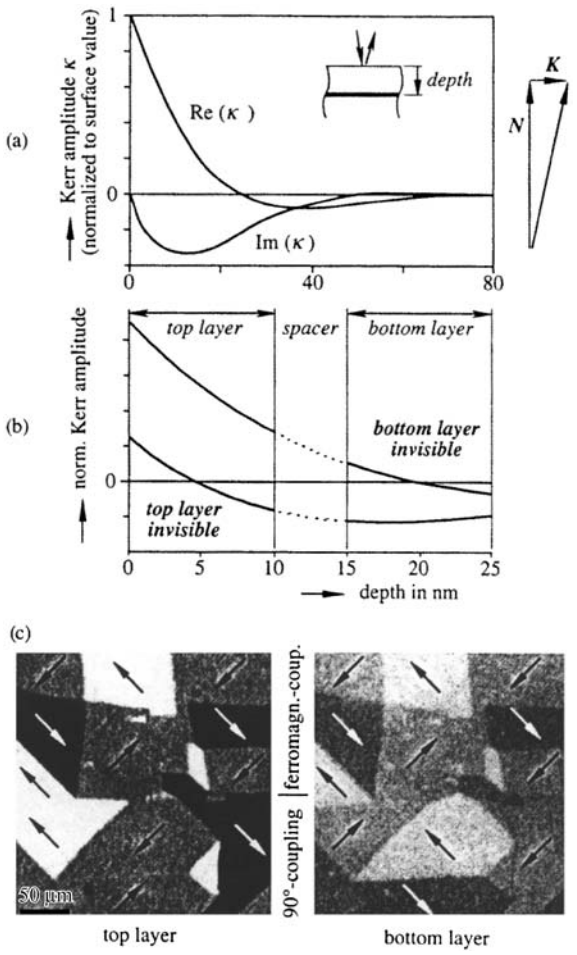

***Figure 8***
(a) Depth-sensitivity of the Kerr amplitude in iron. The relative phase of $K$ and $N$ was selected so that $N$ is allowed to interfere with the $K$ generated right at the surface; (b) proper phase selection allows layer-selective Kerr imaging on thin-film sandwiches; (c) a (100)-oriented Fe (10)–Cr ($\approx 0.5$)–Fe (10 nm) trilayer, showing ferromagnetic and biquadratic (90°) coupling in one image. Note that the contrast of the bottom layer is reduced due to absorption.

which are damped exponentially and which differ in phase according to a complex amplitude penetration function (Fig. 8(a)).

These phase differences can be exploited in Kerr microscopy. Using a rotatable compensator, the phase of the Kerr amplitude, generated at a certain depth, can be adjusted relative to the regularly reflected light amplitude (note that a detectable Kerr rotation is only possible if $K$ and $N$ are in-phase). In this way light from selected depth zones can be made invisible if their Kerr amplitude is adjusted out-of-phase with respect to the regular light. In sandwich films, consisting of ferromagnetic layers that are interspaced by nonmagnetic layers, the zero of the information depth can be put somewhere into the middle of one layer such that the integral contributions of this layer just cancel, leaving only contrast from the other layer (Fig. 8(b)). This kind of layer-selective Kerr microscopy is demonstrated in Fig. 8(c) for an Fe–Cr–Fe sandwich sample (see also (Schäfer 1995)).

## 6. Other Magnetooptical Effects

Two other magnetooptical effects can be used in a Kerr microscope: the Voigt effect and the gradient effect (Schäfer and Hubert 1990). Both effects appear at perpendicular incidence (where a Kerr contrast of in-plane domains is not possible) and require a compensator for adjustment. The Voigt effect is quadratic in the magnetization components, so that only domains magnetized along different axes show a contrast, while the gradient effect is a birefringence effect that depends linearly on magnetization gradients. Both effects (in combination with the Kerr effect) are helpful in the analysis of domains in cubic materials such as epitaxial thin-film systems by considering their contrast laws and depth sensitivities (see (Schäfer 1995) for an overview). The gradient effect can also favorably be applied to image fine transitions and domain modulations.

## 7. Dynamic Domain Imaging

Domain dynamics can be observed visually as fast as the eye can follow. Recording periodic processes with long exposure times yields zones of intermediate contrast that may give valuable information at least on the amplitudes of wall motion (see Fig. 6).

Periodic magnetization processes can be observed stroboscopically either by a triggered video camera or by a pulsed light source. Triggering the light or camera pulses with precise timing relative to a field pulse and sweeping the delay time yields a series of corresponding pictures of periodic or quasi-periodic processes (Petek*et al*. 1990).

## 8. Conclusions

Kerr microscopy is a versatile method for the experimental analysis of magnetic microstructures, only limited by resolution down to a few tenths of a micrometer. Enhanced by image processing, magnetic domains on virtually all relevant materials can be imaged. The dynamic capability and the compatibility with arbitrary applied fields make Kerr microscopy ideally suited for the investigation of magnetization processes. Due to the direct sensitivity and linear

dependence on the magnetic polarization, the method allows the quantitative determination of magnetization vector fields at the surface of soft magnets by calibrating the contrast. In favorable sandwich structures, layer-selective imaging is possible within a depth-sensitivity range of about 20 nm in metals. On bulk materials, however, it is just the surface region that can be seen (like in most other domain observation techniques). Here often theoretical arguments combined with domain studies in magnetic fields are required to obtain a three-dimensional understanding of the magnetic microstructure.

## Kondo Systems and Heavy Fermions: Transport Phenomena

The proximity of the 4*f* or 5*f* shell of certain lanthanide and actinide elements to the Fermi level gives rise to numerous unusual physical properties at low temperature. Among them are heavy fermion behavior and superconductivity, intermediate valence, Fermi- and non-Fermi-liquid as well as reduced magnetic moments in a magnetically ordered ground state. The outweighing number of such phenomena is attributed to a particular interaction of the conduction electron spin $\vec{s}$ with the total angular momentum $\vec{j}$ of the rare earth elements, known as the Kondo effect (Kondo 1964). Here, $\vec{s}$–$\vec{j}$ scattering causes an intermediate stage and as a consequence thereof a spin-flip process. One manifestation of this effect has been known since the early 1930s from a $-\ln T$ contribution to the electrical resistivity $\rho(T)$, observed for 3*d* magnetic impurities diluted in a nonmagnetic host. When this term is added to the phonon contribution of such a system, it is sufficient to explain the well-known minimum in $\rho(T)$.

### *1. Basic Features of Transport Phenomena in Kondo Systems and Heavy Fermions*

The physics of Kondo systems and heavy fermions is usually accounted for in terms of the Anderson model (Anderson 1961)

$$H = \sum_{k,\sigma} \varepsilon_k c^+_{k,\sigma} c_{k,\sigma} + \sum_{i,\sigma} E_0 f^+_{i,\sigma} f_{i,\sigma} + V \sum_{i,\sigma} (c^+_{i,\sigma} f_{i,\sigma} + c.c.) + U \sum_{i,\sigma} n^{\uparrow}_{f,i} n^{\downarrow}_{f,i} \quad (1)$$

where $n^{\sigma}_{f,i} = f^+_{i,\sigma} f_{i,\sigma}$. It describes the conduction electrons $c_{k,\sigma}$ with dispersion $\varepsilon_k$ and width $W$ which hybridize with the localized electrons of energy $E_0$. The hybridization matrix element is usually approximated by a constant $V$. $U$ represents the on-site Coulomb repulsion between $d(f)$ electrons. For large Coulomb repulsion $U$ the $d(f)$ spectral weight is split into two parts at $E_f$ and $E_f + U$, having a width $\Delta \approx V^2/W$.

The Anderson model exhibits various parameter regimes. (i) $E_0 + U \gg E_F$, $E_0 \ll E_F$ with $|E_0 + U - E_F|$, $|E_F - E_0| \gg \Delta$. For such parameters local magnetic moments exist which interact antiferromagnetically with the conduction electrons. (ii) If $E_0$ or $E_0 + U$ approach the Fermi energy so that $E_0 - E_F$ or $E_0 + \mathrm{U} - E_F$ become comparable with $\Delta$, or even smaller, the charge fluctuations of the impurity become important. This regime is known as the intermediate valence regime. (iii) In the case of only small admixtures of localized and delocalized electrons, the Schrieffer–Wolff transformation allow transformation of the hybridization matrix element $V$ of Eqn. (1) into an effective exchange coupling $J$, equivalent to the Heisenberg $s$–$d$ model, $H = J\vec{s}\vec{S}$.

The Anderson Hamiltonian is then led over into the Coqblin–Schrieffer model (Coqblin and Schrieffer 1969), which is used for practical reasons in most of the theoretical treatments of Kondo physics. The most powerful methods to diagonalize the Anderson, and in particular the Coqblin–Schrieffer Hamiltonian are the renormalization group calculations, the exact Bethe-ansatz solution and the large-$N$ approximation. Perturbation-type calculations and Fermi-liquid theories are also used. An excellent review of these subjects can be found in Hewson's textbook (Hewson 1993) (see *Electron Systems: Strong Correlations*).

#### *1.1 Transport Coefficients*

In a general treatment of transport phenomena, the linearized Boltzmann equation yields the following

transport coefficients (Ziman 1964):

$$\sigma \equiv 1/\rho = e^2 K_0 \tag{2}$$

$$S = -\frac{K_1}{|e|TK_0} \tag{3}$$

$$\lambda = \frac{1}{T}\left(K_2 - \frac{K_1^2}{K_0}\right) \tag{4}$$

where $\sigma$ is the electrical conductivity, $\rho$ is the electrical resistivity, $S$ the Seebeck coefficient and $\lambda$ the thermal conductivity. In simple metallic systems, the second term of Eqn. (4) is usually neglected. The transport integrals $K_n$ are given by:

$$K_n = \frac{k_F^3}{3\pi^2 m} \int \varepsilon_k^n \tau(\varepsilon_k)\, \mathrm{d}\varepsilon_k \left(-\frac{\mathrm{d}f_k}{\mathrm{d}\varepsilon}\right) \tag{5}$$

where $k_F$ is the Fermi wave vector, $m$ is the carrier mass, $\varepsilon_k$ is the carrier energy and $f_k$ is the Fermi–Dirac distribution function.

The key magnitude of the transport integrals is the relaxation time $\tau(\varepsilon_k)$. Since conduction electrons are scattered in and out of the $d$ or $f$ impurity orbitals, the density of states (DOS) of such impurities, $\rho_{d(f)}(\varepsilon)$, determines the scattering rate. Formally, the energy- and temperature-dependent scattering rate is given per unit impurity concentration $c_{\mathrm{imp}}$ by (Hewson 1993):

$$\tau^{-1}(\varepsilon_k) = 2\pi c_{\mathrm{imp}} |V|^2 \rho_{f(d)}(\varepsilon) \tag{6}$$

Once $\tau(\varepsilon_k)$ is known for particular interaction processes, all the transport coefficients can be calculated.

### 1.2 Electrical Resistivity

#### (a) Single impurity Kondo systems

If 3*d* elements such as iron or manganese, or *f* elements such as cerium, ytterbium or uranium, are dissolved in a nonmagnetic host such as copper, aluminum or $LaAl_2$, spin-flip scattering occurs, responsible for the generation of a spin-compensating cloud of conduction electrons around the impurity. As a result, the impurity magnetic moment becomes screened, thus forming a singlet ground state. In order to take account of the removed spin and orbital degrees of freedom, a narrow many-body resonance develops close to the Fermi energy (Kondo resonance), which is responsible for extraordinary low temperature features of physical quantities. In particular, enhanced scattering of conduction electrons at low temperatures affects transport coefficients, owing to an increased density of low energy excitations in the Kondo resonance near to $E_F$, and the large DOS at $E_F$ owing to the Kondo resonance is synonymous with extraordinarily enhanced effective masses of the carriers.

The first successful ansatz to account for the observed anomalous behavior of such systems dates back to Kondo (1964), who assumed that a local magnetic moment with a spin $\vec{S}$ is coupled via an exchange interaction $J$ with the conduction electron spin $\vec{s}$, i.e., $H = J\vec{s}\vec{S}$. Using a third-order perturbation-type calculation in $J$ leads to singular scattering of the delocalized electrons near to $E_F$ and to a $-\ln T$ contribution to the electrical resistivity $\rho(T)$, i.e.,

$$\rho_{\mathrm{imp}} = \rho_B \left[1 - 2JN(E_F)\, \ln\left(\frac{2\gamma}{\pi}\frac{D}{k_B T}\right)\right] \tag{7}$$

with

$$\rho_B = \frac{\pi m c_{\mathrm{imp}} N(E_F)}{e^2 \hbar} J^2 S(S+1) \tag{8}$$

where $2\gamma/\pi = 1.13$, $D$ is a cut-off parameter and $N(E_F)$ is the electronic density of states at the Fermi energy $E_F$.

For antiferromagnetic $s$–$d$ coupling, ($J<0$), $\rho_{\mathrm{imp}}(T)$ increases logarithmically with decreasing temperature. However, since the ln $T$ term diverges for $T \to 0$, Kondo's calculation becomes invalid at low temperatures. If the leading-order logarithmic terms are summed up, a divergence is obtained for $J<0$ at a finite temperature $T_{\mathrm{K}}$, known as the Kondo temperature (Hewson 1993). The electrical resistivity then reads:

$$\rho_{\mathrm{imp}} = \rho_B \frac{1}{\left[1 + JN(E_F)\, \ln\left(\frac{2\gamma}{\pi}\frac{D}{k_B T}\right)\right]^2} \tag{9}$$

and the characteristic temperature $T_{\mathrm{K}}$ is given by

$$k_B T_{\mathrm{K}} = \frac{2\gamma}{\pi} D e^{-1/(|J|N(E_F))} \tag{10}$$

The divergence of physical properties at $T = T_{\mathrm{K}}$ is unphysical since a supposed phase transition is suppressed from very strong fluctuations. Besides, this temperature marks the breakdown of the validity of perturbation-type calculations as many-body interactions become dominant.

Owing to the screening of magnetic moments by the conduction electron spin density within a sphere of radius $\xi \sim (W/k_F)T_{\mathrm{K}}$, $W$ … bandwidth, (Schlottmann 1989), magnetic scattering processes die out for $T \ll T_{\mathrm{K}}$ and the resulting singlet object acts entirely like a simple potential scatterer. Hence, Fermi-liquid (FL) results are applicable. In the scope of the $n$-channel Kondo model ($n = 2S$) $\rho_{\mathrm{imp}}$ is expressed as (Schlottmann and Sacraqmento 1993):

$$\rho_{\mathrm{imp}} = \rho_{\mathrm{imp}}(0)\left[1 - c_2\left(\frac{T}{T_K}\right)^2\right]$$
$$\text{with } c_2 = \frac{1}{8}\left(\frac{5\pi}{n+2}\right)^2 \tag{11}$$

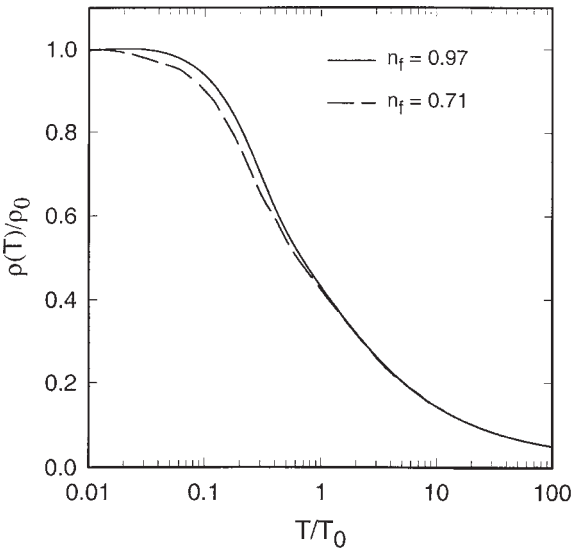

***Figure 1***
Temperature variation of the scaled resistivity $\rho(T)/\rho_0$ calculated in the scope of the noncrossing approximation for various values of $n_f$.

where $n=2$ represents the ordinary Kondo effect. A model calculation for $\rho_{\text{imp}}$ over the full temperature range requires knowledge of the density of states over the low frequency range at all temperatures (Hewson 1993). By applying the noncrossing approximation (NCA) to the Anderson model (Bickers *et al*. 1987), resistivity results were derived for $N=6$ ($N=2j+1$). Results are shown in Fig. 1 for various values of the $f$ occupation number $n_f$.

The NCA data exhibit an almost universal behavior over a significant temperature range when plotted as a function of $T/T_0$, where $T_0=wT_{\text{K}}$. $w$ is Wilson number (Hewson 1993) and $T_0$ can be associated with the position of the Kondo resonance with respect to the Fermi energy. Good overall agreement is found from this model with experimental data of, for example, cerium diluted in $LaB_6$ or Fe**Cu** (Schlottmann and Sacramento 1993). The resistivity is roughly logarithmic in $T$ near $T_0$; at low temperatures $\rho(T)$ saturates quadratically, in agreement with the Fermi-liquid theory (Eqn. (11)). Based on an approximation scheme (Fulde *et al*. 1993), a simple analytical expression is available for the transport coefficients, applicable over an extended temperature range.

For $N=2$, corresponding to $j=1/2$ or to a doublet as ground state, the NCA calculations can no longer be used. Instead, Costi and Hewson (Hewson 1993) adopted the numerical renormalization group method to account for the temperature dependence of the dynamic response function, which allows derivation of appropriate results for the resistivity, at least in the crossover regime.

### *(b) Kondo impurity versus concentrated Kondo systems*

The above-outlined features primarily trace the temperature dependence of the electrical resistivity of impurity systems, that is, alloys where a statistically small amount of 3*d*, 4*f* or 5*f* elements are dissolved in a nonmagnetic host such as gold, silver or copper. Since in such a case the *d* or *f* wave-functions do not overlap, the system will not order magnetically. In *f* systems, however, it is possible to increase the number of magnetic impurities up to a level where, for example, cerium, ytterbium, or uranium build up a fully ordered sublattice in the compound without losing those appearances associated with the Kondo effect. Basically, two features make a lattice different from an impurity system: (i) intersite interactions between the magnetic moments on the various lattice sites may no longer be negligible, and (ii) coherent scattering of the conduction electrons with the periodically arranged 4*f* and 5*f* magnetic moments is responsible for dramatic change of $\rho(T)$ on lowering the temperature.

The definition of coherence corresponds simply to Bloch's theorem: at zero temperature and excitation energy, inelastic scattering is frozen out so that translational invariance of a perfect sublattice of the magnetic ions requires zero resistance (Cox and Grewe 1988). This coherent ground state of the $10^{23}$ particles is most likely caused from the development of antiferromagnetic correlations, as is proven from neutron inelastic scattering, nuclear magnetic resonance, and muon-spin relaxation (Thompson and Lawrence 1994). While in the impurity case the resistivity grows continuously, reaching the unitarity limit for $T\to 0$ (associated with a phase shift $\eta=\pi/2$), coherence causes for a lattice of Kondo scatterers a substantial decrease of $\rho(T)$ upon a temperature decrease and the occurrence of a maximum at $T\approx T_0\propto T_{\text{K}}$. In the low temperature limit, the frequently observed power law $\rho=\rho_0+AT^2$ evidences electron-electron scattering in a FL state with $A\propto N(E_F)^2$.

Cox and Grewe (1988) calculated the temperature-dependent resistivity for both circumstances by applying the self-consistent NCA (Bickers *et al*. 1987) to the periodic Anderson lattice, where they explicitly included coherence, but intersite interactions are neglected. Results are shown in Fig. 2, matching the expected features almost perfectly. If intersite interactions of the RKKY type gain weight with respect to the Kondo interaction, the system is able to order magnetically below a certain transition temperature $T_{\text{mag}}$. Both the magnitude of the ordered moments as well as $T_{\text{mag}}$, however, can significantly be reduced when compared to a system without the Kondo effect. Such a transition into a magnetically ordered ground state will modify the low-temperature behavior of transport coefficients.

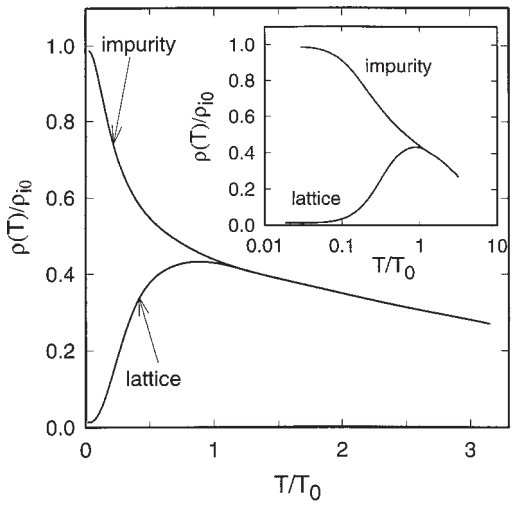

***Figure 2***
Normalized resistivity $\rho(T)/\rho_{i0}$ of the six-fold degenerate Anderson lattice calculated in the scope of the noncrossing approximation. For comparison, the full temperature dependence of the impurity resistivity is shown. $\rho_{i0}$ is the zero temperature resistivity per ion in the dilute limit.

*(c) Fermi- and non-Fermi-liquids*

Although a large number of Kondo systems at low temperature may be accounted for in terms of the FL model, an increasing number of alloys and compounds are already known, showing striking deviations from the simple temperature dependencies of an FL (see *Non-Fermi Liquid Behavior: Quantum Phase Transitions*). This new class of materials was termed non-Fermi-liquid (NFL). In most cases, NFLs are characterized by a transition into an antiferromagnetically ordered ground state at $T=0$, which behaves as a quantum critical point (QCP). Different scenarios were proposed to account for the NFL behavior near to a QCP (Rosch 2000). Among them are: (i) scattering of FL quasiparticles by strong spin fluctuations near the spin-density-wave instability, (ii) breakdown of the Kondo effect, owing to competition with the RKKY interaction, and (iii) the formation of magnetic regions, owing to rare configurations (Griffith phase) of the disorder.

With respect to transport properties, the self-consistent renormalization theory (SCR) of spin fluctuations (Hatatani and Moriya 1995) was successfully applied for ferromagnetic and antiferromagnetic heavy fermion systems around their magnetic instability. Depending on the nature of the interaction and its dimensionality, the calculated resistivity clearly deviates from the FL prediction $\rho \sim T^2$. Some of the results are listed in Table 1.

***Table 1***
Critical behavior of the electrical resistivity just at the magnetic instability of two- and three-dimensional ferro- and antiferromagnets.

| | Two-dimensional | Three-dimensional |
|---|---|---|
| Ferromagnetic spin fluctuations | $\rho(T) \sim T^{4/3}$ | $\rho(T) \sim T^{5/3}$ |
| Antiferromagnetic spin fluctuations | $\rho(T) \sim T$ | $\rho(T) \sim T^{3/2}$ |

*(d) Magnetoresistivity*

The application of a magnetic field to Kondo systems influences details of the DOS in the proximity of the Fermi energy. Hence, properties depending on the DOS are modified. The effect of a magnetic field on the electrical resistivity is described by $\rho(B)/\rho(0)$, where $\rho(B)$ and $\rho(0)$ are the field and zero-field resistivities, respectively.

At $T=0$, the magnetoresistance can be derived from the Friedel sum rule. In the scope of the Coqblin–Schrieffer model (Coqblin and Schrieffer 1969) with $N$-fold degenerate total angular momentum states, the Friedel sum rule yields:

$$\frac{\rho_{\text{imp}}(B)}{\rho_{\text{imp}}(0)} = \left[\frac{\sin^2(\pi/N)}{N}\sum_m \frac{1}{\sin^2(\pi n_m(B))}\right]^{-1} \qquad (12)$$

where $n_m$ is the occupation number of the $N=2j+1$ channels derived from Zeeman splitting. The occupation numbers can be calculated using the Bethe ansatz solution (Schlottmann and Sacramento 1989). Results of model calculations are shown in Fig. 3 for $j$-values ranging from 1/2 to 5/2. The single impurity nature is reflected from the scaling behavior of this quantity.

For large magnetic fields the magnetoresistivity shows Kondo logarithms, which are characteristics of asymptotic freedom and $\rho_{\text{imp}}(B)$ falls off as $\ln^{-2}(B/T_K)$. There are some qualitative differences of the magnetoresistivity results for the different total angular momenta, since for $j=1/2$ the Kondo peak is on-resonance with the Fermi level but is above the Fermi level for all other values of $j$. A magnetic field causes, then, a decrease of the impurity density of states for $j=1/2$ but an increase for $j \geqslant 3/2$.

For $N=2$, the magnetoresistance can also be expressed in terms of the impurity magnetization (Hewson 1993):

$$\rho_{\text{imp}}(B) = \rho_{\text{imp}}(0)\cos^2\left(\frac{\pi M_{\text{imp}}}{g\mu_B}\right) \qquad (13)$$

where $M_{\text{imp}}$ is the magnetization and $g$ is the Landé factor.

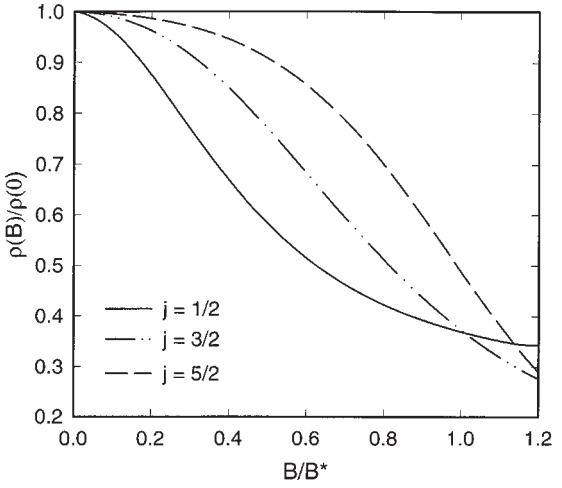

*Figure 3*
Magnetoresistance $\rho(B)/\rho(0)$ versus $B/B^*$ for the $j=1/2$ to $j=5/2$ Coqblin-Schrieffer model. $B$ is the magnetic field and $B^*$ is the characteristic field, closely related to $T_K$.

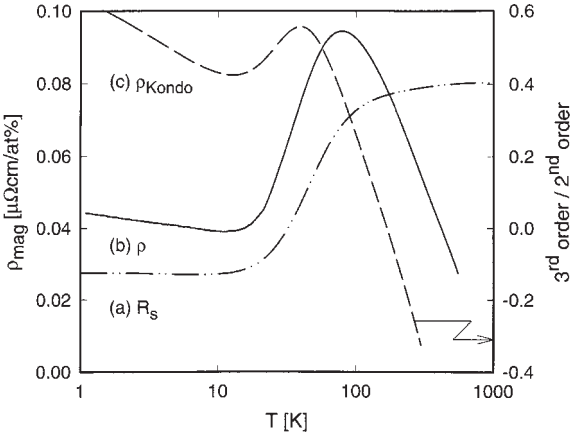

*Figure 4*
Temperature-dependent behavior of (a) the spin-disorder resistivity $R_s$, (b) the total resistivity $\rho$ and (c) the relative Kondo perturbation. The relevant parameters are: cubic symmetry, $\Delta=100\,\mathrm{K}$, $D=400\,\mathrm{K}$, $J=-0.095\,\mathrm{eV}$, $V=0.07\,\mathrm{eV}$, $\bar{V}=0.05\,\mathrm{eV}$, $N(E_F)=0.5$ states/eV, $\alpha_1=2$ and $\alpha_2=4$.

*(e) Crystal field effects*

In 4*f* systems based on cerium or ytterbium, crystal field (CF) effects can no longer be neglected. The thermal population of the various CF levels with increasing temperature changes most of the physical properties, and moreover, the Kondo effect itself changes.

In the scope of a third-order perturbation-type calculation in $JN(E_F)$, Cornut and Coqblin (1972) derived the cumulative effect of Kondo interaction in the presence of crystal field splitting. Results of their calculations have been applied to numerous compounds such as $CeAl_2$ or $CeAl_3$. The relaxation time $\tau_k$ for the above model is obtained as

$$\frac{1}{\tau_k}=\frac{mkV_0c_{\mathrm{imp}}}{\pi\hbar^3(2j+1)}\,(R_k+S_k) \tag{14}$$

where $k$ is the wave vector and $V_0$ the sample volume. $R_K$ describes second-order terms (direct scattering from the initial to the final state) and is proportional to $J^2$, while $S_K$ accounts for third-order terms (spin-flip processes) which are proportional to $J^3$. Direct and resonant (Kondo) scattering yield the following magnetic contribution to the electrical resistivity:

$$\rho_{\mathrm{mag}}(T)=AN(E_F)\left[\bar{V}^2+\frac{\lambda_n^2-1}{\lambda_n(2j+1)}J^2\right]+AN(E_F)\left[J^3N(E_F)\,\frac{\lambda_n^2-1}{2j+1}\ln\left(\frac{k_BT}{D_n}\right)\right] \tag{15}$$

Here, $A$ is a constant, $V$ is the direct interaction strength, and $D_n$ is a cut-off parameter. $\lambda_n=\sum_{i=0}^{n}\alpha_i$, where $\alpha_i$ is the degeneracy of the $i$th CF level with energy $\Delta_i$. The second term describes the usual spin disorder resistivity (second-order perturbation theory). The temperature dependence of this contribution results from the thermal population of the various CF levels. The third term is the Kondo resistivity. The resistivity according to Eqn. (15) is plotted in Fig. 4 for a typical set of parameters which roughly accounts for the case of $CeAl_2$.

### 1.3 Thermal Conductivity

In metallic systems, the thermal conductivity $\lambda$ consists of a lattice contribution $\lambda_l$ and of an electronic contribution $\lambda_e$, i.e., $\lambda=\lambda_l+\lambda_e$. According to Matthiessens's rule, the thermal resistivity $W_{l(e)}\equiv 1/\lambda_{l(e)}$ is given by a sum resulting from different scattering events, like electron–phonon scattering or scattering of electrons or phonons on static imperfections. Thus, $W_{l(e)}=\Sigma_i W_{l(e),\,i}$. The temperature dependence of $\lambda$ follows from Eqn. (4), using the appropriate relaxation time. Thermal conductivity limited by magnetic scattering processes in the presence of CF splitting is then derived from Eqn. (14) as (Bhattacharjee and Coqblin 1988)

$$\lambda_{e,\mathrm{mag}}(T)=\frac{(2j+1)\hbar^3k_F^2}{3\pi m^2v_0c}\,\frac{1}{T}\,(W_2-W_3) \tag{16}$$

with

$$W_2 = \int \varepsilon_k^2 \left(-\frac{\mathrm{d}f_k}{\mathrm{d}\varepsilon_k}\right)\frac{\mathrm{d}\varepsilon_k}{R_K} \tag{17}$$

and

$$W_3 = \int \varepsilon_k^2 \left(-\frac{\mathrm{d}f_k}{\mathrm{d}\varepsilon_k}\right)\frac{S_K}{R_K^2}\,\mathrm{d}\varepsilon_k \tag{18}$$

$\lambda_{\mathrm{e,mag}}(T)$ is plotted in Fig. 5 for a set of typical parameters. It is interesting to note that there are no typical features evidencing Kondo interaction; however, CF effects seem to be of importance.

Experimental data, however, clearly indicates Kondo interaction in the presence of crystal field splitting, when plotted as $W_{\mathrm{e,mag}}T$ where $W_{\mathrm{e,mag}} = 1/\lambda_{\mathrm{e,mag}}$. Figure 6 shows $W_{\mathrm{e,mag}}T$ of $CeAl_2$ displayed on a logarithmic temperature scale. For purpose of comparison, $\rho_{\mathrm{mag}}(T)$ of $CeAl_2$ is added, also. Such a representation of the data exhibits negative logarithmic ranges and a maximum, very similar to that of $\rho_{\mathrm{mag}}(T)$. This particular behavior can theoretically be accounted for by (Bauer *et al.* 1993a)

$$W_{\mathrm{e,mag}}T = \frac{R}{L_0}\left[\bar{V}^2 + \frac{(\lambda^2-1)}{(2j+1)\lambda}\,J^2\right] + 2\,\frac{R}{L_0}\,N(E_F)\,J^3\,\frac{(\lambda^2-1)}{2j+1}\ln\left(\frac{k_B T}{D}\right) \tag{19}$$

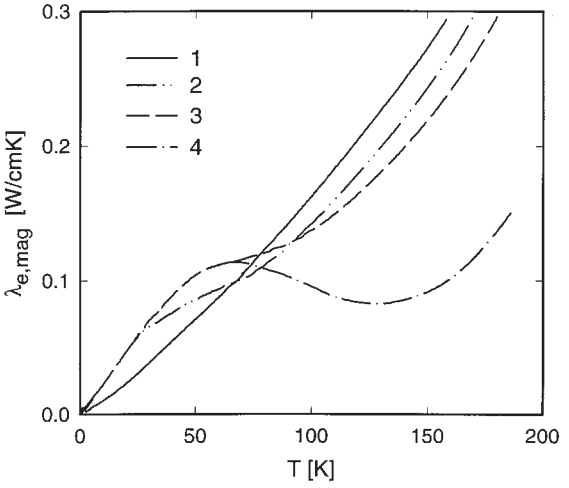

***Figure 5***
Temperature-dependent thermal conductivity $\lambda_{\mathrm{mag}}$ caused by spin-dependent scattering according to Eqn. (16): (1) cubic field with $\Gamma_8$ as ground state and $\Delta = 200\,\mathrm{K}$; (2) hexagonal field with three equidistant doublets at 0, 100 and 200 K; (3) cubic field with $\Gamma_7$ as ground state and $\Delta = 200\,\mathrm{K}$. (4) hexagonal field with three doublets at 0, 200 and 400 K. Additional parameters are $D = 850\,\mathrm{K}$, $V = 700\,\mathrm{K}$, $J = -0.1\,\mathrm{eV}$, $\bar{V} = -0.25\,\mathrm{eV}$, $N(E_F) = 2$ states/eV.

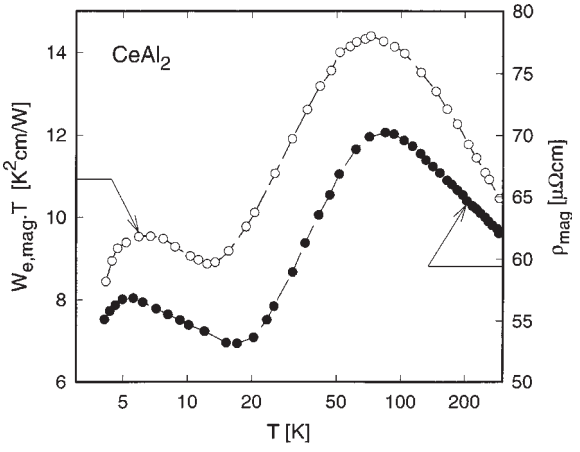

***Figure 6***
Left axis: temperature-dependent magnetic contribution to the thermal resistivity of $CeAl_2$, plotted as $W_{\mathrm{e,mag}}T$ versus $\ln T$. Right axis: temperature-dependent magnetic contribution to the electrical resistivity $\rho_{\mathrm{mag}}$ of $CeAl_2$. $LaAl_2$ was used in both cases to define the electron–phonon interaction.

where $R = (3m\pi v_0 c)/(e^2 h k_{\mathrm{F}}^2)$, and $L_0 = (\pi^2 k_{\mathrm{B}}^2)/(3e^2)$ is the Sommerfeld value of the Lorenz number.

Equation (19) allows various conclusions to be drawn. (i) There are negative logarithmic ranges for $W_{\mathrm{e,mag}}T$ at temperatures $T \gg \Delta_i/k_{\mathrm{B}}$ and $T \ll \Delta_i/k_{\mathrm{B}}$. (ii) $W_{\mathrm{e,mag}}T$ shows maxima in the vicinity of each crystal field level if they are well separated. (iii) The ratio of the logarithmic slopes of $W_{\mathrm{e,mag}}T$ reflects the degeneracy of the crystal field levels involved.

### *1.4 Thermopower*

The temperature-dependent thermopower $S(T)$ can be evaluated from

$$S = -\frac{K_1}{|e|TK_0} = -\frac{1}{eT}\left[\frac{\int_{-\infty}^{+\infty}\varepsilon_k\tau_k\left(-\frac{\mathrm{d}f_k}{\mathrm{d}\varepsilon}\right)\mathrm{d}\varepsilon_k}{\int_{-\infty}^{+\infty}\tau_k\left(-\frac{\mathrm{d}f_k}{\mathrm{d}\varepsilon}\right)\mathrm{d}\varepsilon_k}\right] \tag{20}$$

Owing to strong energy-dependent scattering processes, the Kondo effect sensitively influences the overall shape of $S(T)$, which is calculated from:

$$S = \frac{1}{eT}\,\frac{1}{\sigma^{(2)}}\int_{-\infty}^{+\infty}\frac{S_k}{R_k^2}\left(-\frac{\mathrm{d}f_k}{\mathrm{d}\varepsilon_k}\right)\mathrm{d}\varepsilon_k \tag{21}$$

with $e > 0$ (Bhattacharjee and Coqblin 1976). $R_k$ and $S_k$ are again contributions from the second and third order perturbation type calculations; $\sigma^{(2)}$ is a

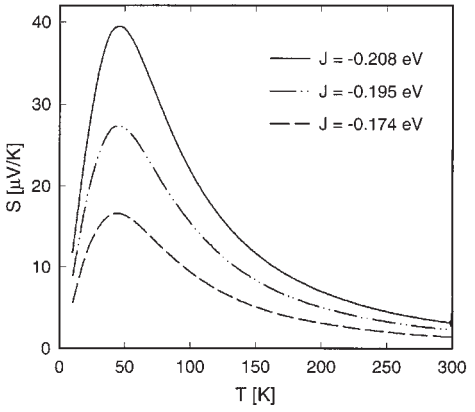

***Figure 7***
Temperature-dependent thermopower for a three-level system according to Eqn. (21) for various values of the exchange constant $J$. The following parameters are used: $\Delta_1 = 87\,\mathrm{K}$, $\Delta_2 = 210\,\mathrm{K}$, $D = 850\,\mathrm{K}$, $\bar{V} = -1.5\,\mathrm{eV}$, $N(E_F) = 2.2$ states/eV, $\alpha_1 = \alpha_2 = \alpha_3 = 2$.

characteristic function:

$$\sigma^{(2)} = \int_{-\infty}^{+\infty} \frac{1}{R_k^2}\left(-\frac{\mathrm{d}f_k}{\mathrm{d}\varepsilon_k}\right)\mathrm{d}\varepsilon_k \qquad (22)$$

In the absence of CF splitting, Kondo scattering is responsible for unusually large thermopower values ($\approx 100\ \mu\mathrm{VK}^{-1}$) with a maximum in the vicinity of $T \approx T_\mathrm{K}$. In real compounds and alloys, CF effects cause a modification of that universal behavior. The maximum in $S(T)$ is then no longer at $T \approx T_\mathrm{K}$, rather, a renormalization of $T_S^{\max}$ takes place with $T_S^{\max} \approx (1/3{-}1/6)\Delta_\mathrm{CF}$, where $\Delta_\mathrm{CF}$ is the overall crystal field splitting of the system. Results derived from Eqn. (21) are shown in Fig. 7.

### 2. *Temperature-, Pressure-, and Field-dependent Transport Coefficients of Kondo and Heavy Fermion Systems*

In order to demonstrate the various interaction mechanisms which generally occur in Kondo and heavy fermion systems, as well as their mutual interplay, the temperature-dependent resistivity of $YbCu_4M$, with M = Ag, Au and Pd, is shown in Fig. 8 (Bauer *et al.* 1993b, 1994). The compounds are isoelectronic and isostructural and crystallize in an ordered variant of the cubic $AuBe_5$ structure. Different dominating interaction mechanisms cause distinct features for each particular compound.

#### 2.1 *$YbCu_4Ag$*

This crystallographic fully ordered ternary compound represents a typical Kondo lattice. At high

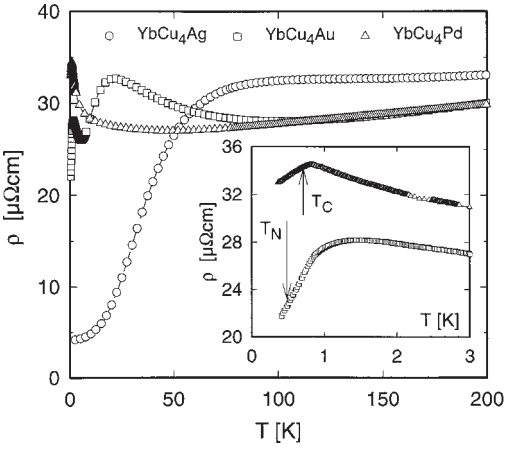

***Figure 8***
Temperature-dependent resistivity $\rho$ of $YbCu_4M$ with M = Au, Ag, Pd.

temperatures, the negative logarithmic contribution to the total electrical resistivity leads to single impurity Kondo interaction of the conduction electrons with the almost localized Yb-4*f* moments. At low temperatures, however, the ordered ytterbium sublattice allows a Bloch-like motion of the conduction electrons, and consequently the resistivity falls. Both regimes are separated by a smooth maximum near 100 K with $T_\rho^{\max} \propto T_\mathrm{K}$ (Cox and Grewe 1988). Therefore, $YbCu_4Ag$ represents a Kondo lattice with a relatively high Kondo temperature.

This provokes a couple of important consequences for physical properties: because $T_\mathrm{K}$ of $YbCu_4Ag$ is large, the associated hybridization prevents pronounced CF effects and the eight-fold degenerate state of the Yb ion ($j = 7/2$) dominates the whole temperature range. Moreover, as $T_\mathrm{K} \gg T_\mathrm{RKKY}$, long-range magnetic order is unlikely and the system remains paramagnetic down to the mK range. Below 10 K the $T^2$ behavior of $\rho(T)$ refers to a FL behavior and the large coefficient $A = 8\ \mathrm{n\Omega\,cm/K^2}$ (Bauer *et al.* 1993b) results from interactions with the heavy quasiparticle bands. The overall $\rho(T)$ behavior matches almost perfectly the theoretical predictions of Cox and Grewe (1988).

#### 2.2 *$YbCu_4Au$*

Although $YbCu_4Au$ is isoelectronic with $YbCu_4Ag$, the ground state properties behave significantly differently. While the latter is nonmagnetic, the former orders antiferromagnetically below $T_\mathrm{N} \approx 0.6\,\mathrm{K}$ (see inset, Fig. 8) with a wave vector $\vec{k} = [0.553,\ 0.415,\ 0.303]$ and an ordered moment $\mu = 0.85\,\mu_\mathrm{B}/\mathrm{Yb}$ (Bauer *et al.* 1997). A comparison with $YbCu_4Ag$ shows that primarily the low value of the Kondo temperature

($T_K \approx 2$ K) is responsible for the appearance of long range magnetic order as $T_{RKKY} \approx T_K$. Additionally, since $T_K \ll \Delta_{CF}$ the eight-fold degenerate ground state is lifted into a doublet, a quartet at about 40 K above and as the uppermost level, a doublet centered at about 80 K (Severing *et al.* 1990).

Owing to these well-separated crystal field levels, Kondo interaction is observed from negative logarithmic resistivity contributions in the various temperature ranges. These ranges are disjoined by a pronounced maximum, thus precisely coinciding with the predictions of Cornut and Coqblin (1972). In the low temperature range the resistivity increase marks Kondo scattering in the CF ground state followed by the development of coherence below 1 K. On further temperature decrease, magnetic ordering occurs below 0.6 K, observed by a distinct change of $d\rho/dT$.

### 2.3 *$YbCu_4Pd$*

Different from $YbCu_4Au$, $YbCu_4Pd$ orders ferromagnetically below $T_C \approx 0.8$ K with an ordered moment $\mu_{ord} = 0.4\mu_B$/Yb (Bauer *et al.* 1997). The $\rho(T)$ of $YbCu_4Pd$ shows a minimum around 50 K and above 100 K $\rho(T)$ is simply described by a linear dependence up to 300 K. The upturn in $\rho(T)$ below 15 K is well accounted for by the Kondo $-\ln T$ term together with an appropriate phonon contribution. A maximum is reached at 0.8 K and the resistivity drop below this can partly be attributed to the onset of long-range magnetic order. Distinct features of crystal field splitting are not obvious from this data. Such a peculiarity is also derived from neutron inelastic scattering where clear inelastic excitations are observed for $YbCu_4Au$, while the INS data of $YbCu_4Pd$ do not exhibit typical features of CF excitations (Severing *et al.* 1990).

To trace in some detail the pressure response of Kondo compounds, two typical members are selected: $CeCu_6$ and $YbCu_4Ag$. The behavior of the latter has already been discussed for ambient pressure values. $CeCu_6$ also stays paramagnetic down to the mK range. The electrical resistivity is displayed in Fig. 9 for various values of applied pressure (Kagayama and Oomi 1993). At ambient pressure, $CeCu_6$ exhibits the well-known behavior of a Kondo lattice, i.e., at high temperatures ($T > 50$ K), $\rho(T)$ shows a logarithmic contribution from independently acting Kondo scatterers, followed by a maximum at $\approx 12$ K with $T_\rho^{max} \propto T_K$. Well below this maximum, $CeCu_6$ enters its coherent ground state, reflected from a $T^2$ behavior in $\rho(T) = \rho_0 + AT^2$ where the huge coefficient $A \approx 110\,\mu\Omega\,\text{cm K}^{-2}$ results from the significantly enhanced quasi-particle density of states at the Fermi energy.

Increasing values of pressure cause different responses. (i) $T_\rho^{max}$ substantially grows, thus reflecting an increase of $T_K$ which is derived from a growing

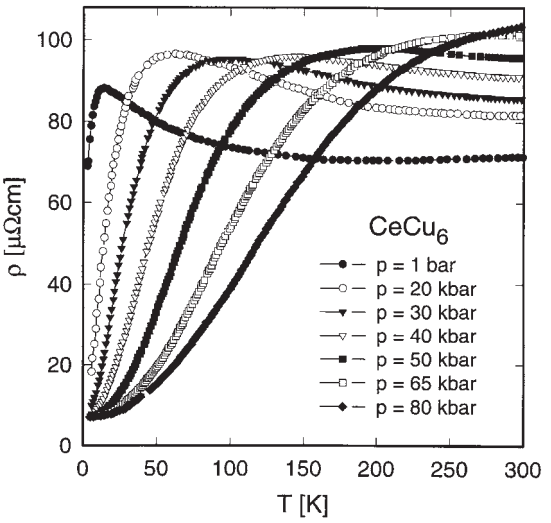

***Figure 9***
Temperature- and pressure-dependent resistivity $\rho$ of $CeCu_6$.

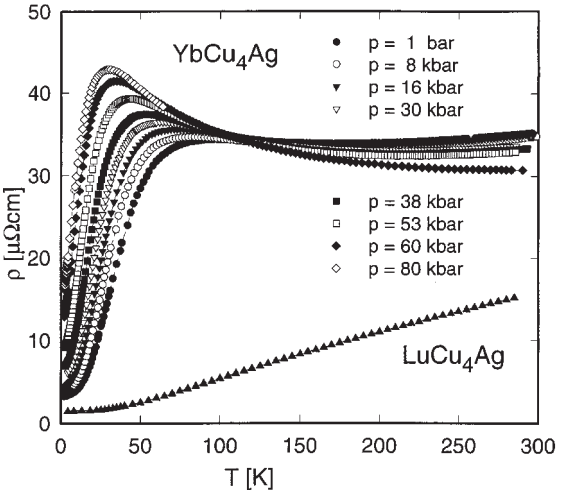

***Figure 10***
Temperature- and pressure-dependent resistivity $\rho$ of $YbCu_4Ag$.

hybridization of the almost localized 4*f* electrons with the delocalized conduction electrons. (ii) The coefficient $A$ decreases, which is associated with a decrease of the density of states at $E = E_F$. The overall effect of pressure on cerium systems basically is the destabilization of the magnetic $4f^1$ state, since the cerium $4f^1$ electron becomes progressively squeezed out of the 4*f* shell.

An opposite "mirror-like" behavior is found for $YbCu_4Ag$ (Fig. 10), representing a typical Yb-based

Kondo lattice: pressure causes both a decrease of $T_\rho^{\max}$ and a significant increase of $A$. Now, the former indicates a lowering of $T_K$ and the latter reflects a growing DOS at the Fermi energy. The total effect of pressure applied to ytterbium systems is therefore a reduction of the hybridization and a stabilization of the ytterbium magnetic moments.

Basically, this "mirror-like" behavior can be understood from an electron-hole analogy of the electronic configurations (EC) of cerium and ytterbium, where the magnetic and the nonmagnetic states depend on the respective volumes. In the case of cerium, the magnetic state $4f^1$ gives rise to the larger volume. Pressure applied to cerium ions will reduce the atomic volume by squeezing out the $4f^1$ electron. Hence, the nonmagnetic small-volume EC $4f^0$ is progressively attained. In the case of ytterbium, the EC with the larger volume is the nonmagnetic $4f^{14}$. Again, pressure will reduce the available volume by squeezing out one electron, which is synonymous with the creation of a hole in the $f$-shell as the small-volume magnetic $4f^{13}$ state is approached.

Magnetic fields applied to systems dominated by the Kondo effect, long-range magnetic order and crystal field splitting can dramatically modify the ground-state properties. This is owing to a possible suppression of Kondo interactions by magnetic fields, a suppression of long-range magnetic order in the case of antiferromagnetism, the quenching of spin fluctuations, or the complete removal of the degeneracy of the CF split levels.

Such a pronounced effect of a magnetic field is obtained in the case of ternary $YbRh_2Si_2$, which crystallizes in the tetragonal $ThCr_2Si_2$ type of structure. Magnetic order is absent down to a few hundred mK (Trovarelli *et al.* 2000). At ambient pressure and at zero field, $\rho(T)$ shows typical Kondo lattice properties and $T_\rho^{\max}$ decreases with growing pressure (Fig. 11). However, a $T^2$ behavior is not resolved for $T \to 0$, which would characterize a FL. Rather, in a range up to 10 K, the resistivity is accounted for by $\rho(T) = \rho_0 + BT^n$ with $n \approx 1$ (Trovarelli *et al.* 2000). Such an exponent may point out a NFL, originating from two-dimensional antiferromagnetic spin fluctuations above the QCP (Hatatani and Moriya 1995). Two-dimensionality seems to be possible in this compound owing to the peculiarities of the $ThCr_2Si_2$ crystal structure. Magnetic fields can suppress such fluctuations and as a result, a FL is recovered with $\rho \propto T^2$, which, in fact, is found for $YbRh_2Si_2$ for $H > 6$T (inset, Fig. 11).

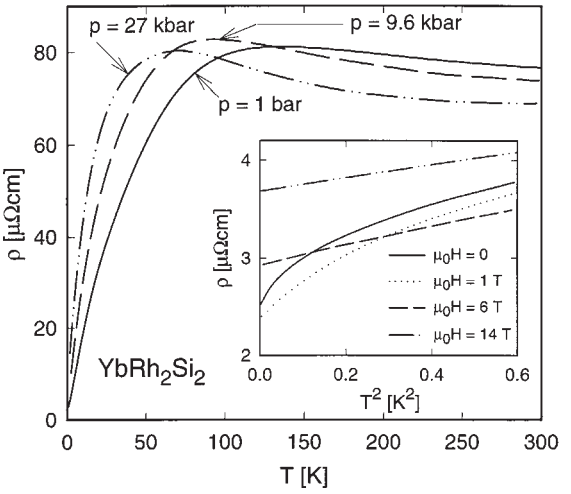

***Figure 11***
Temperature-, pressure- and field-dependent resistivity $\rho$ of $YbRh_2Si_2$.

## 3. Summary

The narrow many-body resonance in the proximity of the Fermi energy of Kondo and heavy fermion systems causes significant changes in temperature-dependent transport coefficients when compared with simple metals. The most well-known is a $-\ln T$ contribution to the electrical resistivity, found both in theory and in experiment.

Depending on a single impurity or a lattice scenario, the conduction electrons are scattered incoherently or coherently at low temperatures, respectively. In the former case the resistivity increases on a reduction of the temperature, eventually reaching the unitarity limit for $T \to 0$. In the latter case a decrease of the resistivity is observed for $T \to 0$ owing to the lattice periodicity of the magnetic ions, which serve as Kondo scatterers.

The particular temperature dependence of transport coefficients is significantly modified if RKKY interactions or CF effects are of equal or larger strength compared with the Kondo scale. A number of control parameters such as appropriate substitution, hydrostatic pressure or magnetic fields are able to tune the most important mutual interactions present in such systems; thus, substantial changes of the ground state properties may become evident.

## Localized 4*f* and 5*f* Moments: Magnetism

An atom (ion) in a solid has a net magnetic moment in cases when an inner *d* or *f* electron shell is incomplete so that the individual electronic moments do not cancel completely. In the periodic table, there are five groups of elements in which this incomplete cancellation occurs: the iron group (3*d*), the palladium group (4*d*), the rare earth (or lanthanide) group (4*f*), the platinum group (5*d*), and the actinide group (5*f*). Note that the 4*d* and 5*d* shells are rather delocalized and their contribution to magnetism is in general very weak. This article focuses on the 4*f* and 5*f* groups. The magnetism of systems containing both 4*f* and 3*d* elements is treated elsewhere (see *Alloys of 4f (R) and 3d (T) Elements: Magnetism*; *Transition Metal Oxides: Magnetism*).

A magnetic rare earth (RE) or actinide (An) ion when placed in a solid is subject to numerous forces, absent in free ions, which in general significantly influence the magnetic properties of a given system. Leaving aside the cases of fluctuating valence (see *Intermediate Valence Systems*) and heavy fermion 4*f* and 5*f* electron systems (see *Electron Systems: Strong Correlations*; *Heavy-fermion Systems*), these forces represent merely a perturbation of the free-ion *f* shell state and the ionic magnetic moment can be considered as well localized.

Two of these perturbations which are particularly important are treated in this article. One is an interaction of the incomplete *f*-shell electrons with the crystal field (CF) produced by the neighboring core charges and valence electronic charge density. The other is the magnetic coupling with neighboring ionic moments which can result in cooperative effects. The magnetic behavior of *f*-electron systems is described using microscopic Hamiltonians reflecting general symmetry properties of the system under consideration. Parameters of these Hamiltonians are either determined from experiment or calculated using various theoretical models. This article mainly focuses on trivalent *f* ions. This oxidation state strongly dominates in the rare earth elements. However, a multiplicity of oxidation states is displayed by many actinides (Wybourne 1965, Fournier 1985).

### 1. Free Ion Interactions

The starting point for understanding of the magnetism of RE and An compounds is the quantum mechanical description of an unperturbed many-electron ion. Assuming that the nucleus of an ion is at rest, the generic nonrelativistic Hamiltonian can be taken as:

$$H = -\frac{\hbar^2}{2m}\sum_{i=1}\nabla_i^2 - Ze^2\sum_{i=1}\frac{1}{r_i} + e^2\sum_{j>i=1}\frac{1}{|\mathbf{r}_i - \mathbf{r}_j|} \quad (1)$$

where $Ze$ is the nuclear charge and summations are over the coordinates of all the electrons. Individual terms describe the kinetic energy of electrons, the Coulomb potential due to the nuclear attraction, and the Coulomb repulsion between the pairs of electrons. No exact solution for the Schrödinger equation of the Hamiltonian of Eqn. (1) is known for a system containing more than one electron.

Fortunately the electrons occupying closed shells can be separated and the corresponding electronic structure can be described (Cai *et al.* 1992, Eliav *et al.* 1995).

The electrons from the outer 6*s*5*d* shell in RE atoms (7*s*6*d* shell in An atoms) participate in the chemical bonding. It follows from *ab initio* calculations that the asphericity in the charge density of these electrons influences significantly the CF splitting of the *f*-electron states (see below). The standard description of the outer electron states is based on the effective one-electron Hamiltonian which contains kinetic and potential energies describing the interaction with the ionic cores and charge density of the remaining valence electrons involved in the bonding of condensed matter. The effective one-electron approach can be formulated using Hartree–Fock (HF) (Freeman and Watson 1962) or density functional theory (DFT) (see *Density Functional Theory: Magnetism*).

#### 1.1 Central Field Approximation

The so-called central field approximation is commonly used to calculate the electronic structure of $N$ electrons in an $f$ shell, where each $f$ electron is assumed to move independently in a spherically symmetric effective potential, $-U(r_i)/e$:

$$H_0 = -\sum_{i}^{N}\left[\frac{-\hbar^2}{2m}\nabla_i + U(r_i)\right] \quad (2)$$

The sum is over the electrons in the $f^N$ shell, i.e., contributions involving electrons in closed shells are neglected. In the HF or DFT method the one-electron eigenfunctions of the Hamiltonian of Eqn. (2) are of the form:

$$\psi_{nlm_lm_s}(\mathbf{r},\sigma) = R_{nl}(r)\,Y_{lm_l}(\theta,\phi)\chi_{m_s} \quad (3)$$

where $R_{nl}(r)$ is the radial wave function $n = 4$, 5 is the principal quantum number, the quantum numbers

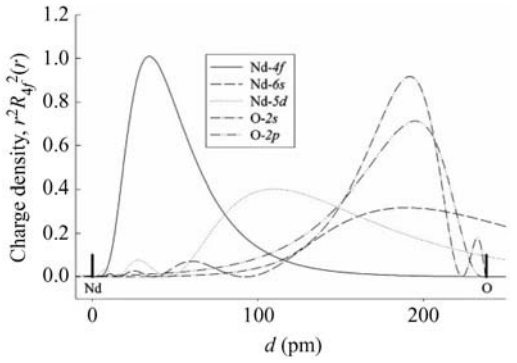

***Figure 1***
Radial 4*f*, 6*s*, and 5*d* charge density of the neodymium atom, and 2*s* and 2*p* charge density of the oxygen atom. The typical nearest-neighbor distance $d = 0.238$ nm in crystals was used for Nd–O pair.

$l = 3$ and $m_l$ characterize the orbital angular momentum, $\chi_{m_s}$ is the one-electron spinor function, and $m_s$ is the spin quantum number. The angular part of the one-electron eigenfunction can be written exactly using spherical harmonics as $Y_{lm_l}(\theta, \phi)$, while the radial part depends on the form of the potential $U(r)$ (Fig. 1). The quantum numbers $n$, $l$ define an *f*-electron *configuration*, entirely degenerate within the central field approximation. For the $nf^N$ configuration the degeneracies are given by the binomial coefficients $\binom{4l+2}{N}$ which are 1, 14, 91, 364, 1001, 2002, 3003, 3432 for $N = 0$–7. For the second half of the *nf* series, the degeneracies are the same as in the first half but in the opposite order.

The degeneracy of the $nf^N$ configuration is lifted by interactions which cannot be accounted for in the central field approximation. The calculation of the matrix elements of the related Hamiltonians is facilitated by the defining of a complete set of many-electron basis states in some well-defined coupling scheme. In the frequently used Russell–Saunders (*LS*) coupling, the orbital angular momentums of the electrons are vectorially coupled to give a total orbital angular $L$ and the spins are coupled to give a total spin $S$. These angular momentums are then coupled to give total angular momentum $J$. The numbers $L$ and $S$ are said to define a *term* ($^{2S+1}L$) of the configuration, $J$ defines a *multiplet* ($^{2S+1}L_J$) of the term. Group-theoretical methods are used to classify terms having the same $L$ and $S$ values (Wybourne 1965). According to Hund's rules (see *Density Functional Theory: Magnetism*) the lowest energy term has, first, $S$ with maximum value compatible with the Pauli principle and then $L$ with maximum value compatible with the $S$ value. The spin–orbit coupling (see Sect. 1.3) lifts the degeneracy of the $^{2S+1}L$ terms producing the $(2J+1)$-fold degenerate $^{2S+1}L_J$ multiplets. The lowest energy multiplet is such that $J = |L - S|$ if the *nf* shell is less than half full and $J = L + S$ in the other case. For instance, in the $f^2$ configuration, the $^3H$ term splits into the $^3H_4$, $^3H_5$ and $^3H_6$ levels, where $^3H_4$ is the ground state.

### *1.2 Coulomb Interaction*

The strongest perturbation, splitting the $nf^N$ configuration into the terms, arises from the Coulomb repulsion between the *f* electrons, described by the third term in Eqn. (1). As a result of expanding this interaction in Legendre polynomials, the corresponding Hamiltonian, $H_1$, can be written as:

$$H_1 = \sum_i^3 E^i \mathbf{e}_i \tag{4}$$

where $\mathbf{e}_i$ are operators that transform according to definite irreducible representations of the groups $G_2$ and $R_7$ (Racah 1949) and represent the angular part of the interaction. Matrix elements of the $\mathbf{e}_i$ operators have been tabulated for all states of the $f^N$ configuration (Nielson and Koster 1963). $E^i$ are linear combinations of Slater integrals $F^{(k)}$. In the case of *f* electrons ($l = 3$), only the integrals, $k = 2$, 4, and 6 need be considered.

Their definition is:

$$F^{(k)} = e^2 \int_0^\infty \int_0^\infty \frac{r_<^k}{r_>^{k+1}} R_{nl}^2(r_i)\, R_{nl}^2(r_j) r_i^2 r_j^2 \, \mathrm{d}r_i \mathrm{d}r_j \tag{5}$$

where $r_<$ and $r_>$ are, respectively, the lesser and greater of $r_i$ and $r_j$. Estimates of Slater integrals can be obtained by *ab initio* calculations. Both nonrelativistic and relativistic HF calculations substantially overestimate their values (Freeman and Watson 1962, Freeman 1979). When $F^{(2)}$, $F^{(4)}$ and $F^{(6)}$ are treated as phenomenological parameters fitted to the observed energy levels, they are found to be some 30–40% below the *ab initio* estimates. This discrepancy is ascribed to a screening mechanism within the free ion. The screening is ascribed to an admixture of higher lying electronic configurations into the $nf^N$ configuration causing the *f* electrons spend part of their time in more delocalized states, so effectively weakening their repulsion. Although the predominant screening mechanism is present in the free ion, there is an additional reduction of the values of the Slater integrals in ionic solids. The underlying mechanism is the hybridization of *f*-electron wave functions with the ligand orbitals. Even greater screening-induced reduction of $F^{(k)}$ is revealed in metallic systems (see *Density Functional Theory: Magnetism*).

### *1.3 Spin–Orbit Interaction*

The free-ion Hamiltonian contains, besides the electrostatic interactions, magnetic interactions. Among

these, the spin–orbit interaction is by far the predominant interaction, given by:

$$H_2 = \sum_{i=1}^{N} \xi(r_i)(\mathbf{s}_i \cdot \mathbf{l}_i) \tag{6}$$

where $r_i$ is the radial coordinate, $\mathbf{s}_i$ the spin, and $\mathbf{l}_i$ the orbital angular momentum of the $i$th electron. Note that the spin–orbit interaction influences the *nl* radial charge density distribution and Eqn. (3) should be modified to satisfy the relativistic Dirac–Fock Hamiltonian (see *Density Functional Theory: Magnetism*). The spin–orbit parameter $\xi(r)$ is then given by:

$$\xi(r_i) = \frac{\hbar^2}{2m_e^2c^2} \frac{1}{r_i} \frac{\mathrm{d}U}{\mathrm{d}r_i} \tag{7}$$

The Hamiltonian of Eqn. (6) can be conveniently rewritten in the form appropriate for matrix elements between $nf^N$ states as follows:

$$H_2 = 2\zeta_{nl}\sqrt{21} \cdot \sum_{\mu}(-1)V^{11}_{\mu,-\mu} \tag{8}$$

where $\zeta_{nl}$ is the spin–orbit radial integral which is a constant for the states of a given configuration and is defined as (Condon and Shortley 1967):

$$\zeta_{nl} = \int_0^{\infty} R_{nl}^2 \xi(r) r^2 \, \mathrm{d}r \tag{9}$$

and $V^{(11)}$ is the unit double tensor (Wybourne 1965).

The matrix elements on the right-hand side of Eqn. (8) can be calculated using available formulas (Wybourne 1965) and tables (Nielson and Koster 1963).

Within the *LS* coupling scheme, the spin–orbit coupling can be represented by the simple formula:

$$H_2 = \lambda(\mathbf{L} \cdot \mathbf{S}) \tag{10}$$

where $\lambda$ is a constant for a given *LS* state. This equation leads to the *Landé interval rule* that causes separation between levels differing by unity in their $J$ values:

$$E_J - E_{J-1} = \lambda J \tag{11}$$

Departures from the Landé interval rule give a measure of the breakdown of Russell–Saunders coupling owing to the spin–orbit interaction (Wybourne 1965). As this interaction is large enough in RE and An compounds it is usual to perform an ''intermediate coupling'' calculation, where the perturbation matrix containing both Coulomb and spin–orbit interactions is diagonalized. The spin–orbit interaction mixes different $^{2S+1}L$ levels with the same $J$ which means that $L$ and $S$ are no longer good quantum numbers. In some cases, it can be difficult to assign a meaningful $^{2S+1}L_J$ label to a particular level, since several terms make nearly equal contributions (Dieke 1968). This is not a serious problem for the lowest lying multiplets of interest for magnetic properties, most of which have a dominant component from one $^{2S+1}L$ term.

There is a considerable increase in $\zeta_{nl}$ with increasing atomic number and $\zeta_{nl}$ is considerably greater in An ions than in the corresponding RE ions. Like the Coulomb interaction (see Sect. 1.2), the spin–orbit interaction $\zeta_{nl}$ is also overestimated in usual *ab initio* calculations, although the discrepancy is smaller, less than 10% (see *Density Functional Theory: Magnetism*). In comparison with the Coulomb interaction, the spin–orbit interaction is much less sensitive to the local environment.

The $f^N$ configuration may have several hundred levels and is of the order of $10^5 \mathrm{cm}^{-1}$ (K) wide (Dieke 1968). When Eqns. (4) and (9), containing respectively three Slater integrals $F^{(k)}$ and spin–orbit parameter $\zeta_f$ are used, discrepancies of up to a few hundred $\mathrm{cm}^{-1}$ (K) remain between the calculated and experimental energy levels. A more complete free-ion Hamiltonian contains several additional interactions arising from the effect of configuration interactions and the couplings of the orbital and spin angular moments on different electrons (orbit–orbit, spin–spin, spin–other orbit). Such a Hamiltonian typically contains 19 parameters. As none of them can, in the majority of cases, be calculated theoretically with sufficient precision, they are usually determined along with the appropriate set of CF parameters (see Sect. 2) in a least-squares fitting to experimental energy spectra (Morrison and Leavitt 1982). Note that more sophisticated large-scale multiconfigurational Dirac–Fock (Cai *et al*. 1992) and coupled cluster methods (Eliav *et al*. 1995) allow one to calculate the multiplet energies of $4f^2(Pr^{3+})$ and $5f^2(U^{4+})$ configurations with very good accuracy.

In general, an understanding of the free-ion Hamiltonian is an important prerequisite for CF study (see Sect. 2).

## 2. Crystal Field Interactions

The $(2J+1)$-fold degenerate energy levels of $4f$ or $5f$ ions in a compound are split by the CF interaction. Its impact on the magnetic properties is important. It ''quenches'' the orbital contribution to ionic magnetic moments (see Sect. 3) and in combination with the spin–orbit coupling (see Sect. 1.3) it is the principal source of magnetic anisotropy, i.e., of the dependence of magnetic properties on direction in the compound (see *Alloys of 4f (R) and 3d (T) Elements: Magnetism* and *Transition Metal Oxides: Magnetism*). Further physical properties influenced by the CF interaction include the magnetoelastic properties (see *Magnetoelastic Phenomena*) (Häfner *et al*. 1981), specific heat (Luong and Franse 1995, Purwins and Leson 1990), and transport properties (Gratz and Zuckermann 1982).

### 2.1 Hamiltonian

The interaction Hamiltonian $H_{\mathrm{CF}}$ of $f$ electrons with the CF potential can always be written in terms of one-electron irreducible tensor operators as:

$$\begin{aligned} H_{\mathrm{CF}} &= \sum_{k,q,i} B_{kq}[c_q^{(k)}(i) + c_{-q}^{(k)}(i)] \\ &= \sum_{k,q} B_{kq} \sum_i c_q^{(k)}(i) + c_{-q}^{(k)}(i) \\ &= \sum_{k,q} B_{kq}[C_q^{(k)} + C_{-q}^{(k)}] \end{aligned} \tag{12}$$

where $C_q^{(k)}$ transform as tensor operators (Racah 1949, Wybourne 1965, Judd 1979) under simultaneous rotations of the coordinates of all the $f$ electrons. The $B_{kq}$ are so-called CF parameters characterizing the CF interaction in a given compound. Once these parameters are available, the matrix representation of $H_{\mathrm{CF}}$ can be constructed. The eigenvalues and eigenstates of the operator $H_{\mathrm{CF}}$ are obtained from the standard secular equation. The matrix elements of $C_q^{(k)}$ with respect to states of a $nf^N$ configuration characterized by quantum numbers $\alpha SLJJ_z$, where $\alpha$ represents the set of quantum numbers necessary to distinguish states of the same $L$ and $S$, are diagonal in the spin $S$ and may be calculated using the *Wigner–Eckart theorem* (Wybourne 1965):

$$\begin{aligned} &(nf^N \alpha SLJJ_z | C_q^{(k)} | nf^N \alpha' SL'J'J_z') \\ &\quad = (-1)^{J-J_z} (f \| \mathbf{C}^{(k)} \| f)(nf^N \alpha SLJ \| U^{(k)} \| nf^N \alpha' SL'J') \\ &\qquad \times \begin{pmatrix} J & k & J' \\ -J_z & q & J_z' \end{pmatrix} \end{aligned} \tag{13}$$

where $U^{(k)}$ is a unit tensor operator. The last factor in Eqn. (13) is a 3-$j$ symbol. The matrix elements on the right-hand side of Eqn. (13), indicated by the double modulus rules around the tensor operator, are called the *reduced matrix elements*. They can be calculated from available formulas (Wybourne 1965) and tables (Nielson and Koster 1963).

In practice the CF parameters are either determined from experimental data or calculated from a semiphenomenological or *ab initio* theory (see Sect. 2.3).

The splitting of the $J$ multiplets by the CF is of the order of $10^2$–$10^3 \mathrm{cm}^{-1}$ (K). The *crystal field strength parameter*, defined as follows (Kibler 1983):

$$s = (2l+1)\left[\sum_{kq} \frac{1}{2n+1} \begin{pmatrix} l & k & l \\ 0 & 0 & 0 \end{pmatrix}^2 |B_{kq}|^2\right]^{1/2} \tag{14}$$

is a quantitative measure of the strength of the CF interaction of a particular $f$-electron ion with a particular host crystal.

Especially in older literature one can find alternative parameterization schemes for the CF interaction of Eqn. (12). This led to a degree of confusion between the meanings of similar or identical symbols used by different authors (Dieke 1968). Widely used is a formula arising from the theory of equivalent operators (Abragam and Bleaney 1970, Stevens 1997). The main disadvantage of this method is that it does not take into account the $J$ mixing, i.e., the mixing of different free-ion levels by the CF interaction. Consequently, the use of this method can lead to considerable error in analysis of optical spectra (Morrison and Leavitt 1982).

In the great majority of cases the single-ion Hamiltonian (Eqn. (12)) is adequate to account for observed CF spectra of $f$ ions in solids. There are, however, a few exceptions. The $^1D_2$ multiplet of the $4f^2$ configuration in $Pr^{3+}$ can serve as an example, where large errors remain in the description of the experimental data. The terms in the CF Hamiltonian involving two-electron interaction ("correlation crystal field") have to be considered in such cases (Judd 1979). Note that attempts to fit the experimental data by the Hamiltonian represented by Eqn. (12) in cases where two-electron effects are significant will lead to a term dependence of the CF parameters (Morrison and Leavitt 1982).

### 2.2 Symmetry

A restriction on the number of nonvanishing parameters $B_{kq}$ in Eqn. (12) arises from symmetry considerations. It follows from the hermiticity and time-reversal invariance of $H_{\mathrm{CF}}$ that $k$ must be even. In addition, if only $f$ electrons are involved, only the terms with $0 \leqslant k \leqslant 6$ are nonzero. Moreover, $B_{kq}$ for $q<0$ are related to those for $q>0$ by:

$$B_{kq} = (-1)^q \cdot B_{kq}^* \tag{15}$$

The first term in the expansion given in Eqn. (12), $k=q=0$, is spherically symmetric. Although this term is by far the largest term in the expansion it gives a uniform shift to all the levels of the configuration and may be ignored as far as the CF splitting is concerned. A further restriction arises from the requirement of invariance under the point group operations. $B_{kq}$ are real in any symmetry group that contains a rotation about the $y$-axis by $\pi$ or a reflection through the $x$–$z$ plane, otherwise they are complex.

The 32 point groups are listed in sets in Table 1, each of which has the same nonvanishing $B_{kq}$. An example is given for each set.

Depending on the site symmetry, the CF removes partly or entirely the $(2J+1)$-fold degeneracy of the free-ion $J$ multiplets. There are two important theorems concerning the degeneracy of the CF energy levels:

***Table 1***
Independent nonvanishing $B_{kq}$ for the 32 point groups.

| Group | Nonvanishing $B_{kq}$ | Example |
|---|---|---|
| $C_1$, $C_I$ | All $B_{kq}$ ($B_{21}$ real) | $NdP_5O_{14}$ |
| $C_2$, $C_S$ ($C_{1h}$), $C_{2h}$ | $B_{20}$, Re$B_{22}$, $B_{40}$, $B_{42}$, $B_{44}$, $B_{60}$, $B_{62}$, $B_{64}$, $B_{66}$ | $LaF_3$ |
| $D_2$, $C_{2v}$, $D_{2h}$ | $B_{20}$, Re$B_{22}$, $B_{40}$, Re$B_{42}$, Re$B_{44}$, $B_{60}$, Re$B_{62}$, Re$B_{64}$, Re$B_{66}$ | $Y_3Al_5O_{12}$, $NdCu_2$, $NdBa_2Cu_3O_7$ |
| $C_4$, $S_4$, $C_{4h}$ | $B_{20}$, $B_{40}$, Re$B_{44}$, $B_{60}$, $B_{64}$ | $CaWO_4$ |
| $D_4$, $C_{4v}$, $D_{2d}$, $D_{4h}$ | $B_{20}$, $B_{40}$, Re$B_{44}$, $B_{60}$, Re$B_{64}$ | $YVO_4$, $Nd_2CuO_4$, $NdCu_2Si_2$ |
| $C_3$, $S_6$ | $B_{20}$, $B_{40}$, Re$B_{43}$, $B_{60}$, $B_{63}$, $B_{66}$ | $LiNbO_3$ |
| $D_3$, $C_{3v}$, $D_{3d}$ | $B_{20}$, $B_{40}$, Re$B_{43}$, $B_{60}$, Re$B_{63}$, Re$B_{66}$ | $Y_2O_2S$ |
| $C_6$, $C_{3h}$, $C_{6h}$, $D_6$, $C_{6v}$, $D_{3h}$, $D_{6h}$ | $B_{20}$, $B_{40}$, $B_{60}$, Re$B_{66}$ | $LaCl_3$, $ErGa_2$ |
| $T$, $T_d$, $T_h$, $O$, $O_h$ | $B_{20}$, Re$B_{44}$, $B_{60}$, Re$B_{64}$ | $ErAl_2$, $PrO_2$, $UO_2$ |

*Kramers' theorem*. This states that for odd-electron systems—Kramers ions—there is a remaining two-fold degeneracy which cannot be removed by any electric fields. It is interesting to note that the entropy of a Kramers ion is at least $S = k_B \ln 2$ at temperatures approaching absolute zero. This degeneracy thus must necessarily be removed by some mechanism if the third law of thermodynamics is to retain its validity.

*The Jahn–Teller theorem*. This states that any atom in a solid with ground state degeneracy of non-Kramers type lifts this degeneracy by lowering its symmetry (see *Transition Metal Oxides: Magnetism*). Such a lowering occurs in many *f*-electron compounds (Gehring and Gehring 1975, Aminov *et al*. 1996).

### 2.3 Crystal Field Parameters

A principal aim of most CF studies is to find a complete and reliable set of the CF parameters in a given compound. The methods used to this end are described in the following.

#### (a) Determination of CF parameters from experimental data

Given the CF energy levels, i.e., the eigenvalues of the secular equation of $H_{CF}$, one can calculate the unknown parameters $B_{kq}$, determining the elements of the matrix $H_{CF}$, solving numerically the *inverse secular problem*. Symmetry of an *f* ion site must to be known from the x-ray or neutron scattering data or assumed before the CF calculation is initiated.

The most straightforward and extensive experimental information on CF energy levels is provided by optical and neutron scattering spectra (see *Crystal Field Effects in Intermetallic Compounds: Inelastic Neutron Scattering Results*). The peaks in these spectra are present owing to electric and magnetic dipole *f–f* transitions, respectively (Dieke 1968, Marshall and Lovesey 1971). Optical methods, including absorption, fluorescence, and Raman scattering measurements, are used for transparent insulators and semiconductors. In general, a combination of several experimental methods allows the determination of a sufficiently complete CF spectrum of an $nf^N$ configuration. The number of experimental CF energy levels then usually exceeds considerably the number of fitted CF parameters that guarantees their reliability (Dieke 1968, Hüfner 1978, Morrison and Leavitt 1982). The cuprate $Nd_2CuO_4$ can serve as an example of a compound studied by optical absorption as well as by inelastic neutron and Raman scattering (Jones *et al*. 1992, Muzichka *et al*. 1992, Jandl *et al*. 1995, 1998). Very sensitive optical absorption techniques also allowed one to detect sharp *f–f* transitions in some metals. Measurement of CF transitions in the superconductor $(Nd,Ce)_2\ CuO_{4-x}$, metallic above $T_C \approx 20$–24K, can serve as an example (Jones *et al*. 1992). There is one earlier example of a metallic system, $CeB_6$, which has been studied by Raman scattering (Zirngiebl *et al*. 1985).

Various techniques are used to circumvent experimental difficulties. For example, instead of in nearly opaque ferrimagnetic iron garnets (see *Transition Metal Oxides: Magnetism*) the CF spectra of RE ions are measured in optically transparent, structurally very similar gallium and aluminum garnets (Winkler 1981). Similarly, to obtain the "CF only" spectra in RE metals one can decrease the magnetic interaction by dilution with nonmagnetic ions (Fulde and Loewenhaupt 1986). Trivalent ions are preferably replaced by scandium, yttrium, lanthanum, or lutetium.

Besides transition energies, relative transition intensities can also be used as input data in the best-fit search of the CF parameters. This is advantageous in the case of Raman and neutron measurements where calculation of matrix elements of electric dipole and magnetic dipole moments, respectively, determining

the transition probability between two CF states, is straightforward (Nekvasil 1982, Hilscher *et al*. 1994). Calculation of relevant matrix elements in the case of optical absorption or emission is more complicated owing to the necessity of considering mixing of opposite-parity configurations by odd-parity components of the CF (Dieke 1968).

Phenomenological CF parameters for *f*-electron ions in various host crystals are widely available in the literature. Mentioned here are the reviews for RE ions in nonmetallic compounds (Morrison and Leavitt 1982, Aminov *et al*. 1996), metallic compounds (Moze 1998), and cuprates (Nekvasil *et al*. 1995, Staub and Soderholm 2000). For actinides CF parameters are also available (Gajek 1995). The precision of the CF values quoted in the literature depends on the number and reliability of the underlying experimental data as well as on their numerical and quantum mechanical processing. In general, the most favorable situation in fitting the experimental data is the diagonalization of the many parameter free-ion Hamiltonian (see Sect. 1), together with the CF Hamiltonian, in a basis that spans the entire $f^N$ configuration. Unfortunately a large quantity of experimental data is required to ensure its success. Therefore, CF data are often obtained by using various approximations. There is a long list of problems that may occur in interpreting the CF values available in the literature (Morrison and Leavitt 1982).

### *(b) Semiempirical models*

The superposition model (SM) was introduced to separate the geometrical and physical information contained in the CF parameters (Newman and Ng 1989). The SM is based on several postulates:

(i) The total CF acting on the open-shell electrons of a paramagnetic ion is the sum of the contributions coming from neighboring ions (commonly referred to as ligands) forming the coordination polyhedron.

(ii) Each ligand contribution to the sum is axially symmetric about the line joining its center to that of the paramagnetic ion. Frequently a third, transferability, postulate is invoked:

(iii) Single-ligand contributions depend only on the nature of the ligand and its distance from the paramagnetic ion, and do not depend on other properties of the host crystal.

Postulates (i) and (ii) allow one to describe each individual contribution by "intrinsic (i.e., geometry-independent) CF parameters" $b_k(R)$ where $R$ denotes the distance between the RE and ligand ion. The CF parameters $B_{kq}$ in Eqn. (13) and intrinsic parameters $b_k(R)$ are related as:

$$B_{kq} = \sum_i S_{kq}(i) \cdot b_k(R_i) \tag{16}$$

where $S_{kq}(i)$ is the geometrical factor determined by angular coordinates of ligands at the same distance $R_i$.

These structural data can be determined with sufficient precision from x-ray or neutron scattering data. Note that independent of the mechanism of interaction between the paramagnetic ion and ligand, the relation $B_{kq}/B_{k0}$ only depends on the geometry of the coordination polyhedron. This explains why in some cases the relation $B_{kq}/B_{k0}$ calculated using the unrealistic standard point charge model provides a useful prediction. The SM does not apply for the $k = 2$ parameters where the long-range electrostatic contribution appears to dominate, which causes a breakdown of postulate (i) of the SM.

A convenient way of expressing the distance dependence of the intrinsic parameters is to assume the power law dependence:

$$b_k = b_k(R_0) \cdot (R_0/R)^{t_k} \tag{17}$$

where $R_0$ is some arbitrarily fixed "standard" paramagnetic ion–ligand distance. For each value of $k$, the values up to $2k+1$, in general complex, CF parameters $B_{kq}$ are determined by just two real SM parameters, $b_k(R_0)$ and $t_k$. In the case of low-symmetry sites an application of the SM thus means a significant reduction of the number of independent parameters required to describe the CF interaction.

The intrinsic parameters and power law exponents have been extracted from the phenomenological CF parameters $B_{kq}$ available for various nonmetallic materials. These include di- and trivalent RE ions with fluorine, oxygen, and chlorine ligands as well as tri-, tetra-, and pentavalent actinides with oxygen and halide ligands. These data confirm the general validity of the SM (Newman and Ng 1989). In particular, having available the intrinsic parameters and power law exponents for a given paramagnetic ion in one host system, postulate (iii) of the SM model makes possible the prediction of the CF interaction for the same paramagnetic ion in other host systems with the same ligand. As an example of such a prediction the CF splitting of the lowest $J$ multiplets of trivalent RE ions in $REBa_2Cu_3O_7$ (RE = Ho, Er), compared to later experimental data in Fig. 2, may serve. It is seen in Fig. 2 that, despite the uncertainty in the values of the second-order CF parameters, the SM calculation using the available structural data and the model parameters available in garnets predicts successfully the main features of the CF spectra.

In metallic systems, applications of the SM are rather scarce. The available data for a few RE binary (Newman and Ng 1989, Diviš 1991) and ternary (Goremychkin *et al*. 1994) intermetallics indicate that, while the model provides qualitative interpretation of the main features of the phenomenological CF data, its general validity has yet to be confirmed in these systems. A useful tool allowing one to examine the model postulates is provided by first principle calculations (see below). It follows from these calculations that in the case of fourth-order CF parameters

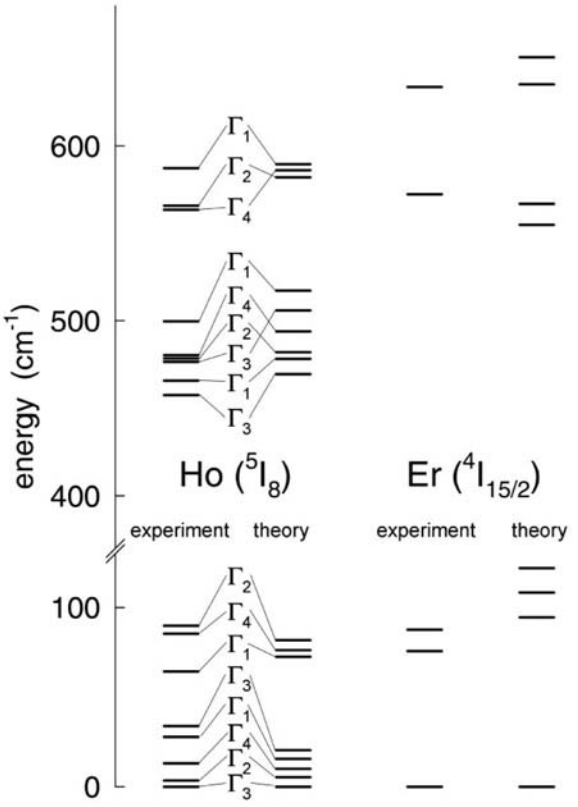

***Figure 2***
Predicted and experimentally measured CF levels of $HoBa_2Cu_3O_7$ ($J=8$) and $ErBa_2Cu_3O_7$ ($J=15/2$). $\Gamma_i$ denote the irreducible representation (point group symmetry) of particular CF eigenstates (Nekvasil *et al.* 1988 and references therein).

the contribution of the charge density from the region of the next nearest neighbor is significant, which throws some doubt on the validity of postulate (i) of the model. This contribution is smaller in the case of sixth-order CF parameters (Diviš *et al.* 1997).

The point charge model (PCM), often used for the charge distribution, can be considered as a special case of the SM. Note the PCM values of the power law exponents, $t_4=5$ and $t_6=7$. Comparison with the SM values $t_4=9.9$ and $t_6=3.9$, obtained by a detailed analysis of 14 sets of reliable phenomenological CF parameters available in RE garnets, strongly indicates that the nonelectrostatic contributions including overlap, exchange, and charge penetration contributions to the CF, none accounted for by the PCM, dominate (Nekvasil 1979).

The angular overlap model parameterizes the CF pair interaction in a formally similar way to the SM, where the intrinsic parameters are replaced by quantities which are functions of the overlap integral of $f$ and ligand wave functions. The angular overlap model can be considered as the semiempirical version of the many-body perturbation theory (Newman and Ng 1989).

*(c) Ab initio calculations*

*Ab initio* calculations of the CF interaction in $f$-electron compounds are usually based either on the DFT or on the many-body perturbation theory (MBPT). These calculations naturally include the contributions from bonding 6*s*5*d* (7*s*6*d*) electrons and the aspherical shielding effects originating from 5*s*5*p* (6*s*6*p*) electrons of a RE (An) ion in a crystalline environment.

Within the DFT the parameters $B_{kq}$ of the CF Hamiltonian (Eqn. (12)) originating from the effective potential $V$ inside the crystal, are written as:

$$B_{kq} = a_k^q \int_0^\infty |R_{nl}(r)|^2 \; V_k^q(r) r^2 \; \mathrm{d}r \qquad (18)$$

where nonspherical components $V_k^q(r)$ reflect, besides the nuclear potentials and Hartree part of the interelectronic interaction, also the exchange correlation (XC) term which accounts for many-particle effects.

The key task of *ab initio* methods is to calculate the components $V_k^q(r)$. Within the linear augmented plane wave method (LAPW), Eqn. (18) is written as a sum of two contributions:

$$B_{kq} = a_k^q \left( \int_0^{R_{MT}} |R_{nl}(r)|^2 U_k^q(r) r^2 \; \mathrm{d}r + \int_{R_{MT}}^\infty |R_{nl}(r)|^2 W_k^q(r) r^2 \; \mathrm{d}r \right) \qquad (19)$$

where $U_k^q(r)$ and $W_k^q(r)$ are, respectively, the components of the effective potential inside the atomic sphere with radius $R_{\mathrm{MT}}$ and in the interstitial region. The conversion factor $a_k^q$ (Novák 1996, Dieke 1968) establishes the relationship between the LAPW symmetrized spherical harmonic and the real Tesseral harmonics. A comprehensive survey of the computational techniques used in the framework of DFT calculations is available (Richter 1998).

In comparison with LAPW, the OLCAO method combines the advantage of a fast computational scheme with a sufficiently accurate representation of the effective potential $V$. The latter method provides a significant insight into the physical origin of the CF interaction. In particular, it allows the determination of where in space the CF creating charges are situated. It turns out that, roughly, a neighborhood extending to 0.7nm (containing $\sim$70 atoms in typical intermetallics) is responsible for the second-order CF parameters, whereas fourth- and sixth-order parameters are created within 0.5nm ($\sim$30 atoms) and 0.4nm ($\sim$20 atoms), respectively.

The second important quantity of Eqn. (18) is the radial $f$ wave function $R_{nl}$. Its atomic value,

***Table 2***
CF parameters, $B_{kq}$ (in $cm^{-1}$), of $SmCo_5$ ($1cm^{-1} = 0.123$ meV).

| | $B_{20}$ | $B_{40}$ | $B_{60}$ | $B_{66}$ |
|---|---|---|---|---|
| Experiment | −250 to −584 | −78 | +100 | +168 |
| Novák 96 | −485 | −205 | +79 | +231 |
| Hummler 96 | −706 | −111 | +21 | (−)40 |
| Daalderop 96 | −1061 | −150 | +40 | +72 |
| Richter 95 | −1056 | −206 | +122 | +212 |

Source: Richter (1998).

determined by Dirac–Fock-type calculations, has to be replaced by the value reflecting the self-consistent DFT crystal potential.

DFT-based methods have been used to calculate the CF parameters in many metallic RE and An systems. As is shown in Table 2 this method interprets well the experimentally observed influence of the chemical composition on magnetic properties (Richter 1998).

The only DFT-based CF data available in insulators are those for cuprates (Diviš *et al.* 1998). It appears that while the sign and magnitude of second-order CF parameters are obtained correctly, those of fourth- and sixth-order CF parameters are only poorly described. This inadequacy is tentatively associated with the underestimation of the strong correlation effects related to the local approximation for the exchange correlation part of the effective crystal potential (see *Density Functional Theory: Magnetism*).

*Ab initio* calculations of CF parameters can also be performed by using a many-body approach (Newman 1971). Its principal idea is to confine all the interactions in a many-electron system to the effective, one-electron potentials by using standard renormalization and averaging procedures within MBPT. The most important assumptions associated with these procedures are (Gajek 1995):

(i) The many-electron wave functions are replaced by determinants built from free-ion orbitals. Only the electrons from outer shells are considered. For instance, in the case of $PrCl_3$ the 4*f*, 5*s*, and 5*p* orbitals of the $Pr^{3+}$ ion as well as the 3*s* and 3*p* orbitals of the six $Cl^-$ ions are taken into account.

(ii) The corrections due to the nonorthogonality of RE (An) and ligand orbitals and configuration interaction effects are described by the second order of the perturbation series.

(iii) The Hamiltonian describing the interactions in the crystal lattice is divided into two parts. The first part represents the interactions within the cluster formed by the central *f* ion and ligands; the second part corresponds to the interactions with the rest of the crystal lattice. It is usually assumed that the interactions within a cluster can be regarded as a sum of axially symmetric interactions calculated for the individual paramagnetic ion–ligand pairs. This simplification, identical with postulates (i) and (ii) of the SM (see above), allows one to neglect the polarization effects. The interaction with the rest of the crystal lattice is approximated by the Madelung-like potential.

In contrast with DFT methods, applied mainly to metallic compounds, the MBPT in its form described above is suitable for *f* ions in insulators (Gajek 1995).

## 3. Ions in Applied Magnetic Fields

### 3.1 Zeeman Effect

The CF-split *f*-electron spectra of the ionic or atomic *J* multiplets may be further perturbed by applying an external magnetic field, $H^a$. Such a perturbation, called the *Zeeman effect*, can be described by the Hamiltonian $H_{\mathrm{Zeem}}$:

$$H_{\mathrm{Zeem}} = -\boldsymbol{\mu} \cdot \mathbf{H}^a \tag{20}$$

where

$$\boldsymbol{\mu} = \mu_{\mathrm{B}}(g_l \mathbf{L} + g_s \mathbf{S}) \tag{21}$$

is the magnetic moment and $g_l$ and $g_s$ are the orbital ($=1$) and spin ($=2.0023$) gyromagnetic factors. For the calculation of the matrix elements of the Zeeman term (Eqn. (20)), it is useful to express $\boldsymbol{\mu}$ by means of the tensor operator $T^{(1)}$ (Wybourne 1965):

$$\begin{aligned} T^{(1)}_{\pm 1} &= \frac{\mp 1}{\sqrt{2}}[(L_x + 2S_x) \pm i(L_y + 2S_y)] \\ T^{(1)}_{0} &= L_z + 2S_z \end{aligned} \tag{22}$$

$$\langle SLJJ_z \left| T^{(1)}_q \right| SLJ'J'_z \rangle = (-1)^{J-J_z} \begin{pmatrix} J & 1 & J' \\ -J_z & q & J'_z \end{pmatrix} \langle SLSJ \parallel T^{(1)} \parallel SLJ' \rangle$$

The reduced matrix elements of $T^{(1)}$ can be obtained by the tensor operator method (Wybourne 1965). Within a given *J* multiplet one can write:

$$\mathbf{L} + g_s \mathbf{S} = g_{\mathrm{J}} \mathbf{J} \tag{23}$$

$$H_{\mathrm{Zeem}} = -g_J \mu_{\mathrm{B}} \mathbf{J} \cdot \mathbf{H}^a \tag{24}$$

where $g_J = 1 + (g_s - 1)[J(J+1) + S(S+1) - L(L+1)]/2J(J+1)$ is the *Landé factor*.

Note that in the absence of the CF the *J* multiplet is split by a magnetic field into $2J+1$ equidistant levels each corresponding to a different value of $J_z$, where *z* is the direction of the applied magnetic field. Two neighboring levels are separated by the energy gap $\mu_{\mathrm{B}} g_J H_z$.

### 3.2 *Paramagnetism*

A paramagnetic system can be treated as an assembly of $N$ noninteracting $f$-electron ions in magnetic field $H^a$. The thermal average of ionic magnetic moments is given by the Boltzmann statistics formula:

$$\mathbf{M} = (1/Z)\sum_i \boldsymbol{\mu}_i \exp(-E_i/k_\mathrm{B}T) \tag{25}$$

where $\boldsymbol{\mu}_i$ is the magnetic moment of the $i$th energy level:

$$\boldsymbol{\mu}_i = -\mu_\mathrm{B}\langle i|\mathbf{L} + g_s\mathbf{S}|i\rangle \tag{26}$$

and where $Z$ is the partition function:

$$Z = \sum_i \exp(-E_i/k_\mathrm{B}T) \tag{27}$$

$E_\mathrm{i}$ and $|i\rangle$ are, respectively, eigenvalues and eigenvectors of the total perturbation Hamiltonian $H_R$ which includes the CF (Eqn. (12)) and Zeeman terms (Eqn. (20)):

$$H_R = \sum_{kq} B_{kq}C_q^{(k)} - \boldsymbol{\mu}\cdot\mathbf{H}^a \tag{28}$$

Note that $E_i$ denotes the energy of the levels with respect to the ground state.

The calculation of the magnetic moment using Eqns. (25)–(28) is straightforward provided that the CF parameters for the given compound are known. The magnetic moment is in general anisotropic, as besides the magnitude of $H^a$ it also depends on its orientation with respect to the crystallographic axes (see Fig. 3). In the absence of the CF and neglecting the higher excited multiplets, the right-hand side of Eqn. (25) can be expressed in terms of the Brillouin function (Gignoux 1991).

The tensor of magnetic susceptibility $\boldsymbol{\chi}$ is given by the formula:

$$\chi_{\alpha\beta} = \left(\frac{\delta M_\alpha}{\delta H_\beta^\alpha}\right)_{H^\alpha\to 0} \tag{29}$$

An alternative perturbation approach to the Zeeman effect allows one to write the susceptibility per ion along the principal axes ($\alpha=\beta=a, b, c$) as (Luong and Franse 1995):

$$\chi^\alpha = \frac{g_J^2\mu_B^2}{Z}\sum_i \times\left\{\frac{1}{kT}\,|(i|J_\alpha|i)|^2 + 2\sum_{j\neq i}\frac{|(j|J_\alpha|i)|^2}{E_j - E_i}\right\}\exp(-E_i/k_BT) \tag{30}$$

where the first term in the braces, temperature dependent, is called the Curie term and the second, temperature independent, is the Van Vleck term. For a polycrystalline sample the susceptibility $\chi^{(p)}$ is obtained by the approximation:

$$\chi^{(p)} = (\chi^{(a)} + \chi^{(b)} + \chi^{(c)})/3 \tag{31}$$

From symmetry considerations it follows that: (a) $\chi$ is isotropic in cubic compounds; (b) $\chi^{(c)} \neq \chi_{\perp\mathrm{c}}$ in hexagonal and tetragonal systems; and (c) $\chi^{(a)} \neq \chi^{(b)} \neq \chi^{(c)}$ in orthorhombic systems. At high temperatures the inverse susceptibility along each axis tends to be linear with the same slope, giving rise to the same effective moment $g_J\mu_\mathrm{B}\sqrt{(J(J+1))}$. For a noncubic compound, the shifts between the high-temperature susceptibilities are proportional to the second-order CF parameters. The low-temperature behavior of the susceptibility is strongly influenced by the CF. In particular the Van Vleck contribution to the susceptibility tends to dominate in the case of non-Kramers ions in which the lowest energy state is a singlet or nonmagnetic doublet. Such compounds are called Van Vleck paramagnets (Gignoux 1991, Aminov *et al.* 1996). As an example of such system the susceptibility of the $Pr^{3+}$ ion in a cubic CF is shown in Fig. 4.

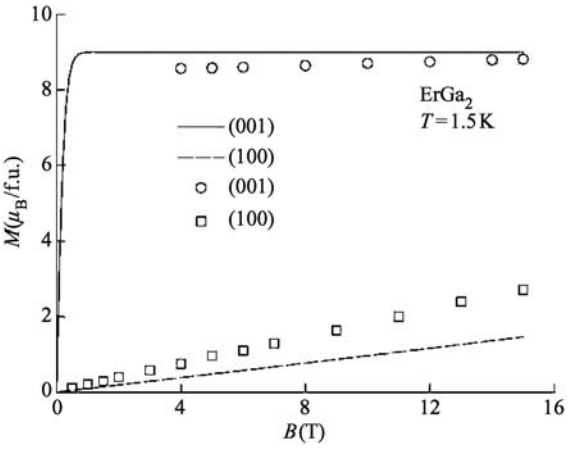

***Figure 3***
Magnetization of $ErGa_2$ as a function of the external magnetic field. In (001) direction, only data for $B>4$T are shown since data below 4T are strongly influenced by exchange interaction inducing two metamagnetic transitions. The lines are obtained from calculations based on CF and Zeeman Hamiltonian (Eqn. (28)), with CF parameters obtained from density functional theory (Diviš *et al.* 1997).

## 4. *Cooperative Effects*

A magnetic state arising from localized moments in a solid is the net effect of competing influences: the

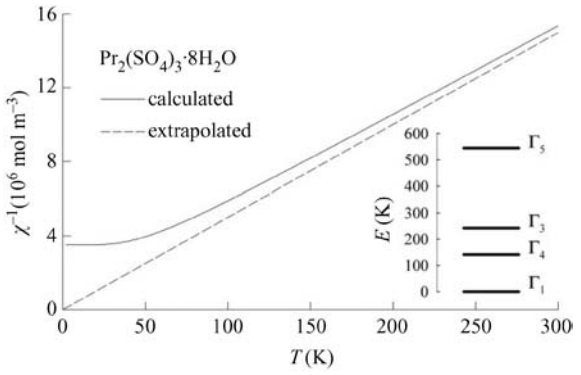

***Figure 4***
Splitting of the ground state multiplet ($J=4$) of the $Pr^{3+}$ ion in $Pr_2(SO_4)_3 \cdot 8H_2O$ (inset). The susceptibility is determined by the temperature independent Van Vleck term in Eqn. (30) (full lines) at low temperatures. The dashed line is the high-temperature asymptote of the thermal variation of the reciprocal susceptibility.

ordering resulting from a magnetic coupling is perturbed by the thermal energy which tends to randomize the orientation of each moment. The cooperative effects are primarily due to pair exchange coupling, derived from the influence of the Pauli principle on the Coulomb repulsion between electrons. One can distinguish two classes of exchange coupling (Hurd 1982). *Direct exchange* operates between moments on ions whose magnetic orbitals have significant overlap. Such interaction, which occurs in 3*d* intermetallic compounds and is responsible for the high ordering temperatures in ferromagnets used for technical applications, gives a strong but short-range coupling (see *Itinerant Electron Systems: Magnetism (Ferromagnetism)*). Weaker, *indirect exchange*, coupling moments over relatively large distances, occurs in *f*-electron compounds. It is mediated by itinerant electrons in metals and by nonmagnetic ions (ligands) in insulators. These couplings are known as the RKKY (after Ruderman, Kittel, Kasuya, and Yosida) and *superexchange* effects, respectively. The physical interaction mechanisms which occur in *f*-electron compounds also include *electric multipole interactions* and *magnetic dipole–dipole coupling* (Wolf 1971, Aminov *et al.* 1996, Jensen and Mackintosh 1991).

### 4.1 Form of Interaction Hamiltonian

The exchange interaction between two $S$ state ions (orbitally nondegenerate) $i$ and $j$, having spins $\mathbf{S}_i$ and $\mathbf{S}_j$, respectively, can be described by an isotropic Heisenberg Hamiltonian:

$$H_{ij} = -J_{ij}\mathbf{S}_i\mathbf{S}_j \tag{32}$$

where $J_{ij}$ is called the exchange parameter which can be positive (ferromagnetism), negative (antiferromagnetism), or oscillatory (e.g., helical structures) as in the case of an RKKY-type interaction. Within the ground state multiplet it is often convenient to express $H_{ij}$ in terms of $\mathbf{J}$ rather than $\mathbf{S}$ (see Sect. 3.1):

$$H_{ij} = -J_{ij}(g_J - 1)^2\mathbf{J}_i\mathbf{J}_j \tag{33}$$

In systems containing *f*-electron ions the isotropic exchange operator (Eqns. (32) and (33)) has to be in general extended by *anisotropic* terms. The anisotropy of the coupling is associated with the orbital moment of the electrons involved. The exchange Hamiltonian then takes the form (Wolf 1971, Baker 1971, Levy 1975, Jensen and Mackintosh 1991):

$$H_{ij} = \sum_{ll'mm'} K_{ll'}^{mm'}(ij)\,T_l^{(m)}(\mathbf{J}_i)\,T_{l'}^{(m')}(\mathbf{J}_j) \tag{34}$$

where the terms that appear in the sum are restricted by symmetry, but otherwise may exhibit a large variety, depending on their origin. The matrix elements of the operator (Eqn. (34)) can be calculated using the methods of Racah algebra (Levy 1975). The general exchange operator (Eqn. (34)) contains, besides the bilinear isotropic term (Eqn. (32)), also higher order isotropic interactions and all types of anisotropic exchange, e.g., the pseudodipole exchange and the antisymmetric Dzyaloshinskii–Moriya exchange (see *Transition Metal Oxides: Magnetism*). The effective spin–spin coupling due to the electric multipole interaction produced by aspherical charge distributions in solids can be also be written like Eqn. (34) (Wolf and Birgeneau 1968, Levy 1975). For *f* electrons there are up to 4096 exchange parameters $K_{ll'}^{mm}$ of which 1954 are independent.

These numbers further increase in cases when the interacting RE ions are not identical (Levy 1975). The exchange anisotropy may be very pronounced:there are systems in which the isotropic Heisenberg-type exchange (Eqn. (32)) alone appears to be completely incapable of explaining the observations (Cone and Wolf 1978, Jandl *et al.* 1999, Nugroho *et al.* 2001). Consequently, it is meaningless to apply the operator (Eqn. (34)) in an arbitrarily simplified form. One of the most important practical roles of the theory is thus the identification of special cases where the real interaction can be described by only a few parameters. This is the case, for example, in the interaction of $Er^{3+}$ impurities with the $Tb^{3+}$ magnetic sublattice in $Tb(OH)_3$ where the number of parameters $K_{ll'}^{mm'}$ can be reduced from the very large number of 21 736 to 8 (Cone and Wolf 1978). In some cases, one can lower the number of parameters required to describe the anisotropic exchange coupling by projection of the operator (Eqn. (34)) onto the states of an *effective* total angular momentum (fictitious spin) $s'$.

The most general operator $H_{ij}$ coupling two $s' = 1/2$ (Kramers) systems is:

$$H'_{ij} = \sum_{\alpha\beta} s'_{i\alpha}\, \mathbf{K}_{\alpha\beta}\, s'_{jb} \tag{35}$$

where the second-order tensor **K** has only nine constants. This number can usually be further reduced. For example, a special nature of low-lying 4*f* states imprinted by the CF can reduce Eqn. (35) to an Ising-like form, determined by a single exchange parameter $K_{zz}$. Magnetic properties of several dysprosium, terbium, and holmium compounds have been analyzed using the Ising-like effective spin Hamiltonian (Wolf 1971, Nekvasil and Veltruský 1994).

Data allowing one to determine a fairly large number of unrelated parameters in Eqn. (34) are obtained using various spectroscopic methods including EPR, optical absorption, and inelastic neutron scattering as well as by measurements of macroscopic properties such as susceptibility and specific heat (Wolf 1971, Jensen and Mackintosh 1991).

Note that although investigators are usually aware of the anisotropic exchange effects, the simple isotropic form of Eqn. (33) is usually used to examine the magnetic structures described in the following.

### *4.2 Magnetic Structures*

The magnetic structures assumed by *f*-electron compounds are usually examined within the *mean field theory*. The essential feature of this conceptually simple method is the approximation of the two-ion interaction (Eqn. (33)) by effective single-ion terms in which the instantaneous values of the **J** operators in the surroundings of any particular ion are replaced by their expectation values (Jensen and Mackintosh 1991). The exchange term then can be written in the Zeeman-like form:

$$H_{\mathrm{ex}} = -\boldsymbol{\mu} \cdot \mathbf{H}^{\mathrm{m}} \tag{36}$$

where the applied field $\mathbf{H}^a$ appearing in Eqn. (20) is replaced by a *molecular field* $\mathbf{H}^{\mathrm{m}}$:

$$\mathbf{H}^{\mathrm{m}} = -\lambda_{\mathrm{m}} g_J \mu_{\mathrm{B}} \langle \mathbf{J} \rangle \tag{37}$$

where the molecular field constant $\lambda_{\mathrm{m}}$ is determined by the strength of the exchange interaction and is calculated from the divergence of magnetic susceptibility $\chi$(T) at the ordering temperature $T_{\mathrm{C}}$. According to the Curie–Weiss law:

$$\frac{1}{\chi(T)} = \frac{1}{\chi_0(T)} - \lambda_{\mathrm{m}} \tag{38}$$

leading to:

$$\lambda_{\mathrm{m}} = \chi_0^{-1}(\{B_{kq}\}, T_{\mathrm{C}}) \tag{39}$$

where $\chi_0(T)$ is the component of the single-ion susceptibility parallel to $\mathbf{H}^{\mathrm{m}}$ (Wang and Cooper 1970):

$$\chi_0(T) = \frac{g_J^2 \mu_B^2}{KT}\left[\sum_n |\langle n|J_z|n\rangle|^2 \frac{\exp(-E_n/k_BT)}{Z} - \left(\sum_n |\langle n|J_z|n\rangle| \frac{\exp(-E_n/k_BT)}{Z}\right)^2\right] + 2g_J^2\mu_B^2 \sum_{n\neq m} \frac{|\langle n|J_z|n\rangle|^2}{E_n - E_m} \cdot \frac{\exp(-E_n/k_BT)}{Z} \tag{40}$$

where $E_n$ and $|n\rangle$ are, respectively, eigenvalues and eigenvectors of the Hamiltonian of the form of Eqn. (28), in which the Zeeman term has been replaced by the exchange term (Eqn. (36)).

The complete Hamiltonian within the ground state multiplet is

$$H'_R = \sum_{kq} B_{kq} C_q^{(k)} - \boldsymbol{\mu} \cdot (\mathbf{H}^{\mathrm{m}} + \mathbf{H}^a) \tag{41}$$

where the only unknowns are the CF parameters $B_{kq}$ and the molecular field constant $\lambda_{\mathrm{m}}$.

Equation (41) is adequate in explaining the occurrence of most observed magnetic structures (Jensen and Mackintosh 1991) as well as various physical properties associated with the *f* electrons (see Sect. 2).

#### *(a) Nonmetallic compounds*

Nonmetallic RE compounds are ferro- or antiferromagnets (see *Magnetism in Solids: General Introduction*) in which the magnetic ordering occurs owing to the superexchange, the electric multipole, and the classical dipole–dipole interactions. The ordering temperatures are typically of the order of 1K. The magnetic properties have been systematically studied in number of compounds including RE ethylsulfates, tetrafluorides $LiREF_4$ with scheelite structure, $REMO_4$ crystals having zircon structure (M = V, P, As), trifluorides $REF_3$, RE elpasolites, and RE cuprates. The highest value among trivalent RE compounds of 17.9K was reported for the antiferromagnetic cuprate $PrBa_2Cu_3O_7$. An even higher ordering temperature of 34K occurs in the antiferromagnetic perovskite $TbBaO_3$, where the terbium ions are tetravalent. The CF ground state in the above-mentioned magnetically ordered RE compounds is usually the Kramers doublet or non-Kramers (quasi)doublet or (quasi)triplet (for a survey of magnetic ordering data see Aminov *et al.* 1996).

An example of localized magnetism in An compounds is $UO_2$ (Fournier 1985). In this semiconductor the special nature of the band structure ensures good localization of the 5*f* electrons (Kelly and Brooks 1980, Amoretti *et al.* 1989, Diviš *et al.* 1996).

$UO_2$ orders antiferromagnetically at $T_N = 31$K. Another example is $UCl_3$, an antiferromagnet with $T_N = 6.5$K (Fournier 1985) (see also *5f Electron Systems: Magnetic Properties*).

*(b) Metallic compounds*

In general, the magnetic ordering temperatures in metallic compounds are lower than room temperature. The most important contribution to the magnetic coupling is provided by indirect exchange. Its origin is due to the polarization of the conduction-electron gas by the spin on one ion, which influences the spin of a second ion.

In the widely used isotropic approximation the exchange parameter in Eqn. (33) takes the Fourier transform form (Jensen and Mackintosh 1991):

$$J_{ij} = \frac{1}{N}\sum_{q} J(\mathbf{q}) e^{i\mathbf{q}(\mathbf{R}_i - \mathbf{R}_j)} \tag{42}$$

where $N$ is the number of ions and

$$J(\mathbf{q}) = (g_J - 1)^2 \left[ J_S(\mathbf{q}) - \frac{1}{N}\sum_{\mathbf{q}'} J_S(\mathbf{q}') \right] \tag{43}$$

and

$$J_S(\mathbf{q}) = \frac{V}{N\mu_B^2} |I(\mathbf{q})|^2 \, \chi(\mathbf{q}) \tag{44}$$

where $I(\mathbf{q})$ and $\chi(\mathbf{q})$ are, respectively, Fourier transforms of the exchange parameter between a conduction-electron spin and the $f$ spins and magnetic conduction-electron susceptibility, and $V$ is the volume. The Fourier transform $[J(\mathbf{q}) - J(\mathbf{0})]$ can be extracted from elastic neutron scattering data. The position of maximum on a $[J(\mathbf{q}) - J(\mathbf{0})]$ vs. $\mathbf{q}$ curve, which in general occurs at nonzero $\mathbf{q}$, determines the type of magnetic order (see below).

The susceptibility $\chi(\mathbf{q})$ is given by:

$$\chi(\mathbf{q}) = \frac{2\mu_B^2}{V} \sum_{nn'\mathbf{k}} \frac{f_{n\mathbf{k}} - f_{n'\mathbf{k}-q}}{\varepsilon_{n'}(\mathbf{k} - \mathbf{q}) - \varepsilon_n(\mathbf{k})} \tag{45}$$

where $f_{n\mathbf{k}}$ is the Fermi–Dirac distribution function. A large contribution to the sum is made by pairs of electronic states, separated by $\mathbf{q}$, one of which is occupied and the other empty, and both of which have energies very close to the Fermi level. Parallel or nesting regions of the Fermi surface tend to produce peaks at the wave vector $\mathbf{Q}$ which separates them. Such peaks are known as Kohn anomalies. The Kohn anomalies in $J(\mathbf{q})$ Fourier transform into Friedl oscillations in $J(\mathbf{R})$. First-principle calculations of $J(\mathbf{q})$ have not been very successful. While the calculated $\chi(\mathbf{q})$ exhibits the expected peaks, the matrix elements determining $I(\mathbf{q})$ are much less tractable.

A simple mean field calculation shows that spontaneous ordering occurs at the wave vector $\mathbf{Q}$ for which $J(\mathbf{q})$ has its maximum value and the Néel temperature $T_N$ is

$$T_N = \frac{J(\mathbf{Q}) J \cdot (J+1)}{3k_B} \tag{46}$$

Considering Eqn. (46) one finds that $T_N$ is proportional to the de Gennes factor $(g_J - 1)^2 J(J+1)$, provided that the susceptibility of the conduction-electron gas is constant. As a representative example of this frequently used approach, the values of $T_N$ for antiferromagnetic $RCu_2$ displayed in Fig. 5 may serve. The remaining discrepancy between the experimental and calculated data in Fig. 5 can be ascribed to variation of $J_S(\mathbf{q})$ across the isostructural series and neglecting of the CF as well as of the anisotropic part of the exchange interaction (Jensen and Mackintosh 1991).

The long-range and oscillatory indirect exchange gives arise to large variety of magnetic structures in RE metals and intermetallic compounds. A compound is ferromagnetic if a maximum on $(\mathbf{q})$ occurs at $\mathbf{Q} = 0$

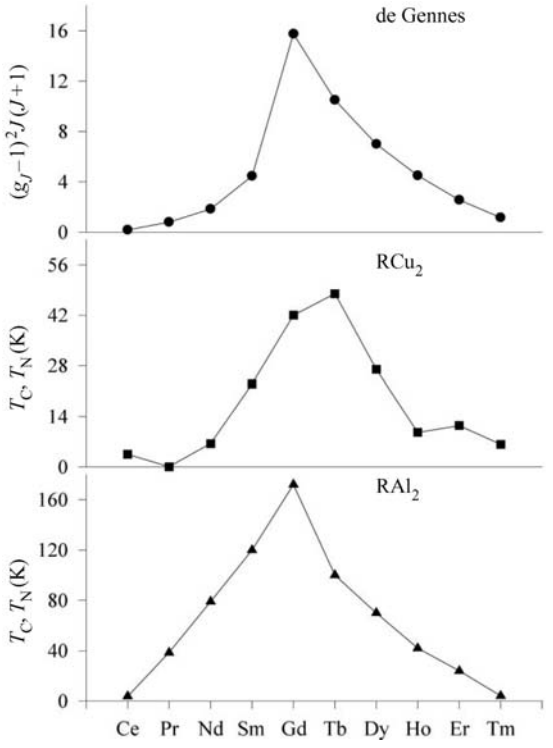

***Figure 5***
Values of the Curie (Néel) temperature in the $RCu_2$ and $RAl_2$ series and values of the de Gennes factor $(g_J - 1)^2 J(J+1)$ across the 4*f* series. The values shown are for $R^{3+}$ ions.

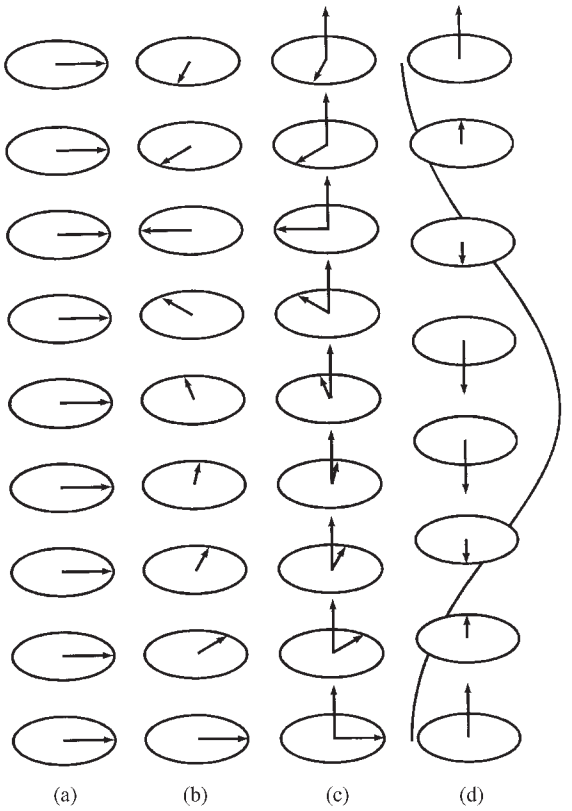

***Figure 6***
Magnetic structures of heavy rare earth metals. (a) In the basal-plane ferromagnet all moments are aligned along the direction of magnetization. (b) The moments in the helix rotate by a specific angle between neighboring planes. (c) The cone is a combination of a helix and an axial ferromagnetic component, so that the total moment rotates on the surface of a cone. (d) In the longitudinal wave structure the *c*-axis component varies sinusoidally, while in the basal plane it is disordered.

and simple antiferromagnetic at the reduced propagation vector $\mathbf{Q} = 1/2$ (0,0,1). Such structures occur, for example, in metallic gadolinium and most of the $REAl_2$ compounds. For $0 < \mathbf{Q} < 1/2$ (0,0,1) different types of magnetic structure occur including the helix, the cone, and the longitudinal wave structures (see Fig. 6). In general, the magnetic easy axis may change from one RE to another owing to the CF interaction.

## 5. Summary

This article has considered *f*-electron compounds in which the RE or An ions are assumed to be present in well-defined ionic states. Most of the magnetic properties of these compounds can be described in terms of two microscopic interactions involving the *f* electrons: the CF interaction and the exchange interaction. Various theoretical and experimental methods used to study and describe these interactions have been discussed. These methods can be also applied to 3*d*–4*f* alloys (see *Alloys of 4f (R) and 3d (T) Elements: Magnetism*, *Magnetoelastic Phenomena*, and *Magnetic Systems: External Pressure-induced Phenomena*) and compounds (see *Transition Metal Oxides: Magnetism*).

# Longitudinal and Perpendicular Recording: Thermal Stability

The magnetization, coercivity, and recorded signal of longitudinal and perpendicular media decrease with time due to thermal effects. In this section, the effects of material parameters (average grain size, film thickness, grain size dispersion, anisotropy energy constant, exchange energy constant between adjacent grains) and recording density on thermal stability of longitudinal and single-layer perpendicular media will be reported. Most of the results were obtained using computer simulation, because it is not easy to change the parameters except film thickness independently in an experiment.

## *1. Thermal Stability of Magnetization of Small Particles*

The stability of the magnetization of small particles or grains, as used in magnetic recording media, is affected by thermal energy, which causes transitions over the energy barriers which give rise to the hysteresis. The stability of the magnetization (and consequently the recorded signal) is dependent on the ratio $K_u V/kT$. Here, $K_u$ is the uniaxial anisotropy constant (including shape anisotropy constant), $V$ is the volume of the particle, $k$ is the Boltzmann constant, and $T$ is the absolute temperature. Therefore, not only the magnetic properties (magnetization, coercivity, squareness, etc.) but also the recorded signal of magnetic recording media may change a long time after recording.

Suppose that a field is applied to a particle. If the field is not large ($< H_k$ if the field direction coincides with the easy direction), the particle has two minimum energy states, state 1 and state 2, and there is an energy barrier between the states 1 and 2. Say that the barrier height from the state 1 is $\Delta E_1$ and that from the state 2 is $\Delta E_2$.

The changing rate of the probability, $N_1$, in which a particle exists in the state 1, is given by

$$\frac{dN_1}{dt} = -f_0\left[N_1 \exp\left(-\frac{\Delta E_1}{kT}\right) - N_2 \exp\left(-\frac{\Delta E_2}{kT}\right)\right] \quad (1)$$

where $N_2$ is the probability in which the particle exists in the state 2. Suppose that $\Delta E_2 \gg \Delta E_1$, then we have

$$\frac{dN_1}{dt} = -\frac{1}{\tau}N_1 \quad (2)$$

where

$$\tau = \frac{1}{f_0}\exp\left(\frac{\Delta E}{kT}\right) \quad (3)$$

These relations are called the Arrhenius–Néel law (Néel 1955). The stability of the magnetization can be quantified by comparing the relaxation time with the characteristic time of measurement $t$. Setting $t/\tau = 1$ gives a critical volume in zero field $V_c = kT\ln(f_0 t)/K$. Because of the rapid variation of $\tau$ with $V$, to a good approximation for $V > V_c$, $t \ll \tau$ and the behavior is thermally stable. However, for $V < V_c$, $t \gg \tau$, and the behavior is referred to as "superparamagnetic." Such grains have zero remanence and cannot be used to store information. Clearly there is a minimum grain size for magnetic recording. Although this is easy to estimate for isolated (noninteracting) grains, it becomes much more difficult for real media where intergranular interactions (exchange and magnetostatic) can be very strong. This problem is in the realm of computer simulation, to which this article is devoted.

## *2. Time Dependence of Squareness, Coercivity, and Output Signal*

Figures 1 and 2 show time dependence of squareness $S$, coercivity $H_c$, and output signal of longitudinal

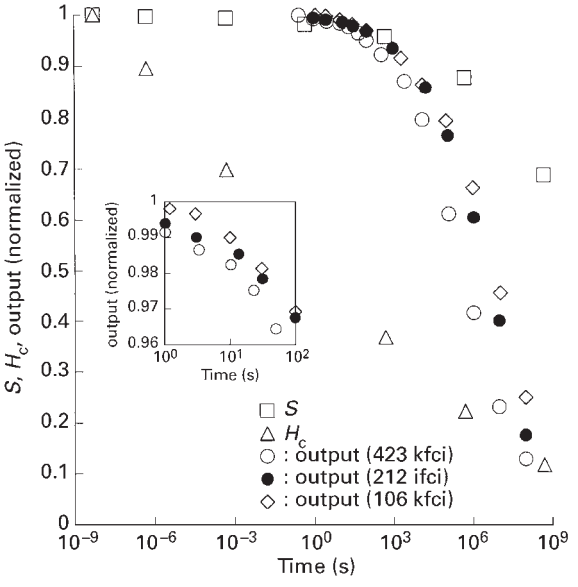

***Figure 1***
Time dependence of squareness, coercivity, and output signal of a longitudinal medium. An enlarged figure for $t = 1$–$100$ s and output $= 0.96$–$1$ is also shown. The physical parameters of the medium is as follows; $K_u = 2 \times 10^6$ erg cm$^{-3}$ ($2 \times 10^5$ J m$^{-3}$), $V = 10 \times 10 \times 10$ nm$^3$, Ms $= 400$ emu cm$^{-3}$ ($4 \times 10^5$ A m$^{-1}$), $T = 350$ K. This is a revised version of Fig. 6 in Uesaka *et al.* (1997).

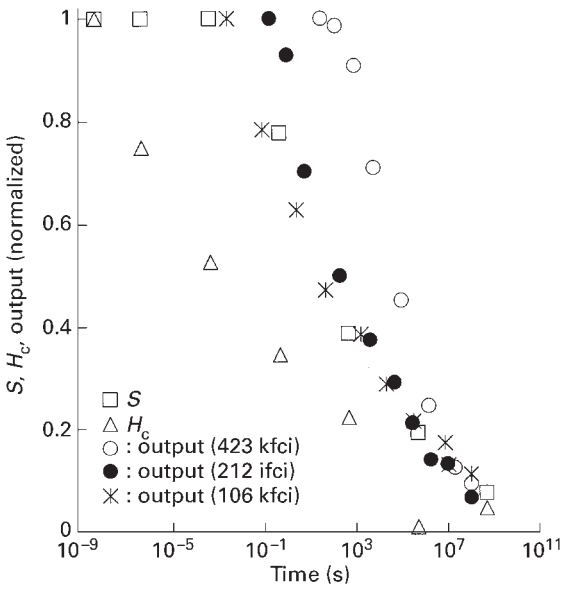

***Figure 2***
Time dependence of squareness, coercivity, and output signal of a perpendicular medium. The physical parameters of the medium is as follows; $K_u = 2 \times 10^6$ erg cm$^{-3}$ ($2 \times 10^5$ J m$^{-3}$), $V = 10 \times 10 \times 10$ nm$^3$, Ms = 400 emu cm$^{-3}$ ($4 \times 10^5$ A m$^{-1}$), $T = 350$ K. This is a revised version of Fig. 7 in Uesaka *et al.* (1997).

and perpendicular media. The vertical axes are the values normalized by those just after recording. The horizontal axes for $S$ and $H_c$ mean half of the time to measure a M–H loop. The results in the figures are simulation results at 350 K for 2 D random films with uniform rectangular grains with uniaxial anisotropy energy constant $K_u = 2 \times 10^6$ erg cm$^{-3}$ ($2 \times 10^5$ J m$^{-3}$), volume $V = 10 \times 10 \times 10$ nm$^3$, frequency factor $f_0 = 1 \times 10^9$s$^{-1}$, Gilbert's damping constant $\alpha = 1$. In both figures, the decrease of output signal is not similar to that of $H_c$, but rather to that of $S$.

It has been reported that the $H_c$ of a longitudinal medium changes according to the following equation (Sharrock 1984);

$$H_c/H_{c0} = 1 - [kT \ln(f_0 t)/(K_u V)]^n \qquad (4)$$

Here, $kT$ is the thermal energy, $f_0$ is a frequency factor of the order of $10^9$–$10^{11}$ s$^{-1}$, $K_u$ is the anisotropy energy constant of a particle (or a grain) in the medium, and $V$ is the volume of the particle. Several $n$ values have been reported. They are listed in Table 1. The time dependence of $H_c$ in Fig. 1 coincides well with $n = 0.735$ case which He *et al.* (1995) reported for the 2D random case.

## 3. Recording Density Dependence of Output Signal

A figure with enlarged time and output scales is inserted in Fig. 1. It is seen from this enlarged figure and from Fig. 2 that the rate of decay of the output signal increases with recording density in the longitudinal medium, whereas the opposite is true in the perpendicular medium. This was in agreement with experiment (Hirayama *et al.* 1996, Sato *et al.* 1997). Figure 3 shows linear recording density dependence of signal output during a time span of 17 h measured for perpendicular (CoCrPt and CoCrTa) and longitudinal (CoCrPt) media (Hirayama *et al.* 1996). This result arises from the fact that switching begins near the transition region in a longitudinal recording medium, though it begins in the saturation region in a perpendicular recording medium, as shown in Figs. 4 and 5. The improved thermal stability of perpendicular recording at high densities is the reason for its continued development.

## 4. Grain Size and Height of a Grain

Figure 6 shows the dependence of the thermal stability of longitudinal and perpendicular media on $K_u V/kT$ obtained using computer simulation. The anisotropy energy constant $K_u$ was fixed at $2 \times 10^6$ ergcm$^{-3}$ ($2 \times 10^5$ Jm$^{-3}$) and the grain size or height of the magnetic layer of the media was varied ("long., grain size" in the figure means that the grain size of the longitudinal media was varied, "long., height" means

***Table 1***
Value of $n$ in Eqn. 4 obtained by various conditions.

| Value of $n$ | Conditions | Method | References |

| 0.735 | 2 D random | computer simulation | Lu and Charap (1995) |

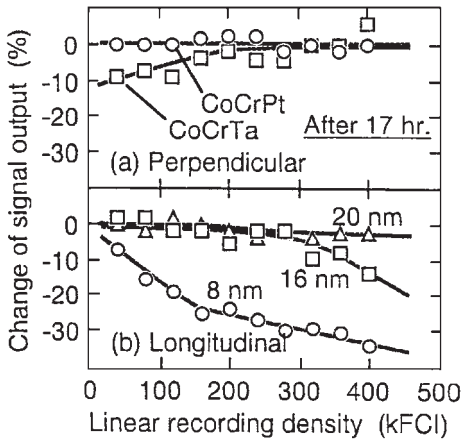

***Figure 3***
Linear recording density dependence of output signal during time span of 17 h measured for longitudinal and perpendicular media after Hirayama *et al.* (1996).

that the height of the longitudinal media was varied, and so on). The standard values of the grain size and height of a grain were 10 nm. The vertical axis is the time when the output signal decreases 5% from that just after recording.

This figure shows that increasing grain size in longitudinal media and increasing height in perpendicular media give larger thermal stability than the other two cases. However, increasing the grain size gives larger noise. Therefore, if much thicker films can be used in perpendicular recording than the films in longitudinal recording, perpendicular recording will be superior to longitudinal recording from a thermal stability point of view.

Abarra *et al.* (1997) and Yu *et al.* (1998) investigated longitudinal recording films with various thicknesses and found that thermal stability increases with increasing thickness.

## 5. *Grain Size Dispersion*

Figures 7 and 8 show time dependence of signal outputs of longitudinal and perpendicular recording media with various grain size dispersions. The output signal of both media decreases faster with increasing grain size dispersion. This is because the magnetic moments of small grains switch faster than those of large grains. This suggests that reducing the number of small grains will increase the thermal stability of longitudinal and perpendicular recording media.

## 6. *Exchange Interaction Between Adjacent Grains*

Figure 9 shows the grain size for which the output signal after three years decreases to 90% of that just

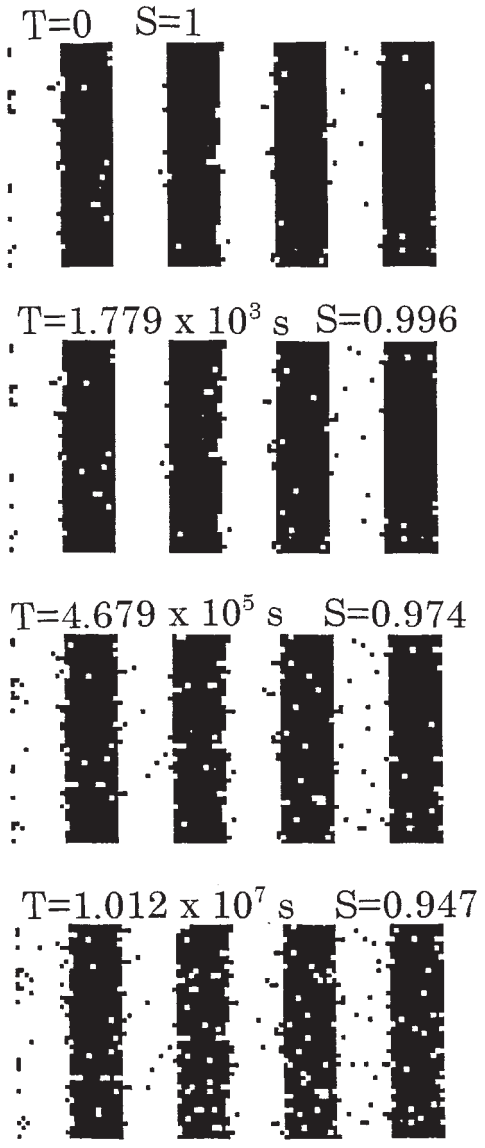

***Figure 4***
Magnetization state of a longitudinal medium after recording. $T$ is elapsed time, and $S$ is normalized output signal. The initial state ($T=0$, $S=1.0$) was obtained from the ideally recorded state using a micromagnetic simulation (Nakatani *et al.* 1979). A white circle indicates that the track direction component of the magnetic moment ($M_x$) of the corresponding grain is positive, and a black circle means $M_x$ is negative. $K_u = 2 \times 10^6\,\mathrm{erg\,cm^{-3}}$ ($2 \times 10^5\,\mathrm{J\,m^{-3}}$), $V = 10 \times 10 \times 15\,\mathrm{nm^3}$, $\mathrm{Ms} = 400\,\mathrm{emu\,cm^{-3}}$ ($4 \times 10^5\,\mathrm{A\,m^{-1}}$), $T = 350\,\mathrm{K}$. This is a revised version of Fig. 8 in Uesaka *et al.* (1997).

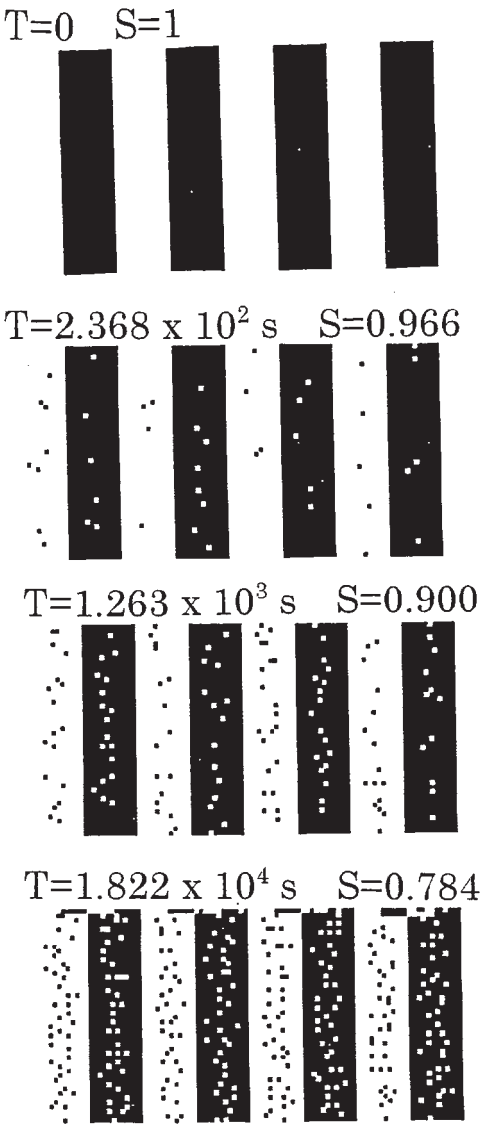

***Figure 5***
Magnetization state of a perpendicular medium after recording. $T$ is elapsed time, and $S$ is normalized output signal. The initial state ($T=0$, $S=1.0$) was obtained from the ideally recorded state using a micromagnetic simulation (Nakatani *et al.* 1979). A white circle indicates that the perpendicular component of the magnetic moment ($M_z$) of the corresponding grain is positive, and a black circle means that $M_z$ is negative. $K_u = 2\times10^6\,\mathrm{erg\,cm^{-3}}$ ($2\times10^5\,\mathrm{J\,m^{-3}}$), $V = 10\times10\times15\,\mathrm{nm^3}$, $\mathrm{Ms} = 400\,\mathrm{emu\,cm^{-3}}$ ($4\times10^5\,\mathrm{A\,m^{-1}}$), $T = 350\,\mathrm{K}$. This is a revised version of Fig. 9 in Uesaka *et al.* (1997).

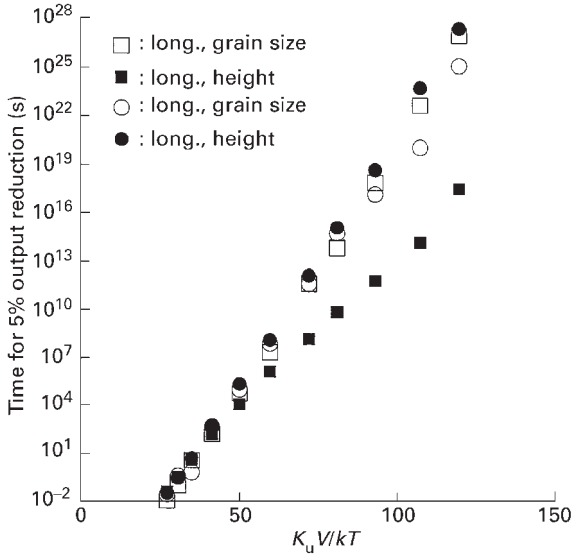

***Figure 6***
Effect of $K_uV/kT$ on the thermal stability of longitudinal and perpendicular media. $K_u = 2\times10^6\,\mathrm{erg\,cm^{-3}}$ ($2\times10^5\,\mathrm{J\,m^{-3}}$). The linear recording density was 423 kfci for both media. Grain size or thickness of the film was varied.

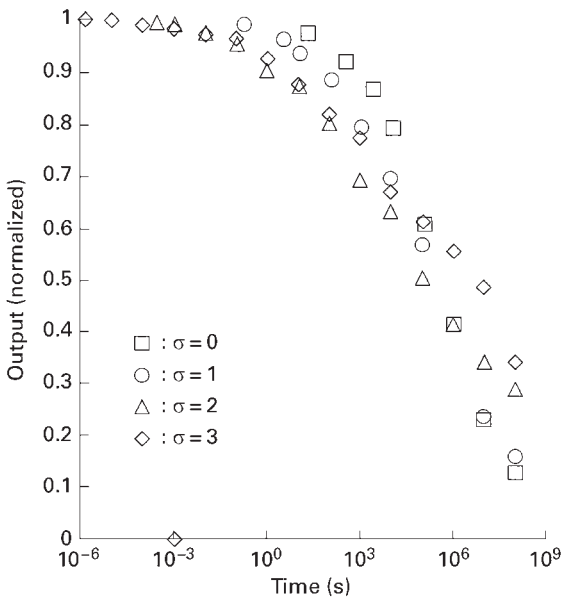

***Figure 7***
Time dependence of output signal of longitudinal media with various grain size dispersion $\sigma$ (nm). This is a revised version of Fig. 3 in Nakatani *et al.* (1998).

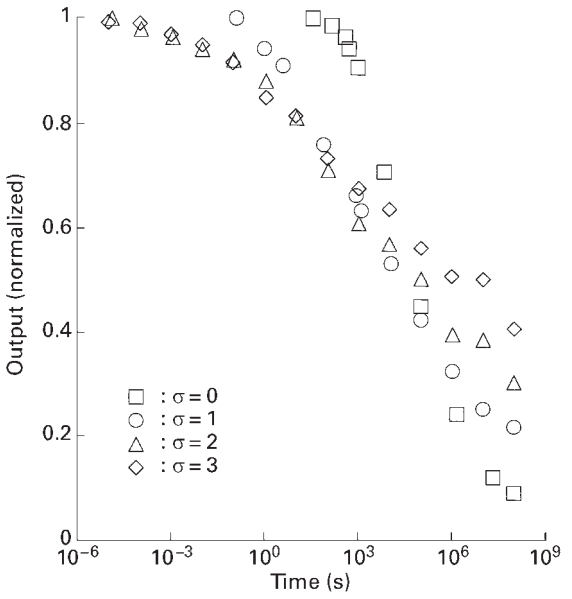

***Figure 8***
Time dependence of output signal of perpendicular media with various grain size dispersion $\sigma$ (nm). This is a revised version of Fig. 5 in Nakatani *et al.* (1998).

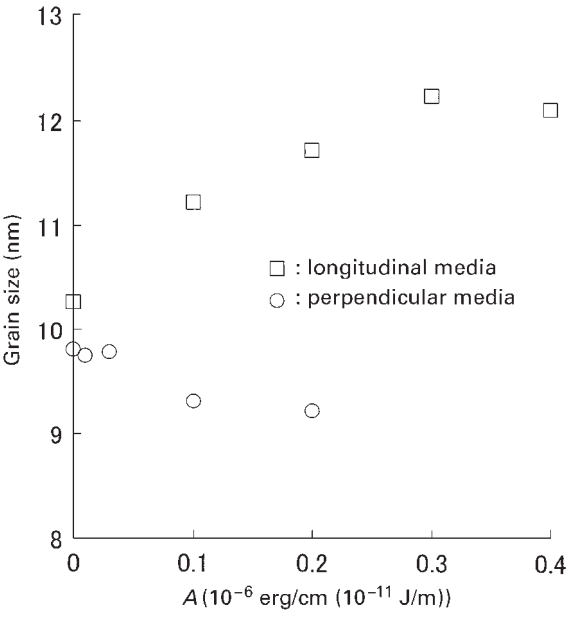

***Figure 9***
Effect of intergranular exchange constant A on boundary grain size in which output signal decreases by 10% after three years' decay. $K_u = 2 \times 10^6\,\mathrm{erg\,cm^{-3}}$ ($2 \times 10^5\,\mathrm{J\,m^{-3}}$), $V = 10 \times 10 \times 10\,\mathrm{nm^3}$, $\mathrm{Ms} = 400\,\mathrm{emu\,cm^{-3}}$ ($4 \times 10^5\,\mathrm{A\,m^{-1}}$), $T = 350\,\mathrm{K}$. This is a revised version of Fig. 6 in Nakatani *et al.* (1999).

after recording, as a function of the intergranular exchange constant A. The thermal stability of longitudinal recording media is degraded with increasing A. On the other hand, the thermal stability of perpendicular recording media is improved as A is increased. The reason for these results is understood as follows: Because the intergranular exchange interaction tends to align the magnetization, it tends to destroy the magnetization structure in the transition region and to support the structure in the saturation region. Therefore, thermal magnetization change is accelerated in longitudinal recording media and suppressed in perpendicular recording media by the introduction of exchange coupling between grains.

## 7. Simulation Model

Lyberatos *et al.* developed a Monte Carlo simulation method to investigate the thermal stability problem of magnetic materials (Lyberatos *et al.* 1985), and Lu and Charap used it to investigate the problem of longitudinal recording media (Lu and Charap 1994, 1995). In the simulations, the frequency factor $f_0$ was fixed at $10^9\ \mathrm{s^{-1}}$. The simulation results mentioned above also used this value. This is appropriate for a magnetic recording medium when the field (magnetostatic, and exchange field) is small and parallel to the easy direction.

However, $f_0$ with the field applied to a different direction from the easy direction is smaller ($1 \sim 1/1000$) than $f_0$ with the field applied parallel to the easy direction Coffey *et al.* (1998). In a perpendicular recording medium, the easy direction of a grain is almost aligned in the direction perpendicular to the film plane and the magnetostatic field is also applied in this direction, but in a longitudinal recording medium the direction of the magnetostatic and/or exchange field in a grain does not necessarily coincide with the easy direction. Therefore, the thermal stability of longitudinal media could be larger than the values stated above.

The simulation results mentioned above were obtained assuming coherent rotation of the magnetic moment of a grain. However, $H_c$ and $S$ of a perpendicular medium obtained using this model are larger than the values obtained experimentally. This may suggest that each grain does not rotate coherently and that the thermal stability of a perpendicular medium is worse than that stated above.

## 8. Conclusion

Thermal stability of longitudinal recording media was compared with that of perpendicular recording media. The decrease of output signal is not similar to

that of $H_c$ but rather to that of $S$. The output signal of higher recording density (higher frequency) decreases faster than that of lower recording density in the longitudinal medium, but it is opposite in the perpendicular medium. $H_c$ of a longitudinal medium changes according to the following equation with $n = 0.5 \sim 0.735$;

$$H_c/H_{c0} = 1 - [kT \ln(f_0 t)/(K_u V)]^n \qquad (5)$$

Perpendicular recording will be superior to longitudinal recording from a thermal stability point of view if much thicker film can be used. Reducing the number of small grains will increase the thermal stability of longitudinal and perpendicular recording media. Thermal stability of longitudinal recording media is degraded with increasing intergranular exchange A, but that of perpendicular recording media is improved as A is increased.

## Longitudinal Media: Fast Switching

Every modern computer has several devices that permanently store information. Of particular interest are those storage devices that enable the user not only to read back information but also to write information. In general, useful storage devices must have sufficient storage capacity with short access time. For fast and nonvolatile mass data storage, as is required in a personal computer or in a server system, magnetic hard disk recording is exclusively in use.

From a practical point of view, it is highly desirable that the data transfer rate is increased together with the storage capacity. Increasing the linear bit density in a hard drive (i.e., the number of bits per unit length in the down-track direction) has the desired effect of increasing storage density and transfer rate. However, the performance of a hard disk drive not only depends on the maximum transfer rate but also on access time. Since the access time includes the latency until the transducer reads a specific sector of

a track, it is controlled by the rotational speed. For high-performance drives, therefore, very high rotational speeds become attractive. Disk drives spinning the disk as fast as 15000 rpm are commercially available.

The practically realizable writing speed depends on the design of the writing head and the driving electronics. Traditionally, the contribution of the medium to the speed of recording has been neglected. For modern high-performance drives, however, the contributions of the media can no longer be disregarded. This article reviews the fundamental parts of the theory of fast switching in media as well as experimental information available in the literature.

## *1. The Different Time Regimes in Magnetization Reversal*

Figure 1 shows the time axis involved in magnetic recording. For "long times," referred to as "viscosity regime", say at times larger than 100 ns, the magnetization reversal behavior is adequately described by the theory of thermally activated magnetization reversal over finite energy barriers (Arrhenius–Néel formalism, see Sect. 1.1). At very short times, intrinsic dynamics lead to precessional motion that determines the reversal behavior, which is reviewed in Sect. 1.2. As a numerical example, consider magnetic recording in a hard disk drive of relatively low performance (1999). Assuming a bit length of 200 nm at a speed of $10\,\mathrm{ms}^{-1}$, the time for one bit is roughly 20 ns. In order to achieve high recording performance, the switching process needs to be completed within a small enough fraction of the bit cell duration, e.g., 4–5 ns. As Fig. 1 illustrates, this time falls between the viscosity regime and the precessional regime, in a timescale in which the dynamic behavior is extremely complex.

### *1.1 Switching in the "Viscosity Regime"*

The theory of thermally activated magnetization reversal is now reviewed. At first sight, thermally activated magnetization reversal does not seem to be related to the switching speed at all, but a closer examination shows that this is not true.

Street and Woolley (1949) first discussed thermally activated magnetization reversal and pointed out that every magnetization reversal process is initiated by the thermal energy $k_\mathrm{B}T$ ($k_\mathrm{B}$ = Boltzmann's constant $= 1.38 \times 10^{-23}\,\mathrm{JK}^{-1}$, $T$ = temperature in K). Néel (1949) expressed the probability of magnetization reversal as

$$r = f_0 \exp\left(-\frac{\Delta E}{k_\mathrm{B}T}\right) \tag{1}$$

where $r$ is the reversal rate, $\Delta E$ is the magnetic energy barrier to be surmounted, and $f_0$ is a frequency factor of the order of $10^{10}$ Hz. Equation (1) has the same form as it appears in the theory of semiconductors; therefore, it is also referred to as the "Arrhenius–Néel" approach. In a simple phenomenological interpretation, Eqn. (1) means that the thermal energy makes $f_0$ trials per second to reverse the magnetization. The magnetic energy, $\Delta E$, and the thermal energy, $k_\mathrm{B}T$, determine the probability of success of these trials; for $\Delta E \gg k_\mathrm{B}T$, the probability of success is virtually zero, while it is large for $\Delta E \ll k_\mathrm{B}T$. Thus, Eqn. (1) predicts a time-dependent magnetization. Clearly, the concept breaks down when $f_0$ is approached.

Magnetic recording media consist of very fine grains or particles. In this case, the (short-range) quantum mechanical exchange forces are sufficiently strong to keep the magnetization in these particles uniform (Brown 1969).

For the case of a single-domain particle, the energy barrier entering in Eqn. (1) can be evaluated easily using the model of coherent rotation (Stoner and Wohlfarth 1948). Consider a single-domain particle with uniaxial anisotropy that can be either of shape or magnetocrystalline origin. As indicated in Fig. 2, the easy axis (dashed line) forms an angle $\theta_0$ with the applied field, $\vec{H}$. The magnetization, $\vec{M}$, makes an angle $\theta$ with the field axis. The magnetic energy, $E(\theta)$, of the particle in the applied field is then given by

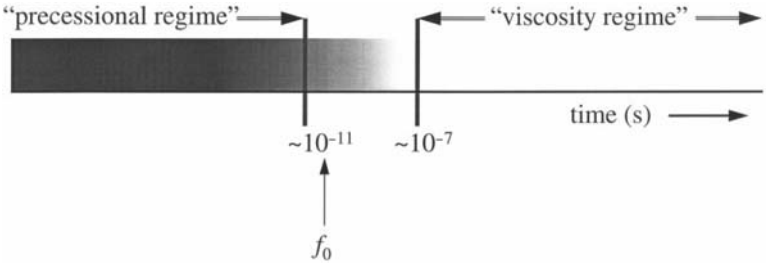

***Figure 1***
Time axis in magnetic recording. For long times ($\geqslant 10^{-7}$ s) the magnetization reversal is governed by thermally activated reversal, while at short times ($\leqslant 10^{-11}$ s) it is governed by spin precession dynamics.

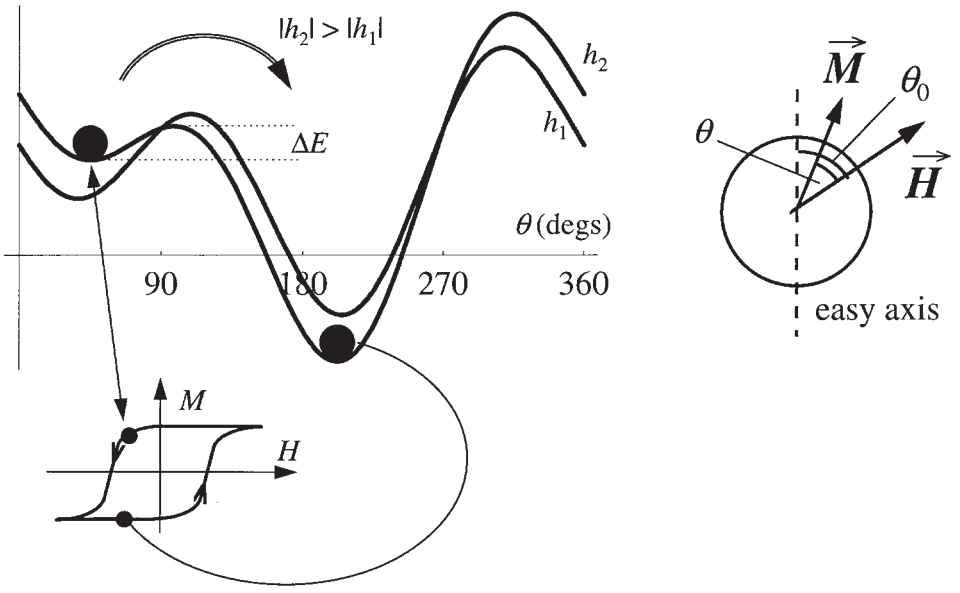

***Figure 2***
Thermally activated magnetization reversal. In the general case, the magnetization can have two local energy minima. The thermal energy can push the magnetization over the energy barrier $\Delta E$.

(assuming uniaxial anisotropy)

$$E(\theta) = -\mu_0 M_s H V \cos\theta + K_1 V \sin^2(\theta - \theta_0) \qquad (2)$$

where $M_s$ is the saturation magnetization of the material, $K_1$ is the anisotropy constant, $V$ is the particle volume, and $\mu_0 = 4\pi \times 10^{-7}\,\mathrm{Vs\,A^{-1}m^{-1}}$. From the anisotropy constant, the anisotropy field, $H_A$, can be derived as $H_A = 2K_1/\mu_0 M_s$. The free parameter of the system is the angle $\theta$ between magnetization and field. As Fig. 2 illustrates, there are two local energy minima in the general case. The local minimum having the lower energy corresponds to the case of alignment between the magnetization and the applied field, whereas the other minimum represents opposing magnetization and field. The latter state is stable if the energy barrier, $\Delta E$, which has to be overcome at magnetization reversal is larger than zero. Note that the energy barrier is field dependent, as illustrated in Fig. 2. The field strength at which the energy barrier becomes zero is the maximum attainable switching field (Stoner and Wohlfarth 1948):

$$|h_{SW}(\theta_0)| = \frac{1}{(\cos^{2/3}(\theta_0) + \sin^{2/3}(\theta_0))^{3/2}} \qquad (3)$$

Most theoretical analyses have considered the case $\theta_0 = 0$, i.e., alignment of the applied field with the easy axis. The energy barrier then simplifies to

$$\Delta E(\theta_0 = 0, h) = K_1 V (1 + h)^2 \qquad (4)$$

If there are $N_0$ grains, the number of grains not yet switched, $n(t)$, is given by the exponential $n(t) = N_0 \exp(-rt)$. Together with the rate equation (Eqn. (1)) and the condition that $n(t) = N_0/2$ at remanent coercivity (the remanent coercivity is the field which switches 50% of the magnetization), one can derive (Kneller and Luborsky 1963, Sharrock and McKinney 1981) the following:

$$|H_r(\theta_0 = 0, t)| = H_A \left(1 - \sqrt{\frac{k_B T}{K_1 V} \ln \frac{f_0 t}{\ln 2}}\right) \qquad (5)$$

Equation (5) gives the field that is required to reverse 50% of the magnetization of a previously saturated magnetic sample subjected to a field pulse of duration $t$.

For thin-film media, the grains are oriented at random in the film plane, so that the case of a magnetically easy axis aligned with the field is highly exceptional. Victora (1989) gave an approximation for the energy barrier for the general case $\theta = 0$:

$$\Delta E(\theta_0, h) \cong 2K_1 V \left(\frac{2}{3}\right)^{3/2} \left(1 + \frac{h}{h_{SW}(\theta_0)}\right)^{3/2} \sin[2(\theta_{SW}(\theta_0) - \theta_0)] \qquad (6)$$

where $\theta_{SW}(\theta_0) = \theta_0 + \tan^{-1}(\sqrt[3]{\tan\theta_0})$.

Bertram and Richter (1999) and Richter and Ranjan (1999) have shown that for thin-film media consisting of noninteracting grains with their easy

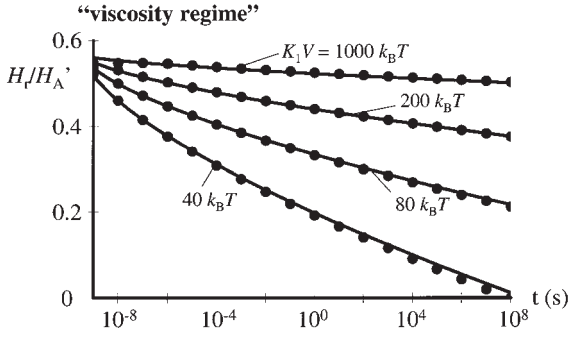

***Figure 3***
Time-dependent coercivity in the "viscosity regime." The curves hold for an assembly of single-domain particles with their easy axes in plane. The lines are calculated using Eqn. (7) and the dots are exact solutions for the entire particle assembly.

axes oriented at random in the plane, the time-dependent coercivity of the entire film can be approximated by

$$|H_r(t)| = 0.566 H_A \left(1 - 0.977 \left[\frac{k_B T}{K_1 V} \ln \frac{f_0 t}{\ln 2}\right]^{2/3}\right) \quad (7)$$

Equation (7) assumes that there is no magnetic interaction between the grains. Figure 3 illustrates the time dependence of the remanent coercivity for a two-dimensional, isotropic, noninteracting particle ensemble. As can be seen, for low values of the ratio $K_1V/k_BT$, the coercivity at long times (storage) is significantly lower than at short times (writing). Since very small grains are required to achieve high signal-to-noise ratios (Richter 1999), it is important to note that, especially in high-density recording, the coercivity obtained for typical magnetometer measurements is considerably lower than that relevant for the writing process.

### *1.2 Precession Dynamics*

According to quantum theory, a magnetic moment, $\vec{\mu}$, is accompanied by an angular momentum, $\vec{L}$. The ratio between the magnetic moment and the angular momentum is called the gyromagnetic ratio, $\gamma$:

$$\vec{\mu} = \gamma \vec{L} \quad (8)$$

where $\gamma = -1.761 \times 10^{11} \mathrm{m^2\ V^{-1} s^{-2}}$.

Since magnetization is created by electrons that have the electrical charge $-e$, $\gamma$ in Eqn. (8) is written as a negative value. If the magnetic dipole is subjected to a homogeneous magnetic field, $\vec{H}$, it experiences a torque, $\vec{T}_M$, which seeks to orient it with the field

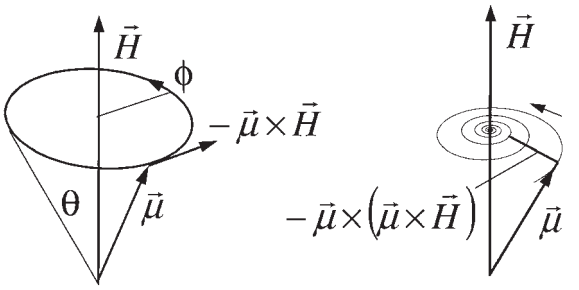

***Figure 4***
Precession. An undamped system would precess forever, while in a damped system (right) the magnetization approaches equilibrium asymptotically.

direction:

$$\vec{T}_M = \mu_0 \left(\vec{\mu} \times \vec{H}\right) \quad (9)$$

Since $\vec{T}_M = \mathrm{d}\vec{L}/\mathrm{d}t$, Eqns. (8) and (9) give

$$\frac{\mathrm{d}\vec{\mu}}{\mathrm{d}t} = -\mu_0 |\gamma| (\vec{\mu} \times \vec{H}) \quad (10)$$

Equation (10) is the magnetic torque equation and means that the magnetization precesses counterclockwise around the direction of the field, as illustrated in Fig. 4. Since there is no damping considered, the precession lasts forever.

The inclusion of damping leads to the Landau–Lifshitz equation (Landau and Lifshitz 1935), which was later modified by Gilbert (1955). The *Landau–Lifshitz–Gilbert equation* for the magnetization is

$$\frac{\mathrm{d}\vec{M}}{\mathrm{d}t} = -\mu_0 |\gamma| (\vec{M} \times \vec{H}) + \frac{\alpha}{M}\left[\vec{M} \times \frac{\mathrm{d}\vec{M}}{\mathrm{d}t}\right] \quad (11)$$

where $\alpha$ is a dimensionless phenomenological damping constant. Landau and Lifshitz (1935) considered only very small damping and gave an expression that can be written as

$$\begin{aligned}\frac{\mathrm{d}\vec{M}}{\mathrm{d}t} &= -\frac{\mu_0|\gamma|}{1+\alpha^2}(\vec{M}\times\vec{H}) - \frac{\mu_0|\gamma|\alpha}{(1+\alpha^2)M}[\vec{M}\times(\vec{M}\times\vec{H})] \\ &= -\mu_0|\gamma'|(\vec{M}\times\vec{H}) - \mu_0\lambda[\vec{M}\times(\vec{M}\times\vec{H})] \end{aligned} \quad (12)$$

It is customary to write the Landau–Lifshitz equation in the form given on the right-hand side of Eqn. (12). As shown in Fig. 4(b), the vector $-\vec{\mu} \times (\vec{\mu} \times \vec{H})$ (or $-\vec{M} \times (\vec{M} \times \vec{H})$, respectively) points towards the direction of $\vec{H}$ (as it should) and the magnetization aligns with the field for $t \to \infty$. However, Eqn. (12) implies that only the precessional part of the motion of the magnetization vector, namely $(\vec{M} \times \vec{H})$,

experiences damping. This means that losses owing to any nonprecessional magnetization changes are neglected—which is only true for small damping.

Although the two equations can formally be transferred into one another, they describe different physics and the Gilbert form should be preferred (Kikuchi 1956, Mallinson 1987). Safonov has since pointed out that both the Landau–Lifshitz as well as the Gilbert form are compatible with thermodynamics only for very small damping (Safonov 1999).

In the following, the magnetization reversal of a single spin, or, alternatively, that of a homogeneously magnetized single-domain particle is considered. For many applications, it is useful to write the Landau–Lifshitz–Gilbert equation in a parametric form in which the magnetization vector is described by the polar angle $\theta(t)$ and the azimuth angle $\phi(t)$, as indicated in Fig. 4. In this case, the following pair of equations has to be solved (Bertram and Mallinson 1970):

$$\frac{\mathrm{d}\theta}{\mathrm{d}t} = \frac{-|\gamma|}{M_\mathrm{s} V(1+\alpha^2)}\left(\alpha\frac{\partial E}{\partial\theta} - \frac{1}{\sin\theta}\frac{\partial E}{\partial\phi}\right) \tag{13a}$$

$$\frac{\mathrm{d}\phi}{\mathrm{d}t} = \frac{-|\gamma|}{M_\mathrm{s} V(1+\alpha^2)}\left(\frac{1}{\sin\theta}\frac{\partial E}{\partial\theta} + \frac{\alpha}{\sin^2\theta}\frac{\partial E}{\partial\phi}\right) \tag{13b}$$

Evaluation of the partial derivatives of the magnetic energy, $E$, yields

$$\frac{\mathrm{d}\theta}{\mathrm{d}t} = \frac{-|\gamma|\mu_0 H_\mathrm{A}\alpha}{1+\alpha^2} \times \begin{bmatrix} h(\cos\theta_0\sin\theta - \sin\theta_0\cos\theta\cos\phi) \\ +\sin\theta\cos\theta - \dfrac{h}{\alpha}\sin\theta_0\sin\phi \end{bmatrix} \tag{14a}$$

$$\frac{\mathrm{d}\phi}{\mathrm{d}t} = \frac{-|\gamma|\mu_0 H_\mathrm{A}\alpha}{1+\alpha^2}\left[\frac{h}{\alpha}(\cos\theta_0 - \sin\theta_0\cot\theta\cos\phi) + \frac{\cos\theta}{\alpha} + h\sin\theta_0\frac{\sin\phi}{\sin\theta}\right] \tag{14b}$$

It is useful to define the natural precession frequency, $f_\mathrm{nat}$ (Hempel 1962):

$$f_\mathrm{nat} = \frac{\Omega_\mathrm{nat}}{2\pi} = \frac{|\gamma|\mu_0 H_\mathrm{A}}{2\pi} \tag{15}$$

At zero applied field, the precession of the magnetization is driven only by the anisotropy field which gives $f_\mathrm{nat}$ its name. For modern hard disk media, $H_\mathrm{A} \approx 800\,\mathrm{kA\,m^{-1}}$ (10 k Oe) and $f_\mathrm{nat} \approx 28\,\mathrm{GHz}$.

For $\theta_0 = 0$, which represents alignment of the easy axis with the applied field, Eqns. ((14a) and (14b)) become

$$\frac{\mathrm{d}\theta}{\mathrm{d}t} = \Omega_\mathrm{nat}\frac{\alpha}{1+\alpha^2}\sin\theta(h+\cos\theta) \tag{16a}$$

$$\frac{\mathrm{d}\phi}{\mathrm{d}t} = \Omega_\mathrm{nat}\frac{1}{1+\alpha^2}(h+\cos\theta) \tag{16b}$$

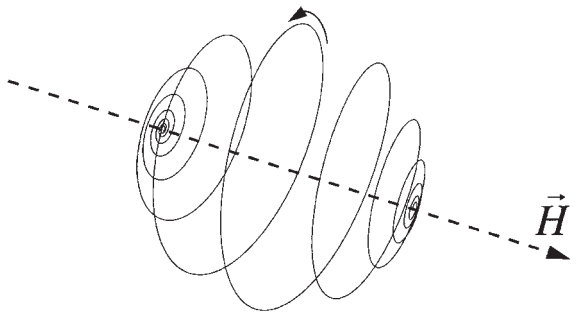

***Figure 5***
Trajectory of the tip of the magnetization vector during reversal. The field is applied along the easy axis.

Consider first the case of vanishing damping, $\alpha \to 0$. According to Eqns. (16a) and (16b), the polar angle $\theta$ remains constant and the magnetization continues with its precession movement—regardless of the applied field value. The magnetization cannot switch, because there is no mechanism by which the spin system can transport energy to the lattice. For small damping, however, the polar angle of the magnetization can change with time and the applied field can switch the magnetization (see Fig. 5). Equations (16a) and (16b) show that for small damping the precession movement, $\mathrm{d}\phi/\mathrm{d}t$, depends only very weakly on the damping, but the rate of change of the polar angle, $\mathrm{d}\theta/\mathrm{d}t$, is directly proportional to the damping constant. Larger damping therefore accelerates the switching speed, as long as the system does not become critically damped. Kikuchi (1956) first analyzed the switching problem and showed that the switching time is proportional to $(1+\alpha^2)/\alpha$. The switching time is therefore minimized for $\alpha = 1$, which corresponds to the critically damped case.

For the case of alignment of the easy axis with the field ($\theta_0 = 0$, see Eqns. (16a) and (16b)), the differential equation for the polar angle $\theta$ can be solved analytically:

$$t = -\frac{1+\alpha^2}{\alpha\Omega_\mathrm{nat}}\left\{\begin{array}{l} \dfrac{\ln\left(\dfrac{\cos(\theta(t)/2)}{\cos(\theta(0)/2)}\right)}{1-h} \\ +\dfrac{\ln\left(\dfrac{h+\cos\theta(t)}{h+\cos\theta(0)}\right)}{h^2-1} \\ +\dfrac{\ln\left(\dfrac{\sin(\theta(t)/2)}{\sin(\theta(0)/2)}\right)}{1+h} \end{array}\right\} \tag{17}$$

Note that the initial value of the polar angle, $\theta(0)$, determines the reversal time. For $\theta(0) = 0$, the solution degenerates and the magnetization never switches. In order to reverse, the magnetization needs an "initial

kick" away from the metastable orientation $\theta = 0$, which can, for instance, be provided thermally. In Sect. 1.3, the combination of thermal activation and precession dynamics is discussed.

### *1.3 Transition between Viscosity and Precession Regime*

In Sect. 1.1, the rate equation (Eqn. (1)) is introduced phenomenologically. Brown (1963) first treated thermal fluctuations of a single-domain particle in depth and derived the rate equation as well as an expression for the frequency factor, $f_0$. Brown treated the problem in an analogous way to that of a particle undergoing Brownian motion. This approximation is valid, because the correlation time of the thermal energy ($\approx 10^{-13}$ s) is much shorter than the response time of a spin system ($\approx 1/\Omega_{\text{nat}} \approx 10^{-11}$ s).

The starting point for further calculation is the Landau–Lifshitz–Gilbert equation (Eqn. (11)) in which the thermal forces are considered by adding a random field term to the effective field. This extra field term has a statistical average of zero and is normally distributed with a variance given by the fluctuation dissipation theorem (Brown 1963). The modified Landau–Lifshitz–Gilbert equation is called the "Langevin equation". For the simplest case in which the easy axis is aligned with the field, Brown solved the Langevin equation and obtained a relaxation rate of the form given in Eqn. (1). An expression was obtained for the frequency, $f_0$, which typically yields values of the order of $10^{10}$Hz. During the derivation, Brown used the approximation that the magnetic energy barrier is much greater than the thermal energy. Note that the energy barrier is field dependent and that large reverse fields inevitably make the energy barrier so small that the assumption $\Delta E \gg k_B T$ is no longer valid.

The general solution for the aligned case including energy barriers of arbitrary height has been obtained (Safonov 1999, Safonov and Bertram 2000). When the assumption $\Delta E \gg k_B T$ is dropped it is not legitimate to neglect the occupancies of the magnetization states away from the energy minimum. Therefore, one deals with a variety of magnetization orientations in each state as opposed to a discrete orientation model.

In the classical Arrhenius–Néel case, the relaxation time, $\tau_1$, is governed by the time that it takes the magnetization to find its way to the top of the energy barrier. For the general case, however, the time that the magnetization needs to reach the lower energy minimum, $\tau_2$, cannot be neglected. In addition, one has to consider a third relaxation time, $\tau_{12}$, which reflects that the magnetization does not necessarily switch to a new state once it has reached the energy maximum; it can also fall back into its original state. The three relaxation times add up to the total relaxation time, $\tau$ (Safonov and Bertram 2000):

$$\tau = \tau_1 + \tau_2 + \tau_{12} \tag{18}$$

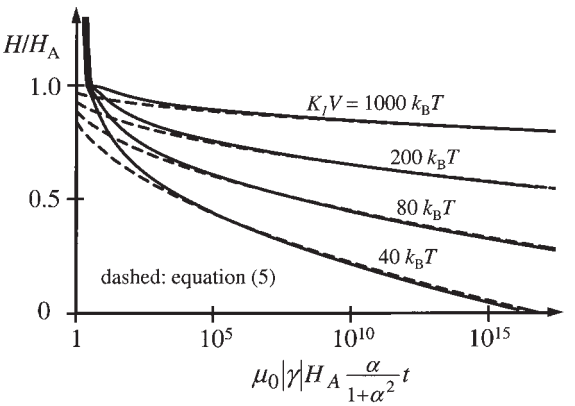

***Figure 6***
Time dependence of coercivity for various energy barriers $K_1 V$. The solid lines give the exact solutions. The dashed lines correspond to purely thermal reversal.

Therefore, the relaxation time is longer than that from the simple Arrhenius–Néel theory, or, equivalently, the faster one desires to switch the magnetization, the higher the required field. Figure 6 compares the time dependence of the coercivity for Arrhenius–Néel behavior with the exact solution, whereby the frequency, $f_0$, (Safonov and Bertram 2000)

$$f_0 = 2\sqrt{\frac{2}{\pi}}\frac{\alpha}{1+\alpha^2}\sqrt{\frac{K_1 V}{k_B T}}\,\mu_0|\gamma|H_A \tag{19}$$

It is important to realize that the precession frequency of the magnetization changes as a function of magnetization orientation. When the magnetization moves from one energy minimum to another, the precession frequency first decreases, then becomes zero at the energy maximum, and finally starts to precess again in the opposite sense. Owing to the low precession frequencies, the magnetization behaves "sluggishly," which explains that deviations from Eqn. (5) are observed at surprisingly long times $\approx 100/f_0 \ldots 1000/f_0$. The problem can be regarded as a "random walk" of a nonlinear oscillator (Safonov 1999). For a typical anisotropy field of a recording medium, $H_A = 800\,\text{kA m}^{-1}$ (10 k Oe), one finds $f_0 \approx 100$ GHz ($\alpha = 0.04$). The steep increase of coercivity is found at $t \approx 1/f_0$, which then amounts to 0.01ns. The phenomenological damping parameter, $\alpha$, which has been set to 0.04 without further consideration, is discussed below.

### *1.4 Switching Dynamics of Recording Media*

The previous sections have dealt with simple systems. Real recording media consist of particle systems, which are magnetically coupled by intergranular exchange and magnetostatic forces. Real systems also show a high degree of disorder. The interactions and the degree of disorder control the details of the switching process.

So far, the damping has been treated on a phenomenological basis. Using ferromagnetic resonance, the damping parameter has been determined to be around 0.02 for cobalt-based recording media (Inaba *et al*. 1997). The damping parameter describes how effectively energy can be transported away from the spin system into the lattice, where it is eventually dissipated and transformed into heat. Peng and Bertram (1998) modeled the switching behavior of a two-dimensional isotropic recording medium using a regular array of hexagons. They solved the full Langevin equation and calculated coercivity as function of field pulse time. The result obtained is similar to that shown in Fig. 6; it also agrees well with the simple formula of Eqn. (7) for times longer than $\sim 100\text{–}1000 \times f_0^{-1}$ (Bertram and Richter 1999).

In complex interacting systems, such as recording media, the spin system does not only perform a simple precession in unison as discussed above. The spin system can be excited in various modes or "spin waves" (Chantrell *et al*. 1998). Irregularities or nonuniform grain size distributions, which are present in real recording media, can disturb regular precession patterns of the magnetization. This means that the energy inherent in the spin system is transported first into complicated magnetization modes before it is finally dissipated in the lattice. Effectively, this increases the damping parameter, and the overall response time of the spin system to an external field is reduced (Hannay *et al*. 1999). For a discussion of the physical origin of damping see Suhl (1998).

The role of disorder in the switching response of a polycrystalline magnetic film to field pulses of varying duration was investigated in the experimental work of Rizzo *et al*. (1999). Their magnetization data as a function of time show a distinct kink at 10 ns, indicating a shift from an exponential to a logarithmic time dependence of the magnetization. Using concepts of statistical physics, they distinguished two regimes, a thermal regime characterized by statistical relaxation between states of metastable equilibrium and a nonequilibrium regime described by the driven response to the applied field. The time constant assigned to the transition between the two regimes is 5 ns. The media used for this experiment had a very low coercivity; in a subsequent experiment, however, no such kink was found for a medium with higher coercivity down to field pulses of 1ns (Rizzo *et al*. 2000).

## *2. Experimental Techniques and Data*

The first experimental investigation of switching speed in recording media was by Thornley (1975). Particulate tapes with low coercivity were subjected to subnanosecond field pulses. These field pulses were created using a recording head equipped with a microstrip-line. Switching speed values of the order of $2 \times 10^{-5}\ \mathrm{A\,s\,m^{-1}}$ were assigned to the various media. Since then switching speed measurements have been reconsidered and more comprehensive measurements have been performed (Doyle and He 1993, He *et al*. 1995, He *et al*. 1996). It was found—consistent with Thornley's early results—that oxide media such as $\gamma$-$Fe_2O_3$, $CrO_2$, and barium ferrite switch more slowly than the more advanced metallic particles and metal-evaporated tape. Since the field created by the stripline is insufficient to switch high coercivity media, such as metallic particles, it is inevitable to use an additional bias field to assist the switching process. It has also been reported that the damping constant measured using FMR is inversely correlated with the switching speed observed (Yu and Harrell 1996).

Microstrip-line measurements have been extended to thin-film media (Stinnett *et al*. 1998). In order to achieve higher pulse fields, the minimum achievable pulse time is compromised to about 10 ns. The switching behavior of the thin-film media is found to be similar to that of the particulate media investigated before.

Apart from microstrip techniques, alternative techniques using spin-stands have been suggested to measure the time dependence of coercivity (Rubin *et al*. 1998, Moser *et al*. 1999). Di-bits have been written with pulsed fields from a recording head. The coercivity is identified with the current needed to achieve 50% of the maximum di-bit signal. The data obtained have to be corrected for the dynamic behavior of the head as well for the demagnetizing field associated with the di-bit. A different spin-stand technique uses the idea that each pass of a d.c. excited head presents a field pulse of duration $\Delta t \approx g/v$ to the media, where $v$ is the linear velocity and $g$ is the gap length of the writer (Richter *et al*. 1998). Longer times can be realized by passing the head repeatedly over the media, resulting in a longer exposure of the media to the head field. It has been argued that the repetitive application of a short pulse ("reptation") is very close to exposing the media only once with a correspondingly longer pulse.

This technique breaks down for very short-time pulses for which the magnetization reversal process is dominated by precession dynamics. The magnetic state is characterized by the integrated noise, whereby the noise is at a maximum when the medium is demagnetized; i.e., it is in the remanent coercive state. Wachenschwanz and Alex (1999) suggested a modification of the "reptation technique" where the

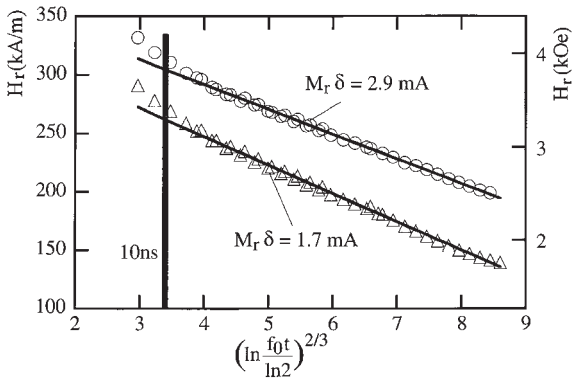

***Figure 7***
Measured time dependence of coercivity for thin-film media (reproduced by permission of IEEE from *IEEE Trans. Magn.*, 1999, **35**, 2790–5).

amount of erasure of a long wavelength square-wave recording rather than the d.c. erased noise is used as an indicator of the magnetization state. Although this modification has practical advantages, the effect of the demagnetizing field associated with the transitions as well as head nonlinearities can alter the result.

Figure 7 shows dynamic coercivity data obtained using the reptation technique for about eight orders of magnitude in time (Richter 1999). As Eqn. (7) suggests, the data should follow a straight line when plotted vs. $[\ln(f_0 t/\ln 2)]^{2/3}$. Deviations are seen for $[\ln(f_0 t/\ln 2)]^{2/3} \leqslant 3.5$, corresponding to $t \leqslant 500/f_0$, which is roughly consistent with the results of Sect. 1.3. On the other hand, these deviations are, at least partially, due to a demagnetization effect inherent to the measurement. The slope can be used to estimate the value for $K_1 V/k_B T$.

The Landau–Lifshitz equation predicts that the media can, in principle, be switched infinitely fast for a sufficiently large driving field. Such an experiment has indeed been done and it is confirmed that the magnetization can be switched with field pulses as small as 6 ps (Siegmann *et al.* 1995), consistent with the Landau–Lifshitz equation (He and Doyle 1996).

More experiments of this kind have shown that the damping for recording media is surprisingly high and can be close to 1, whereas that of perpendicular media is somewhat smaller, about 0.3 (Tudosa *et al.* 2004). In these experiments, the spins inside the grains are excited in a non-uniform manner and the damping so obtained cannot directly be compared with that of traditional FMR experiments in which the magnetization precesses uniformly around the equilibrium orientation.

The high speed experiments have also revealed that the ultimate speed limit for the switching of recording media is of the order of a few pico-seconds which is slower than previously expected (Tudosa *et al.* 2004). For practical applications, this ultimate limit has no consequence, because the linear densities and spinning speeds that would lead to such high data rates cannot be achieved. Moreover, the driving fields used in these experiments are higher than those that can be obtained in disk drives.

## 3. Recording Considerations

The switching speed under recording conditions has only been addressed theoretically so far. The switching speed in the dynamical regime (no thermal activation included) has been calculated (Fang and Zhu 1996, Peng and Bertram 1997). Similarly to the considerations for single grains, small damping parameters—which are likely to be applicable to thin-film media—have been reported to increase the switching time.

The switching speed of longitudinal recording media has been compared theoretically with that of vertically oriented media (Peng and Bertram 1997). Media were compared with equal coercivities, whereby the longitudinal media were subjected to a ring head field and the vertical media were subjected to a field created by a probe head in conjunction with a magnetically soft underlayer. Longitudinal media were found to switch faster, which is fundamentally owing to the effect of the film-demagnetizing field. For longitudinal media, the film-demagnetizing field is perpendicular to the reversal direction and thus creates an extra torque on the magnetization. In the case of vertical media, there is no extra torque, because the demagnetizing field is parallel to the reversal direction.

## 4. Summary

Data rates in magnetic recording begin to approach the intrinsic switching speed limits of recording media. It is thought that precession dynamics limit the switching speed of longitudinal recording media to times of the order of 0.1 ns in practice. For times longer than – 100 ns, dynamical effects are described well by the Arrhenius–Néel formalism. The theoretical understanding of the transition between the viscosity regime and the precessional regime is not fully developed.

## Acknowledgments

I am greatly indebted to V. Safonov and H. N. Bertram for making their results available to me prior to publication and to T. Silva and R. W. Chantrell for helpful comments.

## Magnetic Anisotropy

"Magnetic anisotropy" is an ambiguous term. Since a magnetic field is a vector quantity, it implies by definition direction dependence. In 1821 Poisson assumed an interplay of magnetism with crystallinity. After 1850 the "magnetism of crystals" was experimentally investigated. Since then it has been known that diamagnetism, paramagnetism, and natural ferromagnetism all depend on the properties of the different materials, especially on the crystallographic properties.

Any dependence of the magnetic properties of a material on the direction can be termed magnetic anisotropy. It can be described by a dimensionless "anisotropy function," and it is closely related to space-dependent magnetization patterns, yielding a total (direction-dependent) magnetic free energy. Usually, however, only the magnetic properties of solids in the magnetically ordered state are characterized by magnetic anisotropy.

Several different origins and manifestations of magnetic anisotropy can be distinguished, namely shape anisotropy, exchange anisotropy, stress aniso tropy, surface anisotropy, anisotropy induced by a magnetic field, and, last but not least, magnetocrystalline anisotropy. The last is the most important for modern hard magnetic materials and permanent magnets.

### *1. Definitions of Magnetic Anisotropy*

The term "magnetic anisotropy" is not a primary unit (see *Magnetic Units*), although magnetic anisotropy is of utmost importance for soft and especially hard magnetic materials.

For soft magnetic materials (see *Magnetic Losses*) the smallest possible coercivity ${}_{\mathrm{M}}H_{\mathrm{C}}$ or ${}_{\mathrm{B}}H_{\mathrm{C}}$ is a primary goal. It can be deduced from the hysteresis loop in the M–H or B–H representation, respectively. Since the magnetic anisotropy is linked to coercivity, usually the magnetic anisotropy of any origin is minimized in soft magnetic materials. Medium-soft magnetic materials, especially magnetic recording materials, rely on a sufficiently large (because of long-term stability) but sufficiently small (because of the necessity of frequent remagnetization) coercivity, and is usually in the range of $10^4$–$10^5$ $\mathrm{Am}^{-1}$ (ca. 100–1000 Oe). For such applications materials with shape anisotropy (e.g., $Fe_2O_3$ needles), surface anisotropy (thin films), or magnetocrystalline anisotropy are needed. A clear-cut distinction of the nature of magnetic anisotropy is rarely possible.

Shape anisotropy is nearly always present, since the magnetic medium is never an ideal sphere. The origin of shape anisotropy is the magnetostatic energy. Shape anisotropy can be used to prepare permanent magnets. (In the 1950s elongated single domain magnets were fabricated from pure cubic iron in the shape of needles). Shape anisotropy also plays an important role in the anisotropy of Alnico magnets (see *Alnicos and Hexaferrites*).

Stress anisotropy is the counterpart to magnetostriction. It is observed if an external stress, via magnetoelastic coupling, favors energetically some magnetization directions. The already mentioned surface anisotropy is always present in thin layers or if extended surfaces are present in the material, e.g., nanocrystalline samples (see, e.g., *Amorphous and Nanocrystalline Materials*).

In this article mainly the subject of magnetocrystalline anisotropy (MCA) will be treated in more detail, since it is the basis of modern permanent magnets.

### *2. Experimental Determination of Magnetic Anisotropy*

In principle the measurement of magnetic properties (see *Magnetic Measurements: Quasistatic and ac*) can be performed as a function of the crystallographic directions of the sample and/or an applied magnetic field. From these results frequently information about the magnetic anisotropy can be deduced. Some methods especially suited to probe magnetic anisotropy, however, are mentioned here. If a single crystal of the magnetic material is available, the magnetic anisotropy and the anisotropy coefficients $K$, etc., are obtained by, e.g., a torque magnetometer. An aligned ensemble of powders can be used instead of a single crystal but with reduced accuracy.

Due to the magnetic moment of the neutron, elastic and inelastic neutron scattering (see *Magnetic Excitations in Solids*) is a primary tool to establish the spin structure of magnetic materials and also the magnetic excitations. Since these measurements can be performed at different magnetic fields and at variable temperatures, many magnetic parameters, including the magnetic anisotropy, can be deduced from neutron experiments. By rotating a sample in a magnetic field and detecting the transverse susceptibility the pinning field, which is directly linked to the magnetic anisotropy, can be measured (Elk and Hermann 1992).

"Free moving" particles studied for magnetization at high (pulsed) fields allow an analysis of the coupling of different magnetic sublattices and the associated magnetic anisotropy (Franse and Radwanski 1996).

In their classical measurement of the magnetization of a $YCo_5$ single crystal in two perpendicular

directions Hoffer and Strnat (1966) detected a huge anisotropy field of approximately 13 T (130 kOe) and opened up the area of rare-earth permanent magnets (see *Rare Earth Magnets: Materials*).

## 3. Magnetocrystalline Anisotropy

Disregarding the microscopic origin of MCA this property can be measured and analyzed. It can be described in the following manner (Kirchmayr 1991). Since hexagonal and tetragonal crystal structures are the most important structures for modern permanent magnets, only these two are discussed here. The mean magnetic moment of a ferro- or ferrimagnetic substance is directed, in the absence of an external magnetic field, in the crystallographic direction in which the absolute minimum free energy, $F$, is achieved.

This direction is called the "easy magnetization direction" or "easy axis." A part of the total free energy, therefore, depends on the direction of magnetization with respect to the different crystallographic directions and is called the magnetocrystalline free energy, $F_a$ or the MCA. Usually, $F_a$ is expressed in terms of simple sine or cosine functions. For hexagonal crystals,

$$F_a = K_1\sin^2\theta + K_2\sin^4\theta + K_3\sin^6\theta + K_3'\sin^6\theta\cos 6\phi$$

and for tetragonal crystals,

$$F_a = K_1\sin^2\theta + K_2\sin^4\theta + K_3\sin^4\theta\cos 4\phi$$

where $\theta$ is the angle between the $c$ axis and the vector of magnetization, $\phi$ is the angle between the projection of the magnetization vector in the basal plane of the crystal and one of the $a$ axes, and $K_1$, $K_2$, $K_3$, and $K_3'$ are the coefficients of anisotropy, expressed in J m$^{-3}$ or in GOe; 1 MGOe = 7.9577 kJm$^{-3}$.

The anisotropy constants reflect the magnetic anisotropy only phenomenologically and have no direct connection with the physical origin of magnetic anisotropy.

If an external magnetic field $H$ is applied to a crystal, an additional term appears in the free energy, $F$, which is given by

$$F = F_a - M_s H\cos(\theta - \beta)$$

where $M_s$ is the saturation magnetization, $\beta$ is the angle between $H$ and the $c$ axis, and $(\theta-\beta)$ is the angle between $M_s$ and $H$. In this equation the stray field energy, which depends on the size and the shape of the sample, has been neglected. Equilibrium is achieved when $F$ reaches a minimum, hence

$$\delta F/\delta\theta = \delta F_a/\delta\theta + \mu_0 M_s H\sin(\theta - \beta) = 0$$

or

$$-\delta F/\delta\theta = \mu_0 M_s H\sin(\theta - \beta) = \mu_0|M \times H|$$

where $\mu_0|M \times H|$ is the torque exerted by the crystal anisotropy and is counterbalanced by the external field. For small deviations from the easy axis, $\Delta\theta = 0$, the term

$$(1/\mu_0 M_s).(\delta^2 F_a/\delta\theta^2)\big|_{\Delta\beta=0} = H = H_A$$

is equivalent to a field, called the anisotropy field, $H_A$.

As can be seen from the above discussion, $H_A$ is deduced from small deviations from the easy axis and is therefore defined for small applied fields. It must be distinguished from the anisotropy field, $H_A^*$, which can be measured directly by the singular point detection method, i.e., at high magnetic fields above $H_A$. This method has its merits because it may be applied to polycrystalline samples and in pulsed fields (see *Magnetic Measurements: Pulsed Field*). It yields directly the anisotropy field $H_A^*$.

The magnetic anisotropy can therefore be given by the anisotropy constants $K_1$, $K_2$, and $K_3$ or by the anisotropy field $H_A$ resp. $H_A^*$. ($K_3$ is usually neglected.) The anisotropy field can be measured directly on polycrystalline samples, in contrast to $K_1$, $K_2$, and $K_3$ which are usually not directly accessible but can be determined on single crystals by torque measurements. However, because of the problem of achieving well-developed single crystals with different compositions and because of technical problems to measure the torque at different temperatures, the classical determination of the magnetic anisotropy constants by means of torque measurements is of limited practical use.

## 4. Microscopic Origin of Magnetocrystalline Anisotropy

Long-range spin ordering over macroscopic distances is the result of exchange, i. e., the combination of the electrostatic coupling between electron orbitals and the Pauli exclusion principle. The nature of this exchange is isotropic. Anisotropy, however, is the result of the interaction of the electron orbitals with the potentials of the lattice. The lattice symmetry is therefore responsible for the MCA. A rigorous calculation of the MCA from first principles is at present not possible. A simplified approach is the molecular field calculation. In the case of RE–3$d$ (RE = rare-earth) intermetallics a phenomenological separation into the contributions of the RE and the 3$d$ sublattice is often meaningful. Micromagnetism tries to discuss the behavior of magnetic materials without detailed knowledge of the basic origin of magnetic ordering and anisotropy. Much progress has been achieved by this approach, especially by Kronmüller *et al.* (1994); (see *Coercivity Mechanisms*).

There are three different types of permanent magnetic materials, namely $RECo_5$ and $RE_2Co_{17}$, which

are both hexagonal, and $RE_2Fe_{14}B$ which is tetragonal (Kirchmayr 1996). The basis of the magnetic ordering and the magnetic anisotropy in metallic compounds of RE metals with transition metals (T) are the RE–RE, T–T, and RE–T interactions. (For a review of the phases, crystal structures, and magnetic properties of RE–3*d* intermetallics see Kirchmayr and Burzo 1990). In the $RE_2Fe_{14}B$ compounds the situation is even more complex because of the presence of a third element. Naturally, in a metallic system most of the interactions are mediated by the electrons, especially the conduction electrons, which means that the fullband structure has to be taken into account. While the RE anisotropy is a single-ion anisotropy mainly governed by crystal field effects, the T anisotropy is complex and less well understood. All these interactions plus sublattice anisotropies are responsible for various types of magnetic transitions and peculiarities, such as first-order magnetization processes, critical fields, noncollinarity of ferrimagnetic structures, etc. (see also *Localized 4f and 5f Moments: Magnetism* and *Alloys of 4f (R) and 3d (T) Elements: Magnetism*).

## 5. Magnetocrystalline Anisotropy as a Basis for Modern Permanent Magnets

In Table 1 some basic data for hard magnetic materials are summarized (for the temperature dependence of $K_1$ and $K_2$ of these compounds see also Kirchmayr and Burzo 1990). A comparison of the anisotropy field $H_A$ and the coercivity ${}_MH_c$ shows a large discrepancy. $H_A$ serves as an upper limit for ${}_MH_c$ and is a necessary prerequisite for a good modern permanent magnet with large saturation and coercivity and therefore energy product (see *Hard Magnetic Materials, Basic Principles of*). In practice the B–H representation of the hysteresis loop is used. In this case ${}_BH_c > M_s$ is sufficient to achieve a linear demagnetization curve in the second quadrant. Since the coercivity decreases with increasing temperature, even at the operating temperature ${}_BH_c > M_s$ should be valid. This condition is usually met by modern permanent magnets. In the future a further increase in the energy product seems therefore to be feasible only by increasing the saturation, but not by increasing the coercivity or the magnetic anisotropy.

**Table 1**
Basic data for hard magnetic materials.

| Compound | $T_c$ (K) | $\mu_0 H_a$ (T) | $(K)_1$ (MJ m$^{-3}$) | $\mu_0 M_s$ (T) |
|---|---|---|---|---|
| $SmCo_5$ | 993 | 40 | 17 | 1.05 |
| $Sm_2Co_{17}$ | 1100 | 6.5 | 3.3 | 1.30 |
| $Nd_2Fe_{14}B$ | 585 | 6.7 | 5 | 1.60 |

## 6. Summary and Conclusions

Anisotropy is a basic property of all crystalline materials. Even in nanocrystals and amorphous solids, e.g., metallic glasses, anisotropy is present on an atomic level. Therefore magnetic anisotropy is an intrinsic property of magnetization in general.

In the last decades MCA made possible the development of better and stronger permanent magnets, characterized by a higher coercivity and an ever increasing energy product. This fast development, however, may reach a natural boundary, because the coercivity has reached a value which is sufficient to make full use of the possibilities of modern permanent magnet materials. Any further progress in energy product cannot be achieved by an increase in magnetic anisotropy, but only by the development of materials with larger saturation magnetization while maintaining sufficiently high coercivity. The development of materials with large magnetocrystalline anisotropy attempts to retain this property also at elevated temperature.

From the viewpoint of basic research, the understanding and calculation of magnetic anisotropy from first principles is still in its infancy. Therefore, studies of the magnetic anisotropy will continue to be a fascinating area of basic and applied research for the time to come.

# Magnetic Excitations in Solids

This article is focused on the discussion of one important experimental method for measurements of magnetic excitations in solids, i.e., inelastic neutron scattering (INS): a method that has been in the past and that will be in the future the method of choice in this field.

In the first part, an overview is given on magnetic neutron cross-sections, on the range of experimentally accessible transfers of momentum and energy ($(\boldsymbol{Q},\omega)$-range), and on important types of neutron spectrometers that are used for the measurements of magnetic excitations.

In the second part, the hierarchy of relevant solid-state interactions and the involved energy scales will be discussed for compounds containing the magnetic elements with 3*d*-, 4*f*-, and 5*f*-electrons in open atomic shells.

In the third and last part, elementary magnetic excitations like those from spin waves, crystal-field transitions, inter-multiplet transitions, and spin fluctuations will be presented in relation to their occurrence in bulk magnetic materials containing the elements with 3*d*-, 4*f*-, and 5*f*-electrons.

An early review on magnetic excitations was given by (Stirling and McEwen 1986).

## 1. Magnetic Neutron Cross-sections

The interaction of thermal neutrons with matter is twofold: the nuclear interaction with the atomic nuclei and the magnetic interaction of the neutron's magnetic dipole moment with the magnetic field $\boldsymbol{B}$ created by the unpaired electrons in the sample. A comprehensive theoretical treatment is given in the two volumes of the book by Lovesey (1984). Focusing on magnetic scattering we give as an example the scattering cross-section for unpolarized neutrons (Böni and Furrer (1998); for meaning of symbols look up the cited article):

$$\left(\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega\,\mathrm{d}E_\mathrm{f}}\right)_\mathrm{mag} = \frac{k_\mathrm{f}}{k_\mathrm{i}}\left(\gamma r_0 \frac{g}{2} F(\boldsymbol{Q})\right)^2 \times \sum_{\alpha\beta}\left(\delta_{\alpha\beta} - \hat{Q}_\alpha \hat{Q}_\beta\right) S^{\alpha\beta}(\boldsymbol{Q},\omega) \quad (1)$$

where $S^{\alpha\beta}(\boldsymbol{Q},\omega)$ is the van Hove magnetic scattering function:

$$S^{\alpha\beta}(\boldsymbol{Q},\omega) = \frac{1}{2\pi\hbar}\int \sum_{jj'} \left\langle S_{j'\alpha}(0) S_{j\beta}(t)\right\rangle \times \left\langle \exp\left(-\mathrm{i}\boldsymbol{Q}\cdot\boldsymbol{r}_{j'}(0)\right)\exp\left(+\mathrm{i}\boldsymbol{Q}\cdot\boldsymbol{r}_j(t)\right)\right\rangle \times \exp(-\mathrm{i}\omega t)\,\mathrm{d}t \quad (2)$$

$S^{\alpha\beta}(\boldsymbol{Q},\omega)$ corresponds to the Fourier transform of the magnetic pair correlation function that gives the probability to find a magnetic spin at position $\mathbf{r}_j$ at time $t$ with component $S_{j\beta}(t)$ and a spin at position $\mathbf{r}_{j'}$ at time $t = 0$ with a component $S_{j'\alpha}(0)$. Therefore, the magnetic cross-section depends on magnetic as well as on lattice vibrational degrees of freedom. This is usually taken into account by a Debye–Waller factor, $\exp(-2W(\boldsymbol{Q}))$; in the following this factor has been omitted.

In Eqn. (2), $S^{\alpha\beta}(\boldsymbol{Q},\omega)$ is expressed in terms of expectation values of time-dependent operators (Heisenberg picture). Equivalently, the scattering function can be written in terms of time-independent operators (Schrödinger picture) by replacing the integral over time by a $\delta$-function in energy obtaining

$$S^{\alpha\beta}(\boldsymbol{Q},\omega) = \sum_{jj'} \exp\left(\mathrm{i}\boldsymbol{Q}\cdot\left(\boldsymbol{r}_j - \boldsymbol{r}_{j'}\right)\right) \sum_{\lambda_\mathrm{i}\lambda_\mathrm{f}} p_{\lambda_\mathrm{i}} \left\langle \lambda_\mathrm{i}|\hat{S}^\alpha_{j'}|\lambda_\mathrm{f}\right\rangle \times \left\langle \lambda_\mathrm{f}|\hat{S}^\beta_j|\lambda_\mathrm{i}\right\rangle \boldsymbol{\delta}(E_{\lambda_\mathrm{i}} - E_{\lambda_\mathrm{f}} + \hbar\omega) \quad (3)$$

The magnetic scattering function is also directly related to the imaginary part of the wavevector and frequency-dependent susceptibility via the fluctuation–dissipation theorem by

$$S^{\alpha\beta}(\boldsymbol{Q},\omega) = \frac{\hbar}{\pi}\frac{1}{1-\exp(-\hbar\omega/k_\mathrm{B}T)}\mathrm{Im}\;\chi^{\alpha\beta}(\boldsymbol{Q},\omega) \quad (4)$$

This theorem implies that the magnetic moment of the neutron acts on the sample as a frequency- and wavevector-dependent magnetic field $\boldsymbol{B}(\boldsymbol{Q},\omega)$, monitoring the magnetic response $\boldsymbol{M}(\boldsymbol{Q},\omega)$ of the sample with

$$\boldsymbol{M}^\alpha(\boldsymbol{Q},\omega) = \sum_\beta \chi^{\alpha\beta}(\boldsymbol{Q},\omega) B_\beta(\boldsymbol{Q},\omega) \quad (5)$$

where $\chi^{\alpha\beta}(\boldsymbol{Q},\omega)$ is the generalized susceptibility tensor. The fluctuation–dissipation theorem allows direct comparisons of $\chi^{\alpha\beta}$ as obtained by neutron scattering with bulk measurements of $\chi$ using the Kramers–Kronig relation (see text books on solid-state physics).

For the discussion of the polarization dependence of the neutron cross-section, we refer the reader to the book of (Williams 1988). Here it is sufficient to state that a polarization analysis allows us to separate unambiguously nuclear and magnetic scattering though a loss of overall intensity has to be taken into account. Furthermore, it is possible to determine, for example, individual matrix elements of the spin operators between crystal-field states ($|\langle\lambda_\mathrm{i}|\hat{S}^\alpha_j|\lambda_\mathrm{f}\rangle|^2$).

## 2. Accessible $(\boldsymbol{Q},\omega)$-range

The magnetic scattering functions $S^{\alpha\beta}(\boldsymbol{Q},\omega)$ as given in the previous section depend only on the *transfer* of energy ($\hbar\omega = E_\mathrm{i} - E_\mathrm{f}$) and momentum ($Q = \boldsymbol{k}_\mathrm{i} - \boldsymbol{k}_\mathrm{f}$)

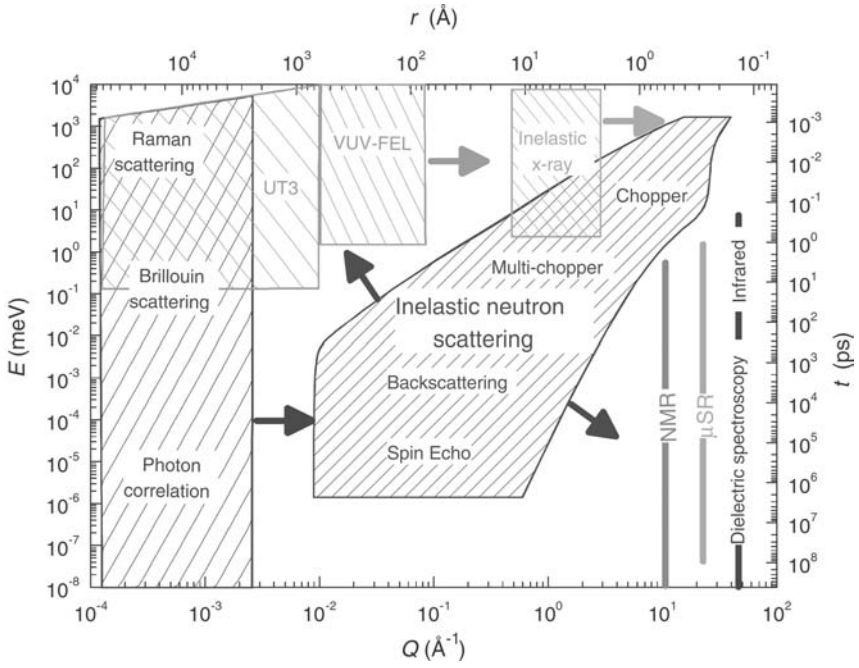

***Figure 1***
Accessible range of transfer in energy ($\hbar\omega$ in meV) and of the modulus of the momentum $Q$ (in Å$^{-1}$) for neutron scattering in comparison to other experimental methods. Also indicated is the corresponding range in time (in ps) and real space (in Å) (from ESS 2003).

from the neutron to the sample. $E_i$ ($\boldsymbol{k}_i$) and $E_f$ ($\boldsymbol{k}_f$) refer to the initial and final energy (wavevector) of the neutron, respectively. The different formulations of the scattering function (Eqns. (2)–(4)) allow for a straightforward interpretation of the measured cross-sections in meaningful theoretical concepts, i.e., spin–spin correlation functions (Eqn. (2)), transition matrix elements (Eqn. (3)), or as generalized susceptibility tensor (Eqn. (4)). The presently accessible range of energy and momentum transfer by neutrons is shown in Fig. 1 (ESS 2003). Also indicated by arrows are its extension for neutron sources of the next generation and the corresponding range of complementary measuring techniques such as x-rays, free-electron-lasers (FEL), NMR, etc.

## 3. *Neutron Spectrometers*

Since the first neutron instrumentation at research reactors in the 1950s and at accelerator-based neutron spallation sources in the 1980s, a large variety of neutron spectrometers has been developed. The two main types of spectrometers for the investigation of excitations in solids depend on the different way the neutron wavevector is determined before and after the scattering process: by reflection from a single crystal or by measuring the neutron time-of-flight.

In a triple-axis spectrometer (Brockhouse 1955, Shirane *et al*. 2002), the reflection from a single crystal (monochromator) selects a well-defined wavevector $\boldsymbol{k}_i$ from the white spectrum of the neutron source (first axis). The monochromatic beam is scattered from the sample (scattering angle = second axis). The scattered beam is reflected from the analyzer crystal (third axis) onto the detector, thus defining the final neutron wavevector $\boldsymbol{k}_f$ and the energy transfer $\hbar\omega$ as well. A schematic view is shown in Fig. 2 (IN1, ILL 2003). Data are taken point-by-point in reciprocal space either with fixed momentum transfer $\boldsymbol{Q}$ (to obtain an energy spectrum) or with fixed energy transfer $\hbar\omega$. This method is typically used for the determination of dispersion relations using single crystalline samples.

Time-of-flight methods are preferentially used for the investigation of polycrystalline samples and at neutron spallation sources taking advantage of the pulsed character of the neutron production in the target. As an example the layout of the MERLIN spectrometer at the ISIS Facility is shown in Fig. 3 (ISIS 2003). The pulsed beam is monochromatized by the (Fermi-) chopper in front of the sample by phasing the chopper opening with the neutron production in the target (spallation target and moderator at upper right side, not shown in the figure). A background chopper additionally suppresses unwanted neutrons

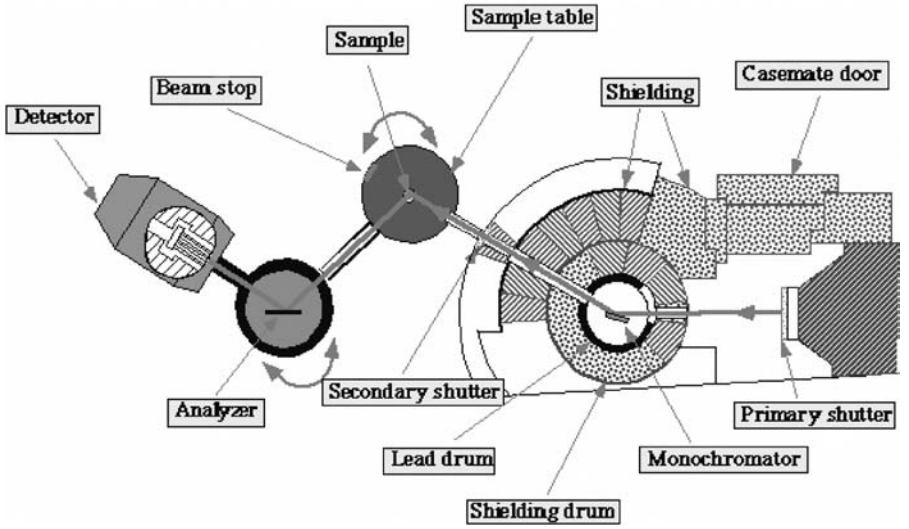

*Figure 2*
Scheme of a neutron triple-axis spectrometer at a neutron reactor (IN1 at the Institute Laue-Langevin, ILL, Grenoble) (from ILL 2003).

from the source. A large array of detectors covers a large solid angle and allows for the simultaneous measurement of a large range in energy transfer and of the modulus of the momentum transfer.

## 4. Magnetic Interactions in Solids

When elements with partly filled shells containing 3*d*-, 4*f*-, and 5*f*-electrons are condensed into the solid state (either as pure elements, intermetallic compounds, semiconductors, or insulators), they often preserve their magnetic properties. As the 4*f*-electrons (elements of the Lanthanide series) occupy inner spatial regions of the atom, they lose only little of their magnetism when embedded in a solid (see *Localized 4f and 5f Moments: Magnetism*). The magnetic ground state is determined by taking into account all three Hund's rules (see textbooks on solid-state physics). The interaction with the crystalline electric field (CF) that surrounds the 4*f*-ion (single-ion interaction) and the magnetic interaction with the magnetic moments of neighboring atoms (two-ion interaction) leads to a (CF-) splitting of the ground-state multiplet and to a dispersion of the magnetic excitations, respectively. Both interaction strengths can be of the same order of magnitude (1–100 meV). In compounds containing 3*d*-elements the interaction leading to the third Hund's rule (the spin–orbit interaction) is much weaker than the CF-interaction (see *Magnetism in Solids: General Introduction*) resulting in a different scenario for the description of the magnetic ground-state (band-type electronic wave functions of $e_g$ and $t_{2g}$ character). In metallic systems this leads to a "quenching" of the orbital moments resulting in a description of the magnetic properties as spin-only moments dominated by the collective magnetic interactions. 3*d*-Insulators will not be considered here (a decoupling of spin, charge, and orbital degrees of freedom is presently discussed in connection with metal–insulator transitions). The situation in systems with 5*f*-elements (elements of the actinide series) is between that of 4*f*-systems (localized) and that of 3*d*-systems (itinerant) and thus rather complicated.

## 5. *Spin Waves, Crystal-field and Inter-multiplet Transitions*

Spin waves (magnons) are the low-energy collective excitations of a magnetically ordered system. For an isotropic Heisenberg interaction of localized magnetic moments, the textbooks on solid-state physics yield for a ferromagnet for small $|\boldsymbol{q}|$ a quadratic dispersion in $|\boldsymbol{q}| = |\boldsymbol{Q} - \boldsymbol{G}|$, with $\boldsymbol{G}$ being a reciprocal lattice vector of the (ferromagnetic) lattice. For an antiferromagnet the dispersion is linear in $|\boldsymbol{q}|$ in the neighborhood of the antiferromagnetic reciprocal lattice vector. The magnetic excitations of the elementary magnets like Fe and Ni have been investigated over many decades resulting in an isotropic and gap-less spin wave-like spectrum in the low-energy region but with drastic modifications when following the dispersion towards the zone boundary. The latter findings have been analyzed in the light of electronic band structure effects or by saying that the sharp collective spin waves interfere with single-particle excitations of the 3*d*-electrons (exhibiting a Stoner continuum) giving rise to strong damping effects (Lovesey 1984, Mook 1988).

Spin waves in the presence of CF-interactions are discussed experimentally and theoretically for the rare earth elements by Jensen and Mackintosh (1991). The excitation spectra of rare earths diluted in nonmagnetic metals and intermetallic compounds are discussed by Fulde and Loewenhaupt (1985, 1988) and for rare earth intermetallic compounds including rare earth-transition metal compounds by Moze (1998). The latter compounds are the base materials for novel permanent magnet production. The types of excitations in a rare earth compound accessible by inelastic neutron scattering are shown exemplarily in Fig. 4. In this case the hierarchy of energies yields a spin wave spectrum in the very low energy part (due to the low magnetic ordering temperature of typical several K), transitions to excited CF-levels (several meV; 1 meV corresponds to 11.6 K), and inter-multiplet transitions (several hundredth of meV). The advent of neutron spallation sources made it possible to investigate also the high-energy region of the magnetic excitation spectra, e.g., inter-multiplet transitions, an area that was usually restricted to light scattering (Hüfner 1978). An early documentation of the possibilities of neutron scattering in the field of investigating inter-multiplet transitions is given by Osborn *et al.* (1991).

To determine the magnetic excitation spectra of an intermetallic rare earth compound (as an example we show the results for orthorhombic $NdCu_2$), time-of-flight spectroscopy on a polycrystalline sample is performed as a first step. In Fig. 5 the CF-transitions from the ground-state doublet to the four excited-state doublets of $Nd^{3+}$ (having the angular momentum quantum number $J = 9/2$ and hence five doublets due to the CF-interaction and Kramers degeneracy)

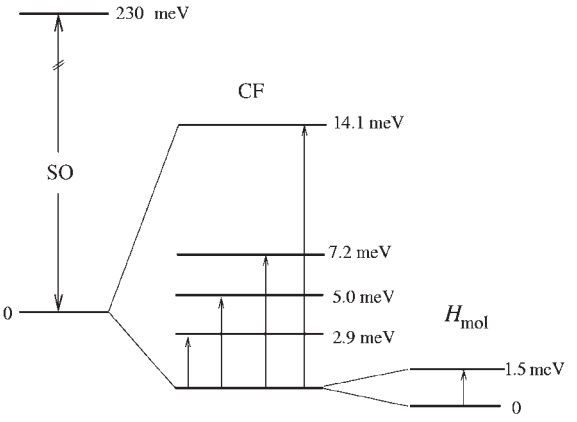

***Figure 4***
Typical splitting of levels in a rare earth system due to spin–orbit (SO), crystal-field (CF), and exchange interaction ($H_{mol}$). Scheme reproducing approximately the situation of $Nd^{3+}$ ions in $NdCu_2$.

can clearly be identified. While the spectrum of Fig. 5 was taken in the magnetically disordered state at 10 K, the spectrum at 2 K in the magnetically ordered state is shown in Fig. 6. The main difference is that in the ordered state a molecular field is present in addition to the CF. This yields a splitting of the doublets and a modification of the transition matrix elements. The transitions within the split ground-state doublet are shown with increased resolution in the inset of Fig. 6. The structure of this part of the excitation spectrum reflects the dispersive nature of the splitting with its intensity being proportional to the magnon density-of-states. To show the power of inelastic neutron scattering on this very low energy side of the range of excitations in 4*f*-systems, we present in Fig. 7 the spin wave dispersion curves measured on a single crystal of $NdCu_2$ in the ferromagnetically induced state in a field of 3 T on a triple-axis-spectrometer employing cold neutrons (Rotter *et al.* 2000). The spin waves have been analyzed by a mean-field model in random-phase approximation (MF-RPA; see, e.g., Jensen and Mackintosh 1991) allowing for anisotropic effects due to the single-ion CF-interaction and also for anisotropic two-ion exchange interactions. From the interpretation of the magnetic-phase diagrams (Rotter 2003), the dispersion relations and the CF-excitation spectra of one compound ($NdCu_2$) predictions could be made for the magnetic properties of the whole series $RCu_2$ with R being any rare earth element.

In general, elementary excitations in solids such as CF-transitions and lattice vibrations (phonons) are considered decoupled and the determination and interpretation of the measured spectra of the two phenomena, i.e., the CF level schemes and the phonon

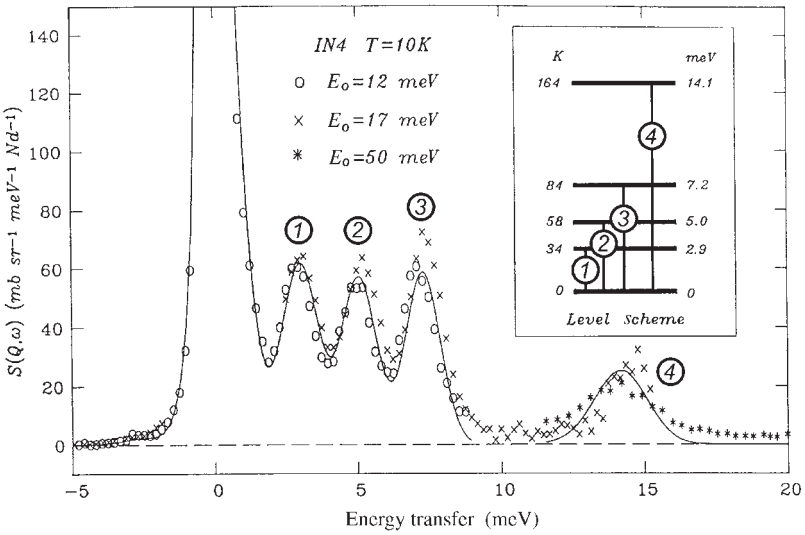

***Figure 5***
CF-transitions from the ground-state doublet to the four excited-state doublets in $NdCu_2$ measured on a time-of-flight spectrometer (IN4, ILL) in the magnetically disordered state at $T = 10\,K$ and zero external field. Inset shows the CF-level scheme (from Gratz *et al.* 1991).

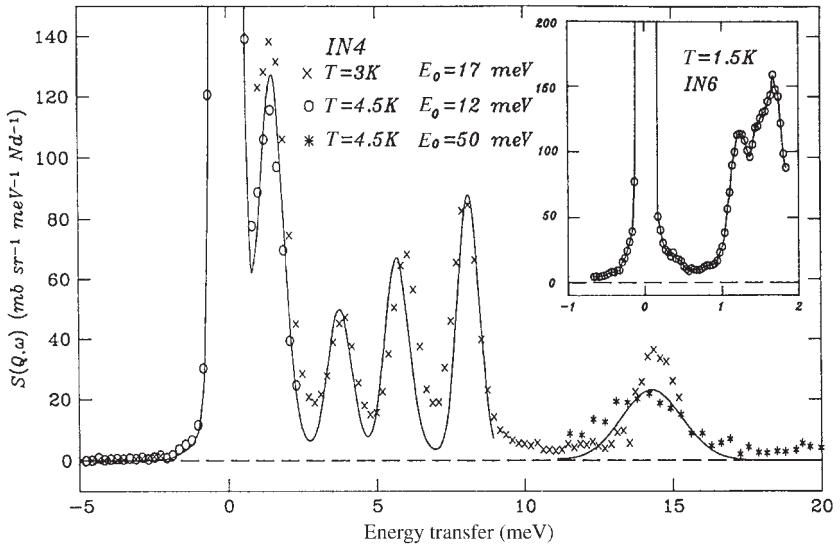

***Figure 6***
CF-transitions and magnon density-of-states (shown on an enlarged scale in the inset) in the magnetically ordered state of $NdCu_2$ at $T = 2\,K$ ($T_N = 6.5\,K$) and zero external field measured on time-of-flight spectrometers (IN4 and IN6, ILL) (from Gratz *et al.* 1991).

dispersion relations, are performed independently of each other. A survey on coupling effects between both phenomena as investigated by INS is given by Loewenhaupt and Witte (2003).

## 6. *Spin Fluctuations*

Spin wave theory in MF-RPA neglects spin quantum fluctuations. However, fluctuations become important

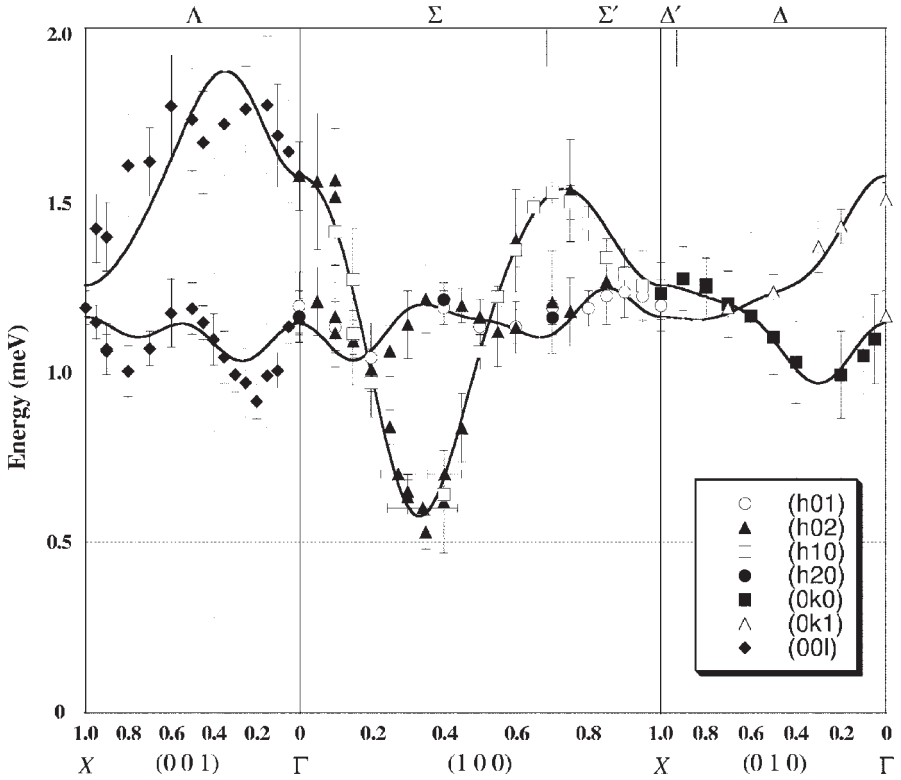

***Figure 7***
Spin waves in $NdCu_2$ measured in the ferromagnetically induced phase at $T = 2$ K and with magnetic field of 3 T applied along the crystallographic *b*-direction measured on a triple-axis spectrometer (IN12, ILL) (from Rotter *et al.* 2000).

for low-dimensional systems and low spin- quantum numbers (see *Non-Fermi Liquid Behavior: Quantum Phase Transitions*). The new phenomena observed in such systems are presently discussed in a wide context from one-dimensional antiferromagnets (Cowley 1998, 2002, Mikeska 2002) via heavy-fermion superconductors (Bernhoeft *et al.* 1998, Thalmeier 2002) to high-temperature superconductors (Bourges *et al.* 2000).

Classical examples of three-dimensional systems exhibiting also strong spin fluctuations are mixed-valent and heavy-fermion compounds (see *Intermediate Valence Systems; Heavy-fermion Systems*). Reviews on the lanthanides (Loewenhaupt and Fischer 1993, Aeppli and Broholm 1994) and actinides (Holland-Moritz and Lander 1994) make the strong coupling between the localized *f*-electrons and the delocalized conduction electrons responsible for the observed magnetic instabilities. Detailed INS measurements were reported for single crystalline samples of the series $CeCu_{6-x}Au_x$ where the variation of $x$ drives the system from Fermi-liquid behavior ($x = 0$) via a quantum critical point ($x = 0.1$) to a magnetically ordered ($x = 1$) system (Schröder *et al.* 1997, Stockert *et al.* 1997).

# Magnetic Fields: Thermoelectric Power

The coefficient of the thermoelectric power ($S$) measured in variable magnetic fields ($B$) is called magnetothermopower. This physical quantity can provide very valuable complementary information concerning details of electronic band structure. In comparison with the magnetoresistivity, the magnetothermopower is not sensitive to a uniform change of mobility of conduction electrons by the Lorentz force. The magnetothermopower of metallic materials basically depends on a relative change of the mobility of conduction electrons with different energy near the Fermi surface.

The effect of magnetic fields on thermopower is important also from a practical point of view. Thermocouples are widely used as temperature sensors. Therefore, in low-temperature thermometry in equipment with strong magnetic fields, such as research cryostats with superconducting magnets, a knowledge of the sensitivity of a thermocouple to the magnetic field is essential. Another significant and expanding field for the application of thermoelectric phenomena is thermoelectric heat–energy conversion and thermoelectric cooling. It is known that the thermoelectric efficiency of some materials can be considerably enhanced in a magnetic field (examples are bismuth-based alloys which are used for low-temperature refrigeration).

## *1. Theoretical Aspects of Magnetothermopower*

The thermopower, or Seebeck, coefficient $S$ is defined as the coefficient in the relation: $\mathbf{E} = S\nabla T$ between

the temperature gradient $\nabla T$ and the electrical field $\mathbf{E}$ in a conducting material, where the net current through the sample is zero (see *Boltzmann Equation and Scattering Mechanisms*). There are two other thermoelectric phenomena: the Peltier heat (characterized by the coefficient $\Pi$) and the Thomson heat (characterized by the coefficient $\mu_T$), which can be observed under different conditions. However, these three coefficients $S$, $\Pi$, and $\mu_T$ are not independent; they are connected to each other by the Thomson relations. For an isotropic medium, without a magnetic field, the relations read: $\Pi = TS$ and $\mu_T = T\mathrm{d}S/\mathrm{d}T$ (Barnard 1972). In a general case, $S$, $\Pi$, and $\mu_T$ are tensors of second rank, which can have as many as nine independent components. The most general form of the Thomson relation is given by the expression: $\Pi_{ik}(B) = TS_{ki}(-B)$ (Landau and Lifshitz 1977).

If there is, in addition to the temperature gradient, an external magnetic field applied to the sample, the thermoelectric field can be written as: $\mathbf{E} = S\nabla T + N\mathbf{B} \times \nabla T$ (Abrikosov 1972). The second term in this equation is the so called Nernst–Ettingshausen (N–E) effect, with $N$ the Nernst–Ettingshausen coefficient. However, apart from the N–E effect, the coefficient $S$ can also be dependent on the magnetic field. The change of $S$ in an external magnetic field is called magnetothermopower: $\Delta S = S(B, T) - S(0, T)$. In the weak field limit, this dependence is a second-order correction of the thermoelectric field $\mathbf{E}$ in the presence of a magnetic field.

With respect to experimental conditions, two different situations are possible, depending on the mutual orientation of the magnetic field and the temperature gradient: the magnetic field parallel to the temperature gradient, and the magnetic field perpendicular to the temperature gradient. One distinguishes, respectively, longitudinal magnetothermopower $\Delta S_L$ and transversal magnetothermopower $\Delta S_T$. In the case of anisotropic materials, special care should be taken to separate $\Delta S_T$ and the influence of the Nernst–Ettingshausen effect. According to the mechanism of the change of thermopower in a magnetic field, the effect can be subdivided into two main categories. In the first category, the effect is connected to the orbital motion of the conduction electrons in a magnetic field caused by the Lorentz force. In the second category, the effect is related to a change in the electronic structure and/or scattering mechanism in a magnetic field.

With regard to the Lorentz force-driven magnetothermopower, two different regimes are distinguishable, depending on the strength of the magnetic field. This field strength can be characterized by the product $\omega_c\tau$, where $\omega_c = eB/m^*c$ is the classical cyclotron frequency, $\tau$ is the average time between collisions of a conduction electron with scattering centers, $m^*$ is the effective electron mass, and $c$ is the speed of light. The low-field regime corresponds to $\omega_c\tau \ll 1$, while $\omega_c\tau \geqslant 1$ is the condition for the high-field range. From a theoretical point of view, the high-field case has been much better understood than the low-field one. In the high-field regime, the scattering processes become unimportant, and galvano- and thermomagnetic phenomena are determined by the topological properties of the Fermi surface. In the high-field limit $\omega_c\tau \gg 1$, the longitudinal magnetothermopower $\Delta S_L$ is independent of the magnetic field for any Fermi surface geometry.

The transversal magnetothermopower $\Delta S_T$ is proportional to $B$ for closed electron orbits in compensated metals, and is independent of the field in other cases (Blatt *et al*. 1976). A special case of the high-field regime is realized under the additional condition $\hbar\omega_c > k_B T$ ($k_B = 1.3806568 \times 10^{-23}\,\mathrm{JK}^{-1}$ is the Boltzmann constant, $\hbar = 1.05457266 \times 10^{-34}\,\mathrm{Js}$ is the Planck constant). Under this condition, Landau quantization of the orbital motion of the conduction electrons in the plane, normal to the magnetic field, becomes important and all electronic properties of metals, including thermopower, show an oscillatory dependence on $B^{-1}$ with a period $\Delta B^{-1}$. The period depends on the extreme cross-sectional area $A_e$ of the Fermi surface in a plane normal to the magnetic field: $\Delta B^{-1} = (2\pi e/\hbar c)(1/A_e)$ (Landau and Lifshitz 1977). These oscillations can best be observed in a very pure single crystal at low temperatures: $T < (\hbar e/m^* c k_B)B \approx 1.34B$, where $B$ is the field in teslas.

In the low-field regime, the scattering mechanism is essential and this makes a theoretical description extremely difficult. Within this limit, the Lorentz force driven magnetothermopower is expected to be proportional to $B^2$ (Abrikosov 1972, Landau and Lifshitz 1977, Ri *et al*. 1994).

The magnetothermopower due to a change of electronic structure can be dominant in non-simple metals, magnetic or nearly magnetic materials, strongly correlated systems, and in conductors with magnetic impurities. The effect essentially depends on details of the electronic structure of a particular system. No general theory has been developed up to now. The influence of a magnetic ordering on the thermopower has been discussed and investigated both theoretically and experimentally. On a qualitative level, the variation of thermopower of itinerant ferromagnets in the vicinity of Curie temperature has been explained by Mott, based on his *s–d* scattering model (Blatt *et al*. 1976). A summary of theoretical and experimental results can be found in Blatt *et al*. 1976, and in Yagasaki *et al*. 1996).

A somewhat special field represents the thermomagnetic phenomena in superconductors. This field has experienced a burst of theoretical and experimental activities in connection with the discovery of high-temperature superconductors. Large thermomagnetic effects were observed in the mixed state of high-$T_c$ materials. These effects are related to the magnetic flux flow driven by a temperature gradient.

For a review, see Huebener (1979) and Ri *et al.* (1994).

A review of the theory of galvanomagnetic and thermomagnetic effects in metals and of experimental results prior to 1957 is given in Jan (1957).

## 2. *Details of the Measurement*

Compared to measurements of the thermopower without a magnetic field, magnetothermopower measurements require several additional considerations:

(i) In the high-field limit, thermopower can be anisotropic even for crystals of cubic symmetry.

(ii) Contributions from galvano- and thermomagnetic effects, different from thermopower, should be carefully eliminated (the Nernst–Ettingshausen effect particularly).

(iii) Calibration of temperature sensors and reference electrodes in a magnetic field is important.

(iv) Care should be taken to avoid a magnetic field gradient.

Several different designs have been introduced for measurements of magnetothermopower. As an example, we mention the apparatus described by Resel *et al.* (1996). With this setup, the thermopower can be measured in magnetic fields from 0 T to 17 T in the temperature range from 3 K to 300 K. The main part of the sample holder is shown in Fig. 1. A special modulation technique for the temperature gradient is used in this setup to eliminate spurious voltages. Two gradient heaters working in opposite directions are utilized to generate an alternating temperature gradient in the sample. The total heating power produced by the two heaters is constant. Therefore, the average temperature of the sample is not affected by the gradient modulation. In order to avoid the N–E effect contribution, a parallel alignment of the temperature gradient and magnetic field direction is chosen. The temperature difference across the sample is measured with the help of two Chromel–Constantan thermocouples.

The sensitivity of this thermocouple is independent of the magnetic field within an error of 5%, in the field range from 0 T to 17 T at temperatures from 3 K to 300 K. For the reference electrode a Chromel wire is used, since the thermopower of this alloy has a comparatively weak and simple dependence on the external magnetic field and the temperature. However, for precise measurements of magnetothermopower of metals, where the effect is small, it is necessary to make corrections in the thermopower of Chromel, so that $S_{\mathrm{Ch}}(B, T) = S_{\mathrm{Ch}}(0, T) + \Delta S(B, T)$. It was found that $\Delta S(B, T)$ can be approximated by an empirical function $f(B, T)$ with an accuracy of $0.1\,\mu\mathrm{VK}^{-1}$. This function reads:

$$f(B,T) = aT\,\exp(bT^2) + cT^2\,\exp(dT)$$

$$a = \frac{2.1\ 10^{-2}B}{-51.4 + 49.1\ \exp(-2.91 \times 10^{-2}B)}$$

$$b = -2.2 \times 10^{-4} - 1.02 \times 10^{-5}\ \exp(0.187B)$$

$$c = -4.18 \times 10^{-5}B$$

$$d = -7.47 \times 10^{-5}B^2 + 2.33 \times 10^{-3}B - 4.38 \times 10^{-2}$$

(where $B$ is the magnetic field in teslas).

## 3. *Experimental Results*

Most systematic and comprehensive investigations of the magnetothermopower have been performed for simple monovalent and divalent metals as well as for noble metals. It was found that in many cases $\Delta S = S(B, T) - S(0, T)$ is large at low temperatures. In noble and divalent metals, a large contribution to $\Delta S$ is referred to as an increase of the phonon drag thermopower in a magnetic field. A summary of these studies is given in Blatt *et al*. (1976). A comprehensive investigation of $\Delta S$ in the high-field regime was made

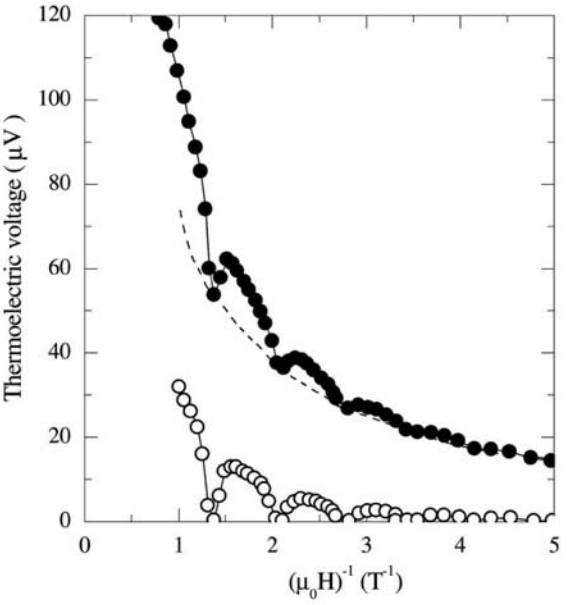

***Figure 3***

for silver (Stanley 1974). Some results for single silver crystals are presented in Fig. 2.

The quantum oscillations of the magnetothermopower and the Peltier coefficient were measured for bismuth, tin, antimony, aluminum, and zinc single crystals. The results of these studies are summarized by Blatt *et al*. (1976). The quantum oscillations of the thermoelectric voltage versus the inverse magnetic field at $T = 4.2$ K for bismuth are presented in Fig. 3.

Very little has been done with respect to the magnetothermopower of magnetic materials and intermetallic compounds. Some results on $\Delta S$ of heavy-fermion compounds can be found in Marcenat (1990): see Fig. 4. Results for magnetic and nearly magnetic compounds are shown in Fig. 5.

Applications of thermomagnetic effects for thermoelectric energy conversion form a separate and large field. Semimetals and heavily doped semiconductors have mainly been used in these applications. Theoretical basics and a review of important experimental results can be found in Hartman and Honig (1967).

## Magnetic Films: Anisotropy

Magnetic anisotropy is the coupling of the magnetization of a material to particular directions, either at a local or a macroscopic level. It means that the measured magnetic properties depend on the direction in which the magnetic field is applied, and that in zero applied field, the magnetization will lie along preferred direction(s). Without magnetic anisotropy, there can be no coercivity and no remanent magnetic moment and hence no permanent magnets or magnetic recording media. For these technologies, high anisotropy is generally advantageous, as it causes the moment to remain fixed in some desired direction.

For magneto-optic recording and proposed perpendicular recording media, perpendicular anisotropy is essential. For present-day longitudinal magnetic recording media, an anisotropy axis along the track direction allows greater thermal stability of magnetic bits, and hence smaller bit sizes. Minimizing anisotropy is equally important for technologies that require high susceptibility, such as transformers. Understanding what causes anisotropy and how to control it is thus crucial to the technological use of nearly all magnetic materials including films.

There are many sources of magnetic anisotropy in solids; for a description (see *Magnetism in Solids: General Introduction*; *Localized 4f and 5f Moments: Magnetism*; *Transition Metal Oxides: Magnetism*; and *Density Functional Theory: Magnetism*). All sources of anisotropy are fundamentally linked to the structure of the material, and therefore must have the symmetry of that structure. However, the symmetry as measured, for instance, by x rays is not necessarily the same as the local symmetry, and some substantial and technologically important anisotropy is found in films that superficially seem to be of a different symmetry. In this case, the material must have a subtle structural anisotropy that is detectable only by the most careful measurements, if at all. Much effort has been devoted to creating anisotropy in films by deliberating making materials whose structure has the desired symmetry, such as multilayers or hexagonal or tetragonal structures with *c*-axes either perpendicular to or along a particular in-plane direction. However, the growth process itself creates in many cases quite a large perpendicular or in-plane axis anisotropy even in amorphous and in structurally cubic materials.

While there can be a wide variety of symmetries, the most important for technologically interesting films are uniaxial and cubic. In all cases, we speak of an easy axis or axes along which the magnetization lies in zero field; it is also possible to have an easy plane of magnetization, which is equivalent to a hard magnetic axis for which the energy would be high if the magnetization were forced in that direction. Films of a wide variety of materials, as well as bulk hexagonal and tetragonal materials, can be approximated quite well with a uniaxial anisotropy. The anisotropy energy density $E_{an}$ in a uniaxial material is written as

$$E_{an} = K_u \sin^2\theta + K_2 \sin^4\theta + \ldots \qquad (1)$$

where $\theta$ is the angle between the magnetization and the easy axis and $K_u$ is the anisotropy constant for the material in ergs $cm^{-3}$ (J $m^{-3}$), and depends on temperature. Often the higher order terms ($K_2$) can be neglected. Figure 1 shows classical magnetic hysteresis curves $M(H)$ for uniaxial magnetic films, one with $K_u < 0$ and one with $K_u > 0$ (and substantial coercivity).

For a film with a perpendicular easy axis, $\theta$ would be measured with respect to the perpendicular and $K_u$ would be $> 0$. In zero applied field, for a uniaxial material, if there were no dipolar coupling, the sample would be completely magnetized with $M$ lying along the perpendicular, either up or down. The long-range nature of magnetic dipolar coupling causes a mixture of up and down domains to form in films with perpendicular anisotropy in the equilibrium state; this state is easily imaged in MFM (see *Magnetic Force Microscopy*) and has a classical stripe domain pattern. Like any other magnetic domain structure, hysteresis is important, so that remanent states with a single domain structure can be created following application of a saturating magnetic field (see Fig. 1(b)), essential to most technological uses (e.g., magnetic and magneto-optic recording). Equation (1) assumes isotropy relative to other directions, e.g., that for $\theta = 90°$, the energy is equal in all directions in plane; this is not always a good assumption.

The anisotropy energy density in a material with cubic symmetry requires two constants and more

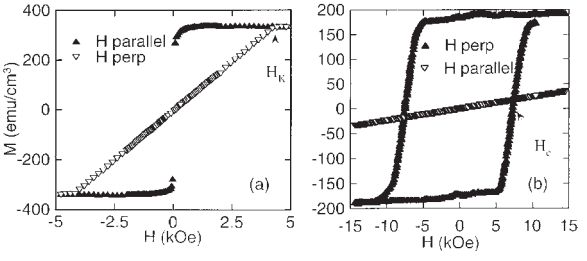

***Figure 1***
$M(H)$ curves for films with (a) a hard perpendicular axis, i.e., easy plane, owing to shape anisotropy; (b) easy perpendicular axis owing to growth-induced anisotropy. $M(H)$ is shown for$H$ applied parallel and perpendicular to the plane of the film. $H_K = 4\pi M_s = 2K_u/M_s$ is shown in (a); for (b), $H_K > 80$ kOe (8 T). In (b), the large coercive field $H_c$ is shown; for (a) $H_c = 25$ Oe. The film in (a) is f.c.c. (111) $CoPt_3$ grown at 800 °C; (b) is amorphous $TbFe_2$ film grown at 45 °C, both by e-beam co-evaporation. Data taken at room temperature.

angles to describe it:

$$E_{an} = K_1(\alpha_1^2\alpha_2^2 + \alpha_2^2\alpha_3^2 + \alpha_3^2\alpha_1^2) + K_2(\alpha_1^2\alpha_2^2\alpha_3^2) + \ldots. \qquad (2)$$

where $K_1$ and $K_2$ are constants for the material, dependent on temperature, and $\alpha_i$ are the cosines of the angles $M$ makes with the crystal axes. Often, $K_2 \approx 0$. In this case, if $K_1 > 0$ (as in bulk b.c.c. iron), the set of $\langle 100 \rangle$ directions are the easy axes, the set of $\langle 111 \rangle$ directions are the hard axes, and the $\langle 110 \rangle$ are intermediate. If $K_1 < 0$ (as in bulk f.c.c. nickel), the $\langle 111 \rangle$ are easy directions and the $\langle 100 \rangle$ hard. When $K_2 \neq 0$, the easy axes depend on the $K_1/K_2$ ratio.

## 1. Anisotropy in Films

Starting from the basic principles of anisotropy, it is possible to distinguish a number of different contributions in films, at least theoretically. In addition to the magnetocrystalline anisotropy expected from measurements on equivalent bulk materials, there are a number of contributions that are unique to films. The simplest to understand is shape anisotropy, which is due to the difference in demagnetization factor in the directions parallel and perpendicular to the film plane. This contribution causes a hard perpendicular axis (an easy plane). Other contributions result from the modified nature of the atomic arrangements in films. The broken/altered bonds at the top and bottom surfaces of a film or interface in a multilayer cause a change in the crystal fields and dipole energies of the atoms/ions at these surfaces and interfaces.

These interfaces will usually result in uniaxial anisotropy, which may have $K_u$ greater or less than 0 (easy perpendicular axis or easy plane). In addition, surfaces and interfaces may cause reconstructions and relaxations of the atomic arrangement such that the atomic structure at top and/or bottom may be quite different from a simple termination of the bulk structure, leading to additional anisotropy. Strain in a material due to intrinsic growth phenomena, epitaxy, or differential thermal contraction will generally give rise to a uniaxial anisotropy.

Experimentally, it is not always easy to separate these contributions. For films with uniaxial anisotropy (the most common), $K_u$ is usually written as a sum of the various contributions (discussed in more detail below):

$$K_u = -2\pi M_s^2 + K_{u\sigma} + K_{ui} + K_s/t \qquad (3)$$

where $-2\pi M_s^2$ is the shape contribution, $K_{u\sigma}$ is the stress-induced contribution, $K_{ui}$ the growth-induced or intrinsic magnetocrystalline term for uniaxial symmetry materials, and $K_s/t$ due to the surfaces, where $t$ is the film or layer thickness. If cubic terms are needed, or if the angles about which the uniaxial anisotropy occurs for each contribution (e.g., growth induced terms can be tilted away from the film normal due to incident atomic beam effects, while shape anisotropy is strictly relative to the film plane), care must be taken to add these contributions more carefully (see, e.g., Hellman *et al.* 1989).

In addition, many magnetic materials of interest are multi-component alloys, amorphous, or nanocrystalline composites. In such materials, local magnetic anisotropy may be large but is expected to be randomly oriented at different sites, possibly giving rise to coercivity but no net macroscopic anisotropy. However, for films made from these materials, strain or local chemical or structural ordering can lead to an alignment of the local anisotropy axes, causing large macroscopic anisotropy. The source of this seemingly extrinsic anisotropy may be quite fundamental: e.g., the growth process of a film, or the epitaxial strain of the magnetic layer on a substrate.

### 1.1 Shape Anisotropy

The source of shape anisotropy lies in the difference in demagnetization factors in the directions parallel and perpendicular to the film plane; this energy is fundamentally a summation of the magnetic dipole–dipole coupling of all the moments in the film. For a film whose thickness is much less than its other dimensions, shape anisotropy gives an easy plane, which is equivalent to a hard perpendicular axis: $K_u = -2\pi M_s^2$ ($-\mu_0 M_s^2/2$ in SI units) for films with thickness that is small compared to their other two dimensions. Uniaxial shape anisotropy (or other film-related uniaxial contributions) often dominate an intrinsic cubic magnetocrystalline anisotropy, as in Fig. 1(a) for f.c.c. $CoPt_3$. There is also a small contribution for antiferromagnets; here the dipolar interaction causes the moments to align side-by-side, which, summed up over the moments in a thin film, means $K_u > 0$. This $K_u$ is however small (compared to $2\pi M_{sa}^2$ where $M_{sa}$ refers to a sublattice magnetization) and is in essence a surface contribution, hence it varies inversely with film thickness.

Columnar microstructures are often found in films. It is important to note that unless the areal density of columns in a film is extremely low (less than 0.5 filling), the shape anisotropy of these columns alone will not produce a net perpendicular anisotropy (Yafet *et al.* 1986). However, effects such as oxidation and the broken/altered bonds at the surfaces of these columns, like the surfaces and interfaces of films discussed below, could lead to anisotropy via the other mechanisms described in this article.

### 1.2 Intrinsic Magnetocrystalline Anisotropy

If the lattice constant and structure of a material is the same for a film as for a bulk material, the intrinsic magnetocrystalline anisotropy is the same. By

manipulating the growth conditions, different types of anisotropy can be created, even for the same crystal structure. Examples of this are growth of h.c.p. cobalt with its *c* axis perpendicular, or using epitaxial relationships to cause the *c*-axis of tetragonal CoPt or FePt to grow along a particular in-plane direction (Coffey *et al*. 1995, Farrow *et al*. 1996). In each case, the easy magnetic axis will lie along the *c*-axis, but the net effect will be perpendicular or in-plane anisotropy. This contribution to anisotropy is independent of thickness as long as the crystal quality is maintained and strain is not a factor.

### *1.3 Strain-induced Anisotropy*

In general, films prepared by vapor deposition processes are not structurally identical to their bulk counterparts. It is of course possible to create structures not observed in bulk materials, e.g., f.c.c. cobalt, which then have the symmetry of this new material. But even if the structure is nominally the same as a known bulk material, vapor deposition produces strains and defects that influence the magnetic properties. There are many sources of strain in vapor-deposited materials, discussed more completely in *Stress Coupled Phenomena: Magnetostriction* and *Magnetoelasticity in Nanoscale Heterogenous Materials*. Differential thermal contraction and epitaxy with a substrate of a different lattice constant are sources of stress produced by the substrate (or by an overlayer, although these are usually thin and hence produce less strain in the film than the substrate). There are also a number of sources of stress intrinsic to the growth process, e.g., bombardment by energetic ions/atoms in sputtering tends to produce compressive strain; early stage coalescence phenomena tend to produce tensile strain. These types of strain tend to be uniaxial relative to the film plane and can be either compressive or tensile.

The link between strain and anisotropy is through magnetostriction. Magnetostriction is fundamentally linked to spin-orbit coupling and to crystal fields as discussed in *Magnetism in Solids: General Introduction* and *Electron Systems: Strong Correlations*. Strain could in fact be regarded to result in anisotropy by simply being magnetocrystalline anisotropy but for an e.g., tetragonal structure instead of the intrinsic cubic structure. However, it is not usually calculated in this way, in part because the strain and hence the tetragonal distortion is typically a few parts in $10^5$. Instead it is treated as a separate contribution to the anisotropy. A uniaxial strain in an isotropic (or nearly isotropic) material results in a uniaxial contribution to the anisotropy:

$$K_{u\sigma} = -3\lambda\sigma/2 \qquad (4)$$

where $\lambda$ is the magnetostrictive constant and $\sigma$ is the strain. The sign convention for strain is $\sigma > 0$ is tensile, and $\sigma < 0$ is compressive.

For materials with positive magnetostrictive constant $\lambda$, this means compressive strain causes a perpendicular easy axis. For cubic materials, or even hexagonal materials since the plane cannot be assumed to be isotropic, the anisotropy produced by various types of strain is more complex (see, e.g., Cullity 1972, p. 250 forward). Magnetostriction is typically measured by measuring the lattice distortion on applying a magnetic field, which eliminates domains. Since most films are on substrates, this is most easily done by measuring deflection (i.e., bending) of the substrate/film combination on magnetizing the film. In this case, a knowledge of the mechanical properties of substrate and film (specifically, Young's modulus and Poisson's ratio) is needed to make quantitative calculations.

An example of strain-induced anisotropy in a film of an otherwise cubic material is strained Laves phase $TbFe_2$, which may be useful for giant magnetostrictive devices (Wang *et al*. 1996).

### *1.4 Growth-induced Anisotropy*

This contribution fundamentally comes from the same sources as magnetocrystalline anisotropy but arises in structures where the underlying symmetry is apparently cubic or isotropic. It is a separate contribution from strain-induced anisotropy, and can be identified in films with extremely low strain, or where the sign of the strain can be changed with no significant change in anisotropy. It originates intrinsically from the growth process producing a subtle anisotropy in short-range order, which can be either structural or chemical or both. The structural or chemical anisotropy in turn produces a magnetic anisotropy, either via crystal field effects (often known as single-ion anisotropy) or via dipolar coupling (sometimes called pair anisotropy). The latter is generally significant only when the crystal field contribution is small, e.g., for $L = 0$ ions such as gadolinium.

The current magneto-optic recording media, quaternary alloys related to amorphous Tb–Fe, rely completely on this source of anisotropy to give a perpendicular easy axis, as in Fig. 1(b) (see, e.g., Hellman and Gyorgy 1992 and references given there). Seemingly cubic (f.c.c.) Co–Pt alloys grown by vapor co-deposition at deposition temperatures near 400 °C have anisotropies nearly 10% of that found in the best Co/Pt multilayers; this effect has been attributed to growth-induced cobalt clustering into platelets within a platinum-rich matrix, much like an incoherent local multilayer (see, e.g., Weller *et al*. 1992, Shapiro *et al*. 1999, and references therein). For both *a*-Tb–Fe and f.c.c. Co–Pt, EXAFS has shown signs of anisotropic local structure (e.g., Harris *et al*. 1992, Tyson *et al*. 1996). The characteristic feature of this source of anisotropy is that it is produced by the vapor deposition process and

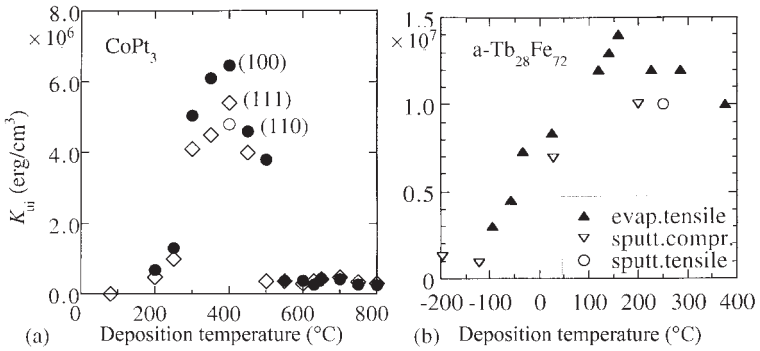

***Figure 2***
Dependence of growth-induced anisotropy $K_{ui}$ (shape contribution $-2\pi M_S^2$ removed) on growth temperature for (a) f.c.c. (as measured by x ray and TEM) $CoPt_3$ and (b) amorphous $TbFe_2$, prepared under various growth conditions (e.g., different epitaxial orientations, sputtered, e-beam co-evaporated, under tensile or compressive strain as grown). In (a), annealing at 450 °C eliminates $K_{ui}$ for all samples; in (b), annealing eliminates $K_{ui}$, but higher annealing temperatures are required for films grown at higher temperatures (see Hellman *et al.* 1999, Hellman and Gyorgy 1992, and Shapiro *et al.* 1999 for details). Data taken at room temperature.

vanishes upon annealing of the material, even at temperatures that produce no obvious structural change. It is largely deduced by experimentally ruling out other sources of anisotropy, e.g., strain, surface, and intrinsic magnetocrystalline anisotropies.

The growth process can break the symmetry of the structure by several quite distinct means. First, there can be a chemical or structural memory of the incident atomic beam directions. This effect is dominant at low growth temperatures, where growth phenomena such as kinetic roughening are important. Columnar microstructure tilted at an angle intermediate to the incident beam direction and the film normal are an obvious structural manifestation of this effect; such shadowing-related effects are much studied in growth simulations. Even in materials where this obvious structure is not seen, the magnetic anisotropy can still reflect the effect of the incident beam angle (e.g., Hellman *et al.* 1987). This effect of the incident beams on anisotropy (and in turn on coercivity) is quite pervasive, and is seen in nearly all alloys, particularly those grown at room temperature and below. In some cases, it may be used to advantage, by giving a preferred in-plane axis, but it can also be detrimental to desired low coercivity materials.

At higher growth temperature, adatom surface mobility typically erases this memory of the incident beam direction(s). However, an even stronger source of growth-induced anisotropy occurs in this growth regime. Here, at intermediate growth temperatures, surface adatom mobility is extremely high compared to bulk mobility (typical root mean square diffusion lengths are tens to hundreds of nanometers during the lifetime of the adatom before it is buried by the next layer of adatoms at typical growth rates, while typical r.m.s. diffusion lengths for an atom once buried in the bulk of the film for the duration of a typical deposition are less than an atomic spacing). As a result, in this intermediate growth regime, an as-deposited film is really a sequence of surface layers, trapped in. At still higher temperatures, typically above approximately one-third of the materials' melting temperature $T_m$, bulk atomic diffusion becomes important and the equilibrium structures are found. The result (shown in Fig. 2) is that for both amorphous Tb–Fe and crystalline f.c.c. Co–Pt films, anisotropy increases with increasing growth temperature up to the onset of appreciable bulk atomic mobility (Hellman *et al.* 1999).

Defects also affect the anisotropy, although if they are point defects randomly distributed, their effect will not add up to a net macroscopic anisotropy. However, the local anisotropy associated with stacking faults, dislocation layers, and internal interfaces in a columnar growth structure can, at least in theory, produce macroscopic anisotropy.

### *1.5 Surfaces of Ultrathin Films*

The broken bonds of the surface of the film (and the bottom of the film, next to the substrate) lead to a uniaxial anisotropy which can be of either sign, as originally described by Néel in 1954. This topic is discussed in *Monolayer Films: Magnetism*, and will be touched on only briefly here. This contribution arises fundamentally from the same sources as cause bulk magnetocrystalline anisotropy. A good example is that f.c.c. cobalt films a few monolayers thick have a perpendicular easy axis, which drops into the plane as

the film thickness increases. This anisotropy is extremely dependent on the details of the surface structure, and hence is affected by impurity adsorption, surface reconstruction, relaxation, segregation, and other properties well known to surface scientists. To the extent that the film structure can be assumed to remain constant, independent of thickness, this contribution to the total anisotropy will fall off as inverse thickness, i.e., $K_u = K_s/t$ where $K_s$ is a surface anisotropy in ergs $cm^{-2}$ (J $m^{-2}$) and $t$ is the film thickness.

### *1.6 Interfaces in Multilayers and Nanocrystalline Films*

This contribution is fundamentally the same as the preceding one for surfaces, except that instead of broken bonds at a vacuum interface, there are bonds to a neighboring layer. The anisotropy in multilayers is generally uniaxial, often quite sizable, and can be of technological significance (e.g., optimized Co/Pt multilayers of particular thickness for each layer have $K_u > 2 \times 10^8$ ergs $cm^{-3}$ ($2 \times 10^7$ J $m^{-3}$), making them possible future perpendicular recording or magneto-optic recording media; see, e.g., Weller *et al.* 1993). Figure 3 shows the dependence of anisotropy on cobalt layer thickness for different orientations. In general, there are contributions both from the strain induced by the lattice mismatch of the two (or more) materials, and from an intrinsic interface contribution, as well as the intrinsic magnetocrystalline anisotropy, which may also be uniaxial. In principle, these can be separated by measuring the dependence of the anisotropy on layer thickness, as in Fig. 3, since the interface contribution to the total anisotropy should drop off as inverse thickness, while the others may remain constant. However, there are dangers in the interpretation of this data since both strain and interface structure may depend on thickness (see *Monolayer Films: Magnetism*).

In nanocrystalline films, internal interfaces between magnetic and nonmagnetic (or other magnetic) materials can also lead to local anisotropy, although it will tend to be randomly oriented and therefore not lead to a net macroscopic anisotropy. However, any alignment of the nanocrystal axes by growth effects would lead to net anisotropy.

### *1.7 Unidirectional Anisotropy*

In principle, the lowest order symmetry possible for anisotropy is uniaxial, which has 180° symmetry. It was however realized many years ago that by taking advantage of exchange coupling between the magnetic material of interest and an antiferromagnet with substantial anisotropy, such as in a bilayer or multilayer, a unidirectional anisotropy could be created (see, e.g., review by Nogues and Schuller 1999). This effect is technologically important for biasing of magnetoresistive read heads or other sensors. The fundamental source of this symmetry breaking is the alignment of the antiferromagnet's Néel vector, most commonly by cooling through the Néel temperature of the antiferromagnet while applying a field sufficient to align the ferromagnet. Exchange coupling then forces the Néel vector and hence one sublattice to lie along a direction set by the cooling field. Subsequent application of a field in another direction is insufficient to reverse the antiferromagnet, owing to its high magnetocrystalline anisotropy and low net moment.

The ferromagnet is exchange coupled to the antiferromagnet and hence does not reverse in low fields. The detailed nature of this exchange biasing becomes

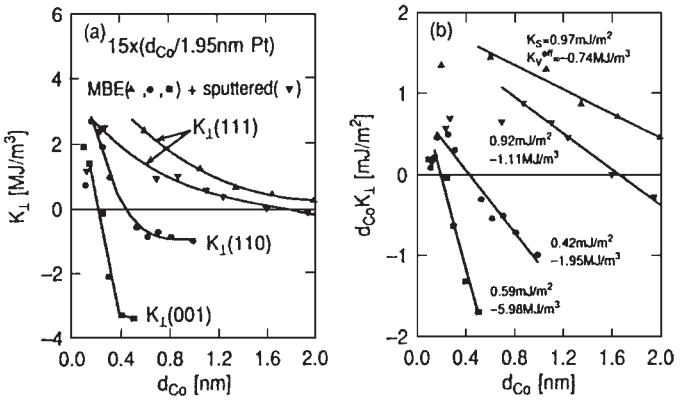

***Figure 3***
(a) $K_\perp$ (i.e., $K_u$ with shape contribution $-2\pi M_s^2$ removed) and (b) $d_{Co} \times K_\perp$ for epitaxial and sputtered Co/Pt multilayers versus cobalt layer thickness $d_{Co}$. Data taken at room temperature (reproduced by permission of the Materials Research Society from *MRS Symp. Proc.*, 1993, **313**, 791–7).

quite complex, owing to the possibilities of canting, antiferromagnetic domains, compensated and uncompensated planes, and surface roughness in the antiferromagnet; the result is that the underlying source is not well understood. It is clear that it is not necessary for a single sublattice defined over the macroscopic dimensions of the antiferromagnet to be aligned, but instead there can be alignment within domains of the locally defined sublattice physically most near the ferromagnet. It is also possible to use ferrimagnets instead of antiferromagnets, or even ferromagnets if their anisotropy is high enough to prevent switching in the low fields used to switch the primary ferromagnetic material (e.g., Hellman *et al*. 1987).

## 2. Measurements of Anisotropy

The first and often most important step is simply to determine the anisotropy symmetry, i.e., cubic or uniaxial, perpendicular easy or hard axis. This may be done in a variety of ways, including $M(H)$ curves, torque magnetometry, Kerr or Faraday rotation observations, magnetic force microscopy, even magnetoresistance with $H$ applied along different directions. The simplest way to measure anisotropy energy is by torque magnetometry. The first step is to technically saturate the magnetization of the film by applying a field $\mathbf{H}$ along an easy axis which is strong enough to eliminate magnetic domains ($H > H_c$, where $H_c$ is the coercive field). Figure 4 shows the geometry for a film with uniaxial anisotropy. Then the direction $\alpha$ of the magnetic field is rotated; for high anisotropy materials, Miyajima's $\alpha = 45^\circ$ method is often used (if $H_c < H < H_K$, we are not in the high field limit often assumed, e.g., by Cullity 1972, p. 215).

The minimum energy would be if the moment $\mathbf{M}$ could follow the direction of the field, by physically rotating the sample so that its easy axis direction remained along the direction of the rotating field. If the sample is physically constrained from doing this, then it will exert a torque $\mathbf{T}$ on the constraint. The energy of this arrangement can be written as

$$E = -\mathbf{M} \bullet \mathbf{H} + E_{an} = -MH\cos(\alpha - \theta) + K_u \sin^2\theta \qquad (5)$$

for a simple uniaxial anisotropy, where $\theta$ and $\alpha$ are the angles $\mathbf{M}$ and $\mathbf{H}$ make with respect to the easy axis, $\alpha$ is fixed, but $\theta$ will adjust to minimize the energy, so

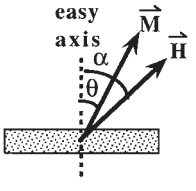

***Figure 4***
Geometry of torque measurement for uniaxial anisotropy film.

$\delta E/\delta\theta = 0$. The torque exerted by the sample on the constraint $\mathbf{T} = \mathbf{M} \times \mathbf{H} = MH\sin(\alpha - \theta)$ is measured using one of several techniques. This then effectively gives $\theta$, and hence $E_{an}$ (see, e.g., Hellman *et al*. 1989 for more details).

It is sometimes possible to make a direct measurement of $\theta$ by measuring the component of $M$ perpendicular to the applied field, using for example quadrature pick-up coils. This is more difficult than measuring torque, because the perpendicular component and $\theta$ become quite small for large $H$, while the torque $\mathbf{M} \times \mathbf{H}$ remains large. There are also specialized techniques used, e.g., *in situ* in a vacuum deposition system where a Kerr measurement can be used to infer the perpendicular component of $\mathbf{M}$ and hence the anisotropy.

Magnetic resonance is another powerful technique for determining anisotropy. The constant applied field is applied usually along an easy axis. For a uniaxial sample, the resonance condition is then given by the sum of the applied field and the anisotropy field $H_K = 2K_u/M_s$. For cubic systems, $K_1$ and $K_2$ can be determined by measuring with $H$ applied along various axes.

In limited cases, magnetic hysteresis curves can also be used. Here, the applied field is usually applied along a hard axis, causing magnetization to rotate. In the limit that there is no domain motion, only rotation, for example in a uniaxial material, the magnetization saturates at $M_s$ for a well defined field $H_K = 2K_u/M_s$ (see, e.g., Fig. 1). Alternatively, the difference in areas between the hard and easy axis curves is proportional to the anisotropy energy.

## 3. Summary and Future Directions

Anisotropy in films is a sum of contributions from the intrinsic magnetocrystalline anisotropy expected from the bulk equivalent material and a number of effects linked to the fact that the structure of a film is for many reasons not equivalent to the bulk. There are many sources of these differences, connected both to the fact that a film is grown on a substrate and has a top and bottom surface whose properties, both structural and magnetic, are not simply related to the properties of the bulk material, and to intrinsic effects of the growth processes used to prepare films which cause a memory of the growth direction to be trapped into the structure. At present, there is almost no way to predict the anisotropy of a film of a new material; there are many contributions and it is difficult to know in advance which effects will dominate.

Experimental efforts to find improved materials often center on taking advantage of the bulk magnetocrystalline anisotropy, or on deliberately prepared multilayers, but in fact growth-induced effects and other less predictable contributions often dominate, certainly for materials presently used for practical applications.

# Magnetic Films: Hard

The scope of this article is to provide a general introduction to hard magnetic films. It discusses application-relevant extrinsic magnetic properties and focuses on a specific hard magnetic material ($Nd_2Fe_{14}B$) to demonstrate the interplay between the film-related microstructure and the magnetic performance. The article by (Kruusing 1999) is a good addendum, as he reviews $Nd_2Fe_{14}B$ thin films and describes preparation-specific topics.

## 1. Applications

One area for application of hard magnetic films are microsystem techniques, especially microelectromechanical systems (MEMS). These devices are prepared from relatively thick films (1–5 μm) and the high-energy product of the rare earth magnets promises smaller lateral device sizes. Until now, however, only a few systems have been realized, for example a sub-millimeter electric motor (Yamashita *et al.* 1991), and a stepper motor (Belmans and Hameyer 1998). The challenge facing rare earth magnets in this field is their high corrosion rate when exposing a large surface after structuring. Another potential application is in monolithic microwave integrated circuits (MMICs) (Levy *et al.* 1996) using thin hard magnetic layers to create bias fields for ferrite devices. Although an optical isolator could be realized this way, this technology has to compete with the conventional technology, which is not based on ferrites.

The largest market for hard magnetic films is in magnetic data storage on computer hard disks. While the bit density increases by about 60% each year, the conventional materials (e.g., CoPtCr, CoCrTa) are expected to reach the superparamagnetic limit by around 2005, where the small magnetic dots used to store the information tend to become thermally unstable. In order to exceed densities of 100Gbit $in^{-2}$, materials with a higher uniaxial magnetic anisotropy are of interest (see *Magnetic Anisotropy*). The high perpendicular magnetic anisotropy of $Nd_2Fe_{14}B$ thin films presents the additional possibility of packing bits closer together using perpendicular recording, where the spins representing the bits are oriented perpendicular to the substrate. Compared to other applications, the required film thickness is small (20–50 nm).

## 2. Structure Formation

The $Nd_2Fe_{14}B$ phase providing the desired intrinsic magnetic properties has a tetragonal unit cell ($a = 8.805$ Å, $c = 12{,}203$ Å) comprising 68 atoms (see *Rare Earth Magnets: Materials*). At room temperature

the magnetic easy axis is along the *c*-axis. When depositing films on heated substrates below temperatures of 500–675 °C, x-ray diffraction patterns reveal only amorphous spectra and the films are soft magnetic. However, using transmission electron microscopy, Mapps *et al.* (1997) observed small inclusions of the $Nd_2Fe_{14}B$ phase with grain sizes below 10 nm (which are invisible to x-ray diffraction) already on films deposited at room temperature. At higher temperatures a significant amount of the hard magnetic $Nd_2Fe_{14}B$ phase forms, but even at temperatures above 650 °C part of the material can remain in the amorphous state (Shima *et al.* 1998).

## 3. Coercivity Mechanism

Magnetization reversal can be inhibited by two different mechanisms (see *Coercivity Mechanisms*). In the nucleation type magnets, domain wall motion inside almost perfect grains is easy, but the nucleation field necessary to create new Bloch walls is high, as no extended defects lower the Bloch wall energy. When magnetizing this type of material in a field below the saturation field, the remaining domain walls cause a lower remanence than when magnetizing by a field strong enough to remove all domain walls. This coercivity mechanism is usually valid when relatively large and perfect grains exist and can be used to describe annealed $Nd_2Fe_{14}B$ films on Ta/Si(111) (Tsai *et al.* 1998) (a system showing no intermixing) and films grown on heated W/Si(111) (Tsai *et al.* 1999a) where only few neodymium-rich precipitates are observed.

In pinning type magnets, the nucleation of reversed domains is not inhibited, but a lot of defects exist—preferably with a size comparable to the Bloch wall thickness—where the domain walls are pinned. Magnetization reversal occurs when the force exerted on the domain wall (pinned at the inhomogeneities) becomes sufficiently strong. In $Nd_2Fe_{14}B$ films deposited on heated Pt/Si(111) (Tsai *et al.* 1999a) and in annealed samples on silicon (Tsai *et al.* 1998) pinning seems to control the coercivity.

## 4. Grain and Domain Size

A very effective way to increase coercivity is to reduce the grain size below the single domain particle size. This is often found in NdFeB films where the domain size is even larger than the lateral grain size (Gouteff *et al.* 1998, Lemke *et al.* 1997). Here exchange coupling between neighboring grains leads to the occurrence of interaction domains. Generally the domain walls follow the grain boundaries, demonstrating their pinning effect. Therefore the coercivity typically increases with decreasing grain size and with decoupling of neighboring grains.

The key parameters for controlling grain growth are the annealing temperature and the annealing time. When the films are deposited at room temperature and annealed afterwards, both parameters can be controlled but the annealed samples are isotropic, eliminating the possibility of preparing textured films (having perpendicular anisotropy with respect to the surface). The crystallization develops via intermediate stages depending on the composition (Linetsky *et al.* 1992). With rapid thermal annealing of 60 s at 500 °C it is possible to obtain grain sizes of 50 nm and a coercive field $H_c$ up to 20 kOe—a two-fold improvement compared to annealing times in the ten minute range (Yu *et al.* 1998).

To achieve a *c*-axis texture (see below), however, structure formation is necessary already during deposition, which requires a substrate temperature above 500 °C. Parhofer (1997) observed an increase in the perpendicular grain size with increasing substrate temperature but as a variation in temperature also influences the phase formation, texture, etc., no systematic examination of the perpendicular and lateral grain size and their influence on the magnetic properties yet exists.

The deposition method also seems to influence the grain size. While sputtered films usually have grain sizes of about 100 nm (Gouteff *et al.* 1998, Tsai *et al.* 1998, 1999c), films prepared by pulsed laser deposition (PLD) have smaller grain sizes (down to 12–20 nm) (e.g., Lemke *et al.* 1997). This is a known effect originating from the significantly higher kinetic energy of the deposited particles during PLD compared to other deposition methods (Fähler and Krebs 1996). The ions are implanted into the topmost monolayers (''subsurface growth'') (Fähler *et al.* 2000) reducing their mobility and the grain size of laser deposited metallic films is usually smaller. On the other hand, this implantation can cause defects which reduce the magnetic order and this may be the reason why the magnetic properties of the PLD films are not improved as expected.

A sharp grain size distribution leads to a simultaneous switching of the grains and a more square magnetization curve. For magnetic recording, a broad grain size distribution can result in the undesirable failure of some bits. A smooth, round grain surface is also favored as at asperities the enhanced stray field favors the nucleation of reversed domains.

## 5. Influence of Composition

The $Nd_2Fe_{14}B$ phase shows only a small existence region so that variations in the concentration result in an inhomogeneous microstructure with additional phases which can be used to improve the magnetic properties. Similar results can be achieved with additives in most magnetic systems, but when additives are solved partly in the main magnetic phase it is difficult to distinguish between changes in the intrinsic and extrinsic properties.

Adding a paramagnetic component such as neodymium in NdFeB forms a neodymium-rich intergranular paramagnetic phase decoupling the ferromagnetic $Nd_2Fe_{14}B$ grains. The decoupling prevents domain nucleation induced by neighboring grains and increases the coercivity. With increasing neodymium content the *c*-axis texture is lost but the grain size is reduced and the energy product can be optimized with neodymium concentrations slightly higher than the stoichiometric composition (Piramanayagam *et al*. 1998).

It has been observed that increasing boron content up to 17 at.% leads to an increase in the *c*-axis texture and increases the perpendicular coercivity significantly (Araki *et al*. 1999). Due to the excess boron a soft magnetic amorphous phase is formed between the columnar $Nd_2Fe_{14}B$ grains. This fine microstructure should be exchange coupled and the authors suggest that the observed sharp interfaces prevent domain nucleation. Boron contents above 17 at.% reduce the coercivity as the amount of the soft magnetic amorphous phase increases.

Of different intention is the addition of a second phase with a higher saturation magnetization $M_s$ by increasing the iron content above the stoichiometric value. Such a composite material can possess a higher saturation magnetization and also a higher remanent magnetization, provided the soft iron phase is coupled to the hard magnetic $Nd_2Fe_{14}B$ phase. Accordingly, in NdFeB films an increase in $M_s$ with the iron content has been observed (Piramanayagam *et al*. 1998). Additionally, the iron content can improve the *c*-axis texture. Both factors should contribute to the observed increase in remanence.

However, as large soft iron grains can act as a nucleus during the magnetic reversal and significantly reduce the coercivity, it is important for a composite film to limit the iron grain size so that the complete iron grains are coupled to the hard $Nd_2Fe_{14}B$ grains (grain size less than $\sim$10 nm—twice the Bloch wall width). Films sputtered at 650 °C show iron grain sizes of $\sim$10 nm, and up to 17 vol. % Fe the coercivity decreases only slowly (Tsai *et al*. 1999b).

## 6. Multilayers

The well-defined preparation of alternating soft and hard magnetic layers should enable the testing of the micromagnetic models of exchange coupling (see Magnets: Remanence-enhanced). Parhofer *et al*. (1996) showed that iron layers below 30 nm are fully coupled to the $Nd_2Fe_{14}B$ layers and the reduced remanence $R = J_R/J_S$ increases significantly when the iron thickness is reduced to this value. He confirmed that the saturation magnetization can be calculated from the volume-weighted sum of both magnetizations, indicating that at the interface no significant structural deterioration occurs.

In nanocomposite magnets, for optimum $BH_{max}$ the following considerations hold: To make use of the high $M_S$ of the soft magnetic phase, its fraction should be increased. On the other hand the nucleation field for magnetization reversal (and consequently $H_C$) is lowered as the thickness of the soft magnetic phase becomes larger. So in order to keep a high fraction of the soft phase, also the thickness of the hard phase must be reduced. But this reduction is limited as the coercivity of the hard magnetic phase is lost if its thickness reaches the same order of magnitude as the domain wall width. Shindo *et al*. (1997) confirmed this trend in experiment and found a good agreement with a micromagnetic calculation when using an interlayer exchange-coupling strength of about 10% of the intralayer couplings. They also confirmed the exchange-spring effect by measuring reversible minor magnetization curves.

In spite of these advantages, such multilayers tend to lose the *c*-axis texture (Parhofer 1997), their crystallinity can be reduced, they show a significant increase in roughness, and intermixing in the range of 10 nm can occur (Shindo *et al*. 1997).

Multilayers of $Nd_2Fe_{14}B$ and a nonmagnetic material should also allow decoupling of the magnetic layers. While experiments with silver failed due to the reaction to form NdAg (Aylesworth *et al*. 1989), multilayers with tunsgten (Panagiotopoulos *et al*. 1997) only break their layered structure during annealing. With an appropriate $Nd_2Fe_{14}B$ thickness of about 5 nm, the resulting microstructure consists of separated isotropic $Nd_2Fe_{14}B$ grains (grain size $\sim$10 nm) in a tungsten matrix and $H_C$ is improved up to 20 kOe.

## 7. Texture

The aim of having a textured film is to use the microscopic anisotropy for an application with a macroscopic anisotropy and to increase $M_R/M_S$ above the limit of 0.5 for a randomly-oriented film. While films deposited at room temperature and subsequently annealed are isotropic, films on heated substrates can be grown with a *c*-axis texture, so that the hard magnetic axis is oriented perpendicular to the substrate. (In contrast to CoSm, the substrate temperature is usually above $T_C$, therefore no stray field forces the *c*-axis to lie within the film surface.) As an explanation for the *c*-axis texture, Cadieu (1987) suggested that a high ion flux onto the substrate (usually obtained at low deposition rates during sputtering) should prevent the formation of long ordered repeat distances parallel to the substrate plane, and materials having a longer *c*-axis (as $Nd_2Fe_{14}B$) should, therefore, favor a *c*-axis texture. In agreement with this, he observed a decrease in the *c*-axis texture with increasing deposition rate.

Another reason for this texture can be the anisotropic growth velocity known from bulk material, which forms longer *c*-surfaces than *a* and *b*. Starting with an isotropic texture, the *c*-axis oriented grains grow faster and cover more and more of the substrate resulting in *c*-axis texture. In agreement with this, films with a rough surface and grown at higher temperatures above 650–700 °C (leading to a stronger reaction with the substrate) lose the *c*-axis texture. Also the film composition can influence the texture: a high iron content (Piramanayagam *et al*. 1998) or boron content (Araki *et al*. 1999) improves the *c*-axis texture.

A buffer also provides the possibility to modify film texture. While films on tantalum and titanium generally obtain a (001) *c*-axis texture, a tungsten or molybdenum buffer can change the texture towards (105), whereas on platinum no texture was observed. With a chromium buffer different textures were observed. Also the grain size and roughness is influenced by different buffers (Piramanayagam *et al*. 1998, Shima *et al*. 1998, Shindo *et al*. 1997, Tsai *et al*. 1998, Tsai *et al*. 1999c, Parhofer *et al*. 1998).

In spite of the reactivity with a silicon substrate, it seems to be possible to deposit epitaxial $Nd_2Fe_{14}B$ films on Si(111) with the *c*-axis lying in plane (Kruusing 1999), while approaches to prepare epitaxial films on Mo(001) with the *c*-axis perpendicular to the substrate have not been successful: here a different, unidentified, phase grows epitaxially at the beginning (Keavney *et al*. 1997).

Since in all the experiments the texture could not be controlled without changing other parameters such as the grain size or composition, it is difficult to deduce the effect of texture on the magnetic properties. However, it occurs, as a general tendency, that the films with the best magnetic properties do not possess the best *c*-axis texture (Parhofer 1998). With a strong *c*-axis texture the angle between the spins in neighboring grains is small and the grain boundaries seem not to provide effective pinning. This effect is described by the coercivity model of Kronmüller (see *Coercivity Mechanisms*) where the microstructural parameter for pinning efficiency increases with stronger grain misalignment. Here it would be useful to separate the grains magnetically while retaining the *c*-axis texture.

## 8. Roughness

Films grown at higher temperatures show an increased film roughness. In general, films with a rough surface exhibit a higher $H_C$ than smooth films. This is attributed to pinning of the magnetic domains at the asperities. But since applications such as microstructuring or hard disks need a smooth surface (danger of head crashes or a too large read/write distance), an increased roughness is not suitable.

## 9. Stability and Thickness

Oxide and silicon substrates react strongly with NdFeB and destroy the magnetic properties—a general problem with rare earth components. Also some metals show interdiffusion: silver (Aylesworth *et al*. 1989); molybdenum (Tsai *et al*. 1999c), tungsten (Tsai *et al*. 1999c, Panagiotopoulos *et al*. 1997). In order to keep the intrinsic properties, inert substrates or buffers such as chromium (Parhofer *et al*. 1998), platinum (Tsai *et al*. 1999c) or tantalum (Piramanayagam *et al*. 1998, Aylesworth *et al*. 1989) can be used.

Though Parhofer *et al*. (1998) showed that a chromium protection layer of 20 nm can limit the decay of $H_C$ below about 10% per year, this is not sufficient for a device lifetime of 10 years and also for use in a hard disk the protection layer thickness must be significantly reduced. Therefore long-term stability will remain a challenge for this material.

With decreasing thickness also the grain size can decrease and a two-fold increase in $H_C$ has been observed when reducing the thickness from some 100 nm to 25 nm (Parhofer *et al*. 1998), a thickness appropriate for a storage material. It should be noted that for NdFeB films deposited directly on quartz (without a chromium buffer) $H_C$ vanishes below 100 nm, interdiffusion seems to destroy the intrinsic properties. Otherwise films on tantalum show an increase of $H_C$ up to a thickness of 500 nm (Piramanayagam *et al*. 1997).

## 10. Conclusions and Perspectives

$Nd_2Fe_{14}B$ thin films show a good example of the application of hard magnetic concepts in thin films and of the possibilities of thin film methods to influence the microstructure. As in bulk material, controlling the microstructure is the key to optimizing the magnetic properties. For thin films an appropriate buffer can control the microstructure in addition to interdiffusion or texture. As a growing film tends to replicate the grain size of the existing film, for example the selection of a binary system (NiAl) instead of chromium could cut the grain size of the buffer and of the conventional magnetic film in half (Feng *et al*. 1994). Another approach is to use the chemical segregation observed for instance in the Cr–Co system. In this system chromium segregates into the grain boundaries which reduce the exchange-coupling between the cobalt-rich grains (Wittig *et al*. 1998). Using similar systems as buffer and replicating this microstructure should allow modification of the microstructure while conserving the intrinsic properties of $Nd_2Fe_{14}B$. These two examples show the potential of binary buffers and their application.

Structuring the films to prepare separate magnetic dots is a potential path for producing magnetic

recording media. The achieved structural size of $0.5 \times 0.5\,\mu m$ (Kubota *et al*. 2000) opens the perspective that the noise caused by a statistical grain ensemble is reduced by a structured media.

## Magnetic Force Microscopy

Magnetic force microscopy (MFM) (Martin and Wickramasinghe 1987, Grütter *et al*. 1992) is a slow-scan, raster-type imaging technique that maps a signal issued from the interaction of a tiny magnetic probe, or tip, with the magnetization distribution within the observed sample. The technique has been demonstrated to yield a resolution below some 20 nm in favorable cases with minimal or even no sample preparation. A magnetic force microscope may be

operated under ambient conditions or ultrahigh vacuum, allowing the study of clean magnetic surfaces and the link between growth and magnetic properties. Static magnetic fields may be applied to the sample during image acquisition, a necessary condition for correlating magnetic microstructures and hysteresis cycles. Because MFM relies on the interaction of two magnetic bodies, the probe and the sample, MFM is an indirect imaging method. It is potentially perturbative and, thus, may not be termed noninvasive.

## 1. Operation Principle

A magnetic force microscope (Fig. 1) may be described as composed of a force transducer, a microfabricated cantilever coated with a magnetic thin layer (Grütter *et al*. 1990), an $x,y,z$ set of translation actuators, and a signal processing and feedback unit. Various types of forces may act on the tip located at the extremity of the cantilever, among them van der Waals forces when the tip and sample surfaces are brought into close contact, capillary forces owing to an adsorbed water layer when the microscope is operated under ambient conditions, electrostatic forces, and magnetostatic forces if both the probing tip and sample are magnetic. Magnetostatic forces are those forces that govern the interactions of, for example, two bar magnets or allow a hard magnetic material body to attract soft magnetic elements. A magnetic force microscope should be operated under such conditions that long-range dipolar-type forces become prominent (Schönenberger *et al*. 1990).

In the static mode or force detection scheme, the restoring force constant of the cantilever opposes the magnetically induced cantilever deflection, thus establishing equilibrium. Although different methods have been developed to monitor the cantilever deflection, optical means now dominate. Interferometric techniques have been used to measure precisely the distance between the cantilever end and a fixed point in space (e.g., Rugar *et al*. 1988). In Fig. 1 a laser beam is reflected from the upper surface of the cantilever into a quadrant detector. Signal combinations $(A+B)-(C+D)$ and $(A+D)-(B+C)$ are proportional to the deflection and torsion of the cantilever, respectively (Meyer and Amer 1990).

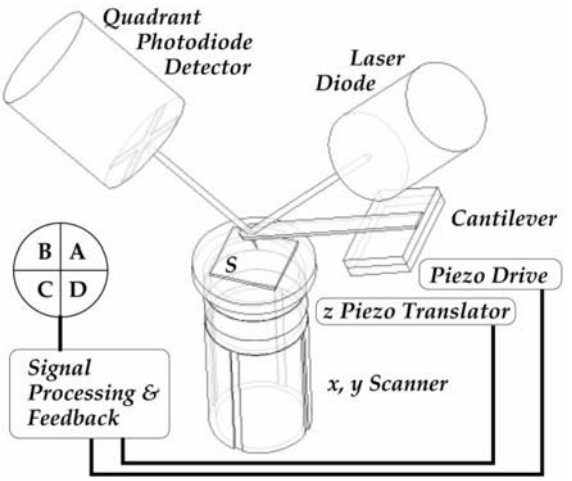

***Figure 1***
Schematic representation of a force microscope (not to scale). S is the sample.

In a second operating mode, the dynamic or a.c. mode (Martin and Wickramasinghe 1987, Hobbs *et al*. 1989), a piezoactuator induces forced oscillations of the cantilever. In the limit of small amplitude oscillations along the $z$ direction and an assumed harmonic oscillator behavior, the resonance frequency of the cantilever varies with the force gradient as

$$\omega = \omega_0 \sqrt{1 - \frac{1}{k}\frac{\partial F}{\partial z}} \tag{1}$$

where $\omega_0$ is the free oscillation cantilever resonance frequency and $k$ is the cantilever restoring force constant. It has been recognized (Albrecht *et al*. 1991) that frequency detection is preferable to amplitude detection because of the long characteristic response time of the latter to a pulse-like change in the force gradient.

An MFM image is therefore a mapping of the position-dependent force or force gradient exerted by the sample on a magnetic tip moving at a given distance from the sample surface. If the distance is too short, van der Waals-type forces may dominate, whereas spatial resolution is bound to decrease with increasing distance. In practice, working (often referred to as "lift") distances between a few nanometers and a few tens of nanometers are used. Since the strength of the force and/or force gradient rapidly decays with distance from the surface, surface relief needs to be compensated for (Schönenberger *et al*. 1990). This may be achieved through three point landmark interpolation for smooth surfaces (Hug *et al*. 1993) or a more advanced protocol including topography monitoring followed by force or force gradient detection at a preset lift height $z_{\text{lift}}$ (Fig. 2) (Babcock *et al*. 1995). Whereas forces as low as 1 pN ($10^{-12}$ N) may be detected with a good signal-to-noise ratio (SNR) in state-of-the-art static experiments (Hug *et al*. 1998), the minimal detectable force gradient against thermal noise (Albrecht *et al*. 1991) is given by

$$\left|\frac{\delta F_{\min}}{\delta z}\right| = 2k\frac{\delta\omega}{\omega_0} = \frac{2}{A}\sqrt{\frac{kk_{\text{B}}T\Delta\nu}{Q\omega_0}} \tag{2}$$

where $A$, $k_{\text{B}}$, $T$, $\Delta\nu$, and $Q$ are the cantilever oscillation amplitude, Boltzmann constant, temperature, detector bandwidth, and cantilever resonance quality factor, respectively. Under ambient conditions

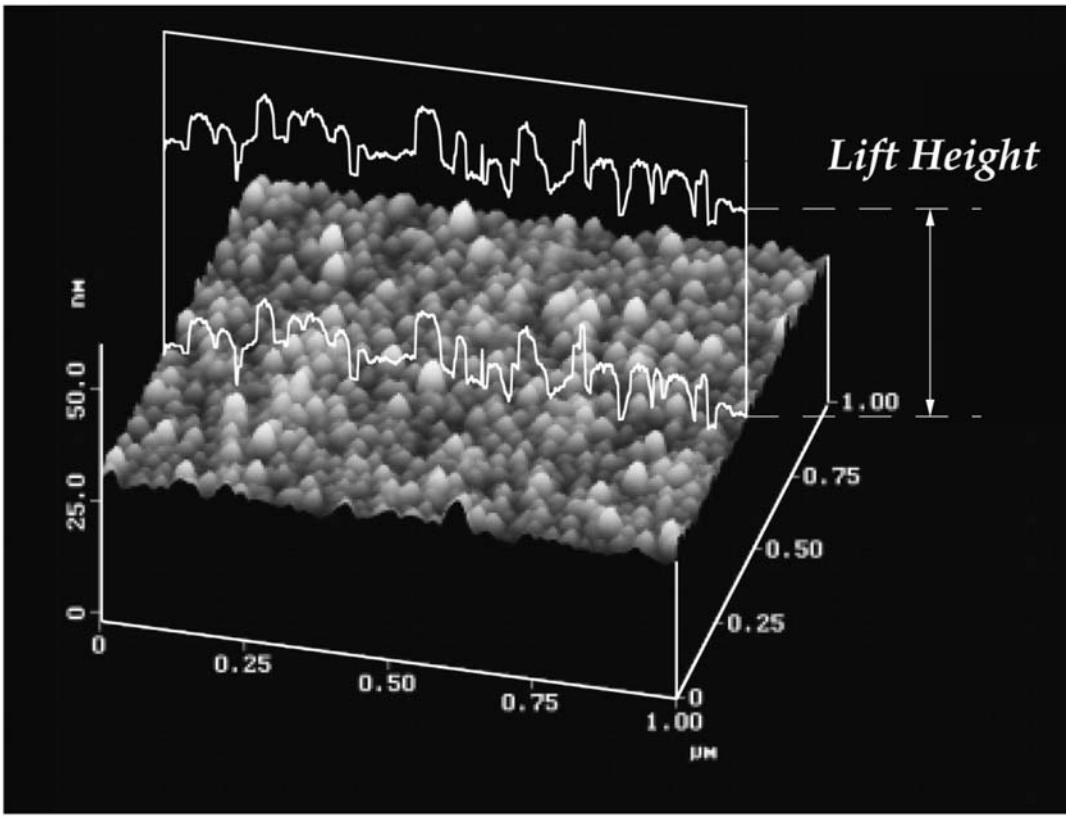

*Figure 2*
MFM operating mode: the influence of the sample topography (here, grains in a NiFe thin film deposited on a sputter deposited NiO underlayer (courtesy of P. Gogol)) is minimized by measuring the frequency shift due to the interaction between the magnetized probe and the sample at a fixed "lift" height above the sample along each line scan. Usual "lift" heights are in the range 20–50 nm.

($Q \sim 100$–150), force gradients as low as $10^{-5}$ N m$^{-1}$ are routinely measured.

## 2. Image Formation

Central to the understanding of MFM is the magnetostatic equivalent to Coulomb's law expressing the force between two magnetic "monopoles" (Fig. 3):

$$\vec{F} = -\vec{F} = \left(\frac{1}{4\pi\mu_0}\right)\frac{pp'}{|r-r'|^3}(\vec{r}-\vec{r}') \qquad (3)$$

In a ferro- or ferrimagnetic body, magnetic charge densities may be defined and related to the magnetization distribution $\vec{M}(\vec{r}) = M_S\vec{m}(\vec{r})$, $m^2 = 1$, through the relationships

$$\begin{aligned} \lambda_V &= -\mu_0 M_S \mathrm{div}\,(\vec{m}) \text{ in the volume} \\ \sigma_S &= +\mu_0 M_S(\vec{m}\cdot\vec{n}) \text{ at free surfaces} \end{aligned} \qquad (4)$$

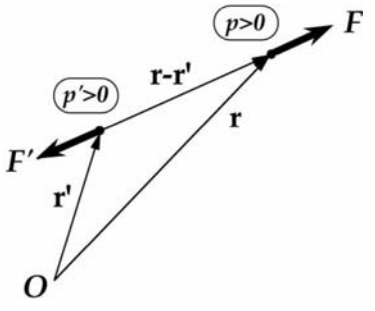

*Figure 3*
(Central) forces between two magnetic point-like charges.

It follows that MFM neither directly maps the magnetization distribution (the unknown in a magnetic imaging experiment) nor the magnetic induction.

In order to improve understanding of image formation processes, the demagnetizing or stray field

$\vec{H}_D(\vec{r})$ arising from volume or surface charge densities located at $\vec{r}'$ is introduced. According to standard electromagnetic theory, it derives from the scalar potential $\Phi_D(\vec{r})$ owing to:

$$\vec{H}_D(\vec{r}) = -\text{grad}[\Phi_D(\vec{r})] \tag{5}$$

with

$$\Phi_D(\vec{r}) = \frac{1}{4\pi\mu_0} \times \left[\iiint_{V'} \frac{\lambda_V(r\vec{}')}{|r\vec{} - r\vec{}'|}\, d^3r' + \iint_S \frac{\sigma_S(r\vec{}')}{|r\vec{} - r\vec{}'|}\, d^2r'\right] \tag{6}$$

For instance, volume and surface charges pertaining to the tip are the source of a demagnetizing field inside the tip itself and a (localized) stray field $\vec{H}_D^{tip}$ acting on the sample. It proves convenient at this point to assume that the magnetization distribution within the tip remains fixed (say pinned) during image acquisition. Let the magnetization within the sample reach its equilibrium configuration as the result of exchange interactions, anisotropy, demagnetizing field distribution (represented by the constants $A$, $K$, and vector field $\vec{H}_D^{sample}$, respectively), and tip-induced stray field $\vec{H}_D^{tip}$ for a given lift height:

$$\vec{m}^{sample} = \vec{m}[A, K, \vec{H}_D^{sample}, \vec{H}_D^{tip}(\vec{r}, z_{lift})] \tag{7}$$

Now assume an infinitesimal variation $\delta z$ of the tip to sample distance. Precisely because $\vec{m}$ has reached its equilibrium configuration, the virtual work done by $\vec{m}$ simply reads

$$\delta E = -\mu_0 M_S^{sample} \times \iiint_{sample} [\text{grad}(\vec{H}_D^{tip}) \cdot \vec{m}^{sample}] d^3r] \delta z_{lift} \tag{8}$$

It follows directly that the force acting on the tip is given by

$$F_Z = \mu_0 M_S^{sample} \iiint_{sample} \left[\frac{\partial \vec{H}_D^{tip}}{\partial z} \cdot \vec{m}^{sample}\right] d^3r \tag{9}$$

Similarly, the force gradient reads

$$\frac{\delta F_Z}{\delta z_{lift}} = \mu_0 M_S \left\{ \iiint_{sample} \left[\frac{\partial^2 \vec{H}_D^{tip}}{\partial z^2} \cdot \vec{m}^{sample}\right] d^3r + \iiint_{sample} \left[\frac{\partial \vec{H}_D^{tip}}{\partial z} \cdot \frac{\delta \vec{m}^{sample}}{\delta z_{lift}}\right] d^3r \right\} \tag{10}$$

In Eqns. (9) and (10), the first and second derivatives of the tip stray field may, for a given tip, be experimentally determined. In view of Eqn. (5), integration by parts of Eqn. (9) leads to the following important result:

$$F_Z = -\left(\iiint \lambda_V \frac{\partial \Phi_D^{tip}}{\partial z}\, d^3r + \iint \sigma_S \frac{\partial \Phi_D^{tip}}{\partial z}\, d^2r\right) = \iiint \lambda_V H_{D,z}^{tip} d^3r + \iint \sigma_S H_{D,z}^{tip} d^2r \tag{11}$$

Equation (11) shows that the force acting on the tip is the convolution product of the charge distribution and the component along the tip displacement direction of the tip stray field. In this sense, MFM may be viewed as a microscopy of the charge distribution within and at the free surfaces of the sample, a result first established by experiments (Rave *et al.* 1994) and derived in the case of the tip stray field not influencing the magnetization distribution in the sample (Hubert *et al.* 1997). It ought to be stressed that the charge densities in Eqn. (11) do include potential perturbations of the sample charge distribution under the influence of the tip stray field.

Since the force exerted by the sample on the tip is necessarily equal and opposite to the force exerted by the tip on the sample, the subscripts "sample" and "tip" may be interchanged in Eqns. (9)–(11). If the tip is to be viewed as a monopole or a point dipole, then the force and force derivative read

$$\text{Monopole}: \; F_Z = \rho^{tip} H_{D,Z}^{sample}; \frac{\partial F_Z}{\partial z} = \rho^{tip} \frac{\partial H_{D,Z}^{sample}}{\partial z}$$
$$\text{Point dipole}: \; F_Z = \vec{\mu}^{tip} \cdot \frac{\partial \vec{H}_D^{sample}}{\partial z}; \frac{\partial F_Z}{\partial z} = \vec{\mu}^{tip} \cdot \frac{\partial^2 \vec{H}_D^{sample}}{\partial z^2} \tag{12}$$

where $\rho^{tip}$ and $\vec{\mu}^{tip}$ are the monopole strength and tip moment, respectively. Equations (12), neglecting altogether perturbations, have provided and still provide a simple although inaccurate interpretation tool for MFM image analysis.

In spite of their concise form, neither Eqn. (9) nor Eqn. (11), notwithstanding Eqns. (12), provide any means of solving the inverse problem, namely finding the magnetization distribution knowing the force map, except if accepting extremely constraining assumptions such as the existence of only two magnetization directions, say, up and down (Hug *et al.* 1998). Rather, MFM image interpretation will in most cases need to rely on a highest likelihood basis and/or estimation of a magnetization distribution and, knowing tip characteristics, simulating the MFM image. Several iterations might prove necessary before a reasonable agreement between experimental data and simulations is achieved.

## 3. *Probes*

Integrated silicon cantilever and pyramid assemblies (Grütter *et al.* 1990) now form the largest basis for

MFM probes. The pyramid (and cantilever, usually) is sputter coated with a suitable magnetic alloy (e.g., CoCr) with thickness up to a few tens of nanometers (Fig. 4). Tip stray fields are by no means small (Thiaville *et al*. 1997, McVitie *et al*. 1997, Lohau *et al*. 1999), typically ranging from 10 mT to 50 mT (Fig. 5). If uniform, such high-amplitude external fields would prove sufficient to saturate low to medium coercivity samples. MFM thus relies on the fact that the lateral extension of the tip stray field remains small. The aspect ratio of tips may be improved either via the growth of carbon needles at the extremity of standard silicon pyramids (Rührig *et al*. 1994) or via micromachining techniques such as focused ion beam etching. Through directional evaporation and shadowing, the amount of magnetic material deposited on the tips may be greatly reduced. The stray field, however, cannot be reduced beyond figures quoted above

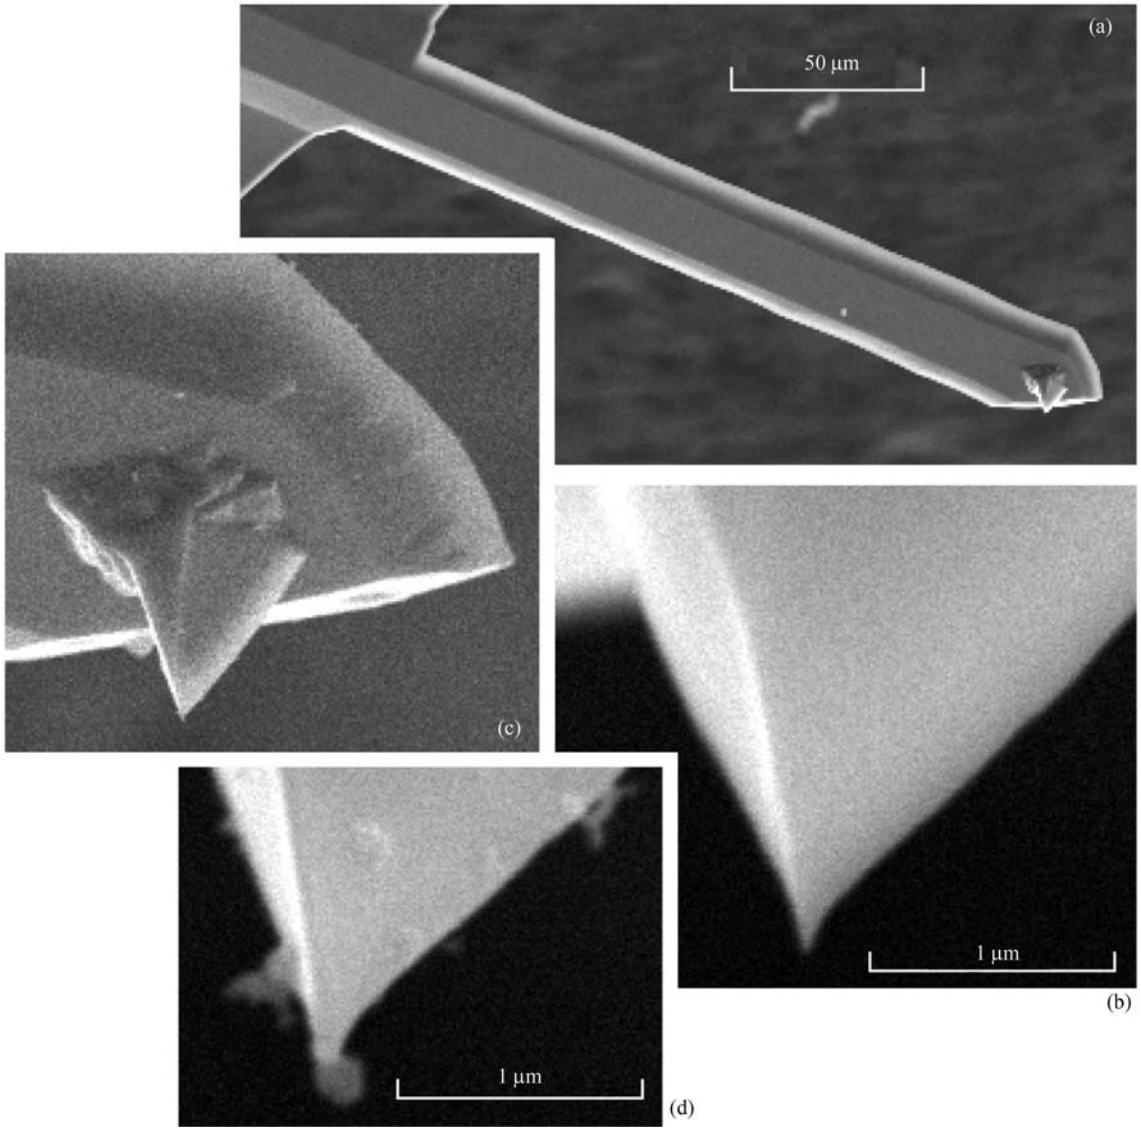

***Figure 4***
Scanning electron microscopy images of microfabricated cantilever tip assemblies (NANO*SENSORS*) (a, b) prior to magnetic film deposition, and (c, d) after deposition and intensive MFM imaging. Note the sharpened pyramid apex in (b) and a similar profile in (d) in spite of a 35 nm CoCr layer sputter coated on the silicon tip and the collection of nanometer debris after use.

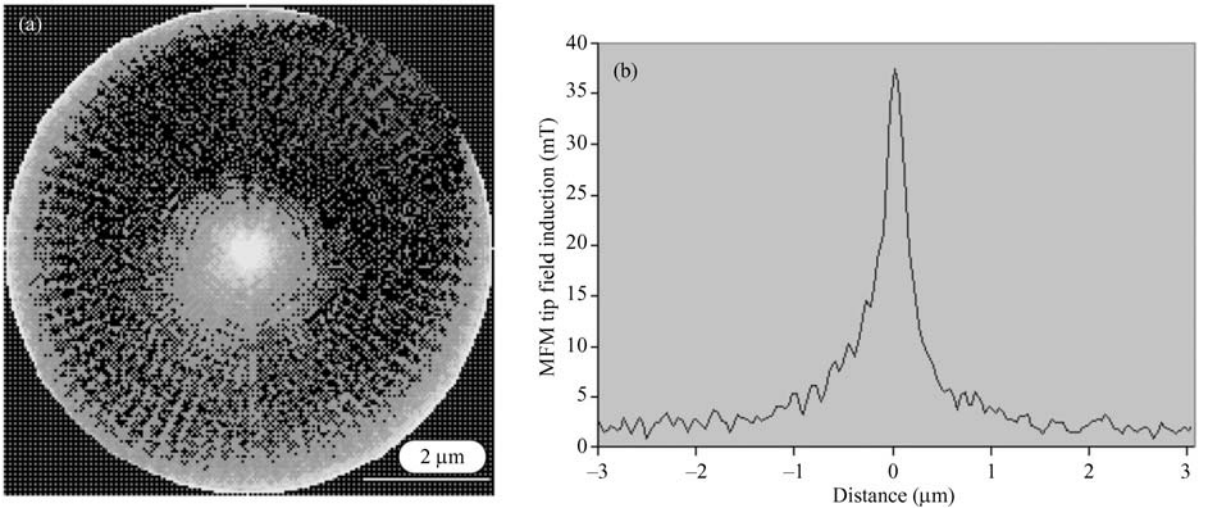

***Figure 5***
Field distribution in a plane perpendicular to the tip axis and about 50 nm away from the tip apex as measured by means of electron tomography (courtesy of S. McVitie).

since it is essential in order to provide a fair SNR. However, a higher aspect ratio helps in reducing the stray field lateral extension. Image interpretation can indeed be greatly simplified if tip stray fields may be approximated by a monopole or well-defined extended dipole for the operating lift height.
