Remanence-enhanced magnets are isotropic hard magnetic materials with remanence exceeding one half of the saturation magnetic polarization expected for a randomly oriented assembly of noninteracting single domain particles of uniaxial magnetic anisotropy. Remanence enhancement is a result of strong ferromagnetic coupling via intergrain exchange interactions among spin magnetic moments belonging to adjacent hard magnetic grains whose sizes are comparable to the ferromagnetic correlation length, or, the ''exchange length.'' Typical exchange lengths in ferromagnets are of the order of a few nanometers. Therefore, remanence-enhanced magnets are normally nanocrystalline.

Typical remanence-enhanced magnets are rapidly solidified $Nd_2Fe_{14}B$-based magnets for which the ratio of remanence to saturation magnetic polarization is about 0.6. Isotropic nanocomposite permanent magnets comprising soft and hard magnetic phases coupled via intergrain exchange interactions are also regarded as remanence-enhanced magnets. In the nanocomposite permanent magnets, the remanence to saturation polarization ratio can be much larger than in the single-phase nanocrystalline magnets because of the small and nonuniaxial magnetocrystalline anisotropy of the soft magnetic phase. Typical examples of this type of magnet include $Fe_3B/Nd_2Fe_{14}B$ and $\alpha$-$Fe/Nd_2Fe_{14}B$. The demagnetization behavior of both types of remanence-enhanced magnets has been successfully simulated using micromagnetic calculations.

## *1. Remanence Enhancement in Nearly Single-phase Hard Magnetic Materials*

Magnetic hardness of most permanent magnetic materials originates from uniaxial anisotropy, either shape anisotropy or magnetocrystalline anisotropy, of at least one ferromagnetic component phase (see *Magnetic Anisotropy*). The shape anisotropy arises from the direction-dependent magnetostatic energy caused by an elongated shape of a ferromagnetic phase and is of the order of $10^{-1}MJm^{-3}$. On the

other hand, magnetocrystalline anisotropy arises from the electrostatic energy associated with the electron charge distribution of the individual atom which interacts with the electronic charge distribution associated with the crystal. It becomes as large as $22\,\mathrm{MJm^{-3}}$. Therefore, most modern permanent magnets are composed of hard magnetic phases such as $MFe_{19}O_{12}$ (M = barium or strontium), $Nd_2Fe_{14}B$, $Sm_2Fe_{17}N_3$, $SmCo_5$, and $Sm_2Co_{17}$ which have a large magnetocrystalline anisotropy.

In the following, an assembly of a large number of single-domain hard magnetic particles of a ferromagnetic material with a uniaxial anisotropy is considered, the easy direction of magnetization being distributed randomly in a three-dimensional space. When a sufficiently large magnetic field is applied in one direction ($z$-axis), all magnetic moments of all particles will lie on a hemisphere and then the applied field is reduced to zero: the assembly of particles has a remanent magnetization of one half of the total saturation magnetization if there are no interactions among the magnetic moments of the particles (Fig. 1(a)), known as the Stoner-Wohlfarth theorem (Stoner and Wohlfarth 1948). However, if there exist magnetic interactions, either dipolar or exchange interactions, among magnetic moments of the particles, which cause a reduction of the total energy when adjacent particles align their magnetic moment parallel, then the remanent magnetization becomes larger than one half of the total saturation magnetization (Fig. 1(b)). This phenomenon is called remanence enhancement.

Intergranular exchange interactions occurs between atoms belonging to adjacent grains along boundaries. The amount of energy associated with this interaction is proportional to the contact area of these grains. On the other hand, the magnetocrystalline anisotropy energy is proportional to the volume of the grain. These two sources of energy are counteracting with each other. When the local magnetic anisotropy dominates, the effect of exchange coupling can be neglected, and the magnet behaves like a Stoner-Wohlfarth magnet. On the other hand, when exchange coupling is very strong, the local magnetic anisotropy is averaged out and the system behaves like a soft magnetic material. Thus, there exists an intermediate situation in which the system behaves as a remanence-enhanced magnet.

The ratio of these two counteracting energy contributions may be defined as

$$\eta = K_u V / J_e S \tag{1}$$

where $J_e$ is the effective intergranular exchange constant, $(1/2)S$ the interface surface area per grain, $K_u$ the anisotropy constant, $V$ the volume of a grain, neglecting distributions of values of these quantities. The parameter $\eta$ is proportional to the grain size. Another parameter which depends on the microstructure of the material is $J_e$, which depends on the atomic and chemical structure of the grain boundaries.

Figure 2 shows calculated hysteresis loops of model magnets composed of uniform cubic grains characterized by various values of the parameter $\eta$. The calculation is based on the hypothesis that the magnetic moment of each cubic cell is represented by a single vector of length $J_s V$, where $J_s$ is the saturation magnetization per unit volume (Fukunaga and Inoue 1992). This figure clearly demonstrates that the remanence ratio increases with increasing exchange interactions (i.e., decreasing $\eta$), whereas the coercivity decreases, and that there exists an intermediate strength of exchange coupling with which the magnetic properties in terms of both remanence and coercivity can be optimized. With realistic values of

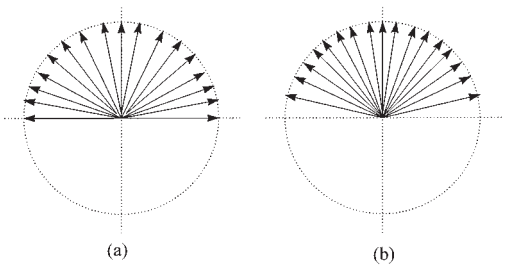

***Figure 1***
Schematic illustration of spin direction distribution of (a) a Stoner-Wohlfarth magnet and (b) a remanence-enhanced magnet.

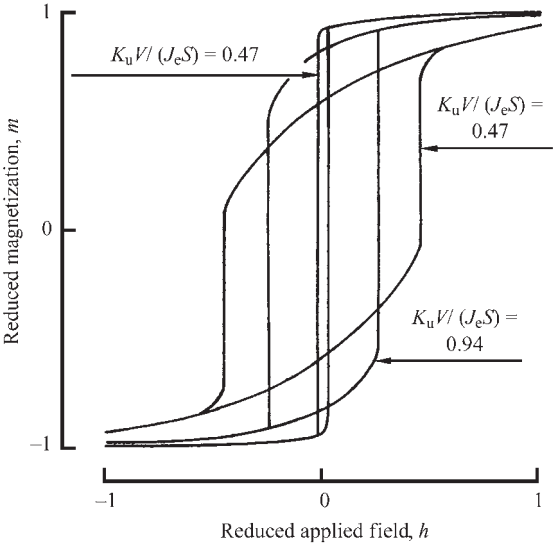

***Figure 2***
Shapes of full hysteresis loops of single-phase isotropic magnets with different exchange-coupling parameters $\eta = K_u V/J_e S$ (after Fukunaga and Inoue 1992).

$K_u$ and $J_e$ expected for rare earth intermetallic compounds such as $Nd_2Fe_{14}B$, optimum magnetic properties are suggested to be obtained with grain sizes of about 10 nm.

A micromagnetically more accurate description of the mechanism of remanence enhancement needs consideration of directional variation of atomic magnetic moments within a grain. Figure 3 shows the results of two-dimensional finite-element calculations of inhomogeneous regions along grain boundaries of a model system with grain diameters of 10 nm and 20 nm in the remanent state after magnetic saturation in one direction (Schrefl *et al.* 1994). The inhomogeneous regions refer to regions in which magnetic moments are largely off from the local easy direction of magnetization. This figure visualizes the effect of grain size on the volume fraction of the inhomogeneous regions in which magnetic moments are inclined towards the common direction of magnetization of the whole magnet.

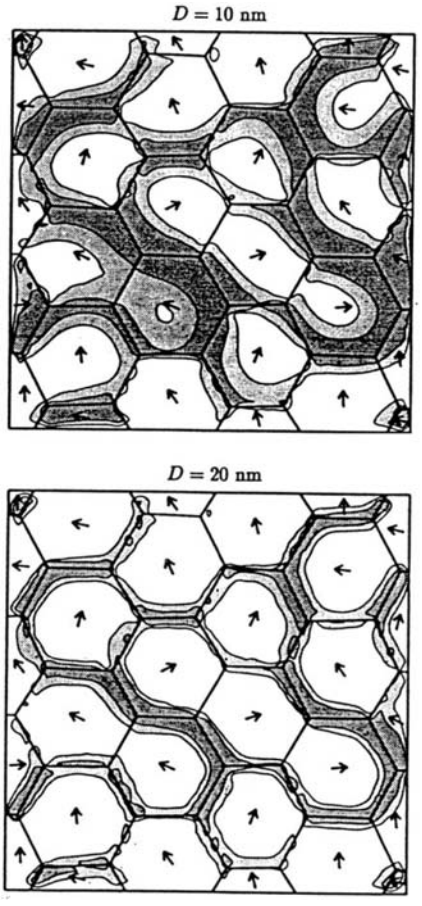

***Figure 3***
Inhomogeneous regions along grain boundaries in two-dimensional model magnets with different grain sizes using the magnetic parameters of $Nd_2Fe_{14}B$. The arrows indicate the easy direction of magnetization. The shaded areas denote the regions where the magnetic polarization deviates from the local easy direction of magnetization by more than 10 degrees (lighter gray) and 20 degrees (darker gray). Periodic boundary conditions are applied in the calculation (after Schrefl *et al.* 1994).

## 2. *Remanence Enhancement in Nanocomposite Magnets*

The class of permanent magnets called nanocomposite permanent magnets or "exchange-spring magnets" (Kneller and Hawig 1991) shows a relatively large remanence of 70–80% of saturation magnetization. These magnets are sometimes considered as remanence-enhanced magnets. One of the reasons that this class of materials maintains such a large fraction of flux density in the remanent state is that they contain a large fraction of nonuniaxial anisotropic phases. The intention to compose a nanocomposite magnet is to increase $J_s$ by combining a hard magnetic phase (phase 1) with other ferromagnetic phases which have a large saturation magnetization (phase 2). Phase 2 does not need to have a large uniaxial anisotropy. Good magnetic properties may be obtained by relying only on strong exchange coupling between the component phases. For instance, b.c.c.-Fe, which is an important component of nanocomposite magnets based on FeNdB or FeSmN systems, has a cubic magnetocrystalline anisotropy.

The remanence ratio of a two-phase isotropic nanocomposite magnet is given by

$$J_r/J_s = [v_1 m_1 J_{s1} + (1 - v_1) m_2 J_{s2}]/J_s \text{with}$$
$$J_s = v_1 J_{s1} + (1 - v_1) J_{s2} \quad (2)$$

where $m_1$ and $m_2$ are the remanence ratios of each component, and $J_{s1}$ and $J_{s2}$ are the saturation magnetizations of phase 1 and phase 2, respectively. For the case in which phase 1 is of uniaxial anisotropy and phase 2 is of planar anisotropy, without any interactions, $m_1 = 0.5$, and $m_2 = 0.79$. For cubic crystals with $\langle 100 \rangle$ easy directions of magnetization (as in b.c.c.-Fe), $m_2 = 0.83$ and for cubic crystals with $\langle 111 \rangle$ easy directions of magnetization (as in f.c.c.-Ni), $m_2 = 0.86$. Therefore, the remanence ratio is always larger than 0.5 for the case of nanocomposite magnets ($v_1 < 1$). A good nanocomposite magnet has a remanence ratio even larger than the value given by Eqn. (2) with the $m_1$ and $m_2$ values given above.

## 3. *Processing Methods of Remanence-enhanced Magnets*

The nanoscopic structure which is required to realize a measurable remanence enhancement is metastable

in that it contains a high interfacial boundary energy. Commonly used techniques to create such a microstructure utilize the instability of a metastable phase such as an amorphous phase or a mixture of quasi-equilibrium phases. Techniques to create such metastable states include rapid solidification, mechanical alloying (see *Magnets: Mechanically Alloyed*), and vapor deposition (see *Magnetic Films: Hard*). A short heat treatment at sufficiently low temperatures transforms the metastable state into another metastable nanoscopic structure. Another mechanism which may be utilized is the "spinodal decomposition" which is believed to be working in production of the FeAlNiCo type of permanent magnets (see *Alnicos and Hexaferrites*) and in the 2-17 type SmCoFeCuZr-type magnets. However, the main body of existing research has used the rapid solidification technique and, in many cases, a subsequent short annealing at relatively low temperatures in the range between 600 and 700 °C is applied.

In the case of rapid solidification, a continuous strand of a molten alloy is poured onto a circumferential surface of a chilled roll. Pour rate of the molten alloy is regulated by the diameter of an orifice at the bottom of a melt container and by keeping the head pressure of the melt in a certain range. A continuous operation of this process is possible if the melt pour rate can be regulated within the optimum range by supplying melt into the melt container.

The design of the alloy composition involves the addition of small amounts of elements which significantly affect the kinetics of crystallization reactions. Examples are aluminum, silicon, niobium and zirconium in nanocrystalline $Nd_2Fe_{14}B$ (Matsumoto *et al*. 1988) and in $Fe/Nd_2Fe_{14}B$ nanocomposites, and copper in $Fe_3B/Nd_2Fe_{14}B$ nanocomposites (Hirosawa *et al*. 1998). Experiments have indicated that $Nd_2Fe_{14}B$-based nanocrystalline or nanocomposite magnets can be obtained by a single-stage rapid solidification process without further heat treatment (Manaf *et al*. 1991). This process is often called "direct quenching." Another route to produce nearly the same microstructure is to rapidly solidify alloys at a slightly larger cooling rate and apply a subsequent heat treatment. This procedure is often referred as "overquenching and annealing."

The cooling rate during solidification can be controlled by adjusting both the melt pour rate and the substrate (i.e., the chilled roll) speed. The industrially preferred process is the overquenching and annealing route because of a wider processing window in comparison to the direct quenching route. The α-Fe/$SmFe_7N$-type nanocomposites can be produced also by the rapid solidification and annealing route, and a subsequent nitrogenation treatment, which is applied in order to convert the soft magnetic $SmFe_7$ into the hard magnetic $SmFe_7N_x$ phase by a gas-phase interstitial modification of the lattice structure.

The mechanical alloying process is able to produce a metastable mixture of phases and/or elements having a large density of structural defects such as grain boundaries and nonequilibrium vacancies (Schultz *et al*. 1987). On annealing, such a structure of a large internal energy can be transformed into a nanocrystalline or nanocomposite structure. In order to produce a bulk magnet, the resulting mechanically alloyed powder has to be compacted. The metallic materials being processed must be protected in an inert gas atmosphere in order to avoid severe oxidation particularly in the case of rare earth magnets. The mechanical alloying process, therefore, is operated in batch. On a laboratory scale, this process has been successfully used to produce nearly the same material as obtained by the rapid solidification route.

## 4. Typical Magnetic Properties of Remanence-enhanced Magnets

Some typical examples of remanence-enhanced magnets include $Nd_2Fe_{14}B$, $Fe_3B/Nd_2Fe_{14}B$, α-Fe/$Nd_2Fe_{14}B$, and α-Fe/$SmFe_7N_x$. Single-phase $SmCo_5$- and $Sm_2Fe_{17}N_3$-based materials are usually difficult to process into materials showing a marked remanence enhancement because of the very large uniaxial anisotropy which requires the grain sizes to be very small. Table 1 gives a few examples of remanence-enhanced magnets composed of nearly single phase $Nd_2Fe_{14}B$-type compounds. Typical $J_r/J_s$ values are 0.6. For NdFeB and SmFeN nanocomposites, even higher $J_r/J_s$ values of 0.7 to 0.8 are obtained (Table 2). Figure 4 shows an example of the dependence of

***Table 1***

## Magnets: Sintered

Sintered magnets are manufactured by powder metallurgy in many shapes and dimensions in large volumes. Besides hard magnetic hexaferrites and Alnico materials (see *Alnicos and Hexaferrites*), mainly rare earth (RE)–transition metal (TM) alloys are applied. By powder metallurgy the magnetocrystalline anisotropy of hard hexaferrites, of samarium (Sm)–cobalt (Co) compounds, $SmCo_5$ as well as modified $Sm_2(Co, Cu, Fe, Zr)_{17}$, and of the neodymium (Nd)–iron (Fe)–boron (B) compound, $Nd_2Fe_{14}B$, can be exploited in order to achieve anisotropic magnets with a high remanent polarization $B_R$ and a strong coercivity $H_{cJ}$ (see *Rare Earth Magnets: Materials*).

The basic principles of the production route, in particular the benefits of the different powder compaction processes and their impact on the

dimensions and magnetic properties are reviewed in this article.

## 1. Alloying and Powder Processing

Nd–Fe–B or Sm–Co alloys can be prepared from RE metals, mainly neodymium and samarium, transition metals, iron or cobalt, and master-alloys Fe–B, Fe–Nb, or additions, e.g., aluminum, copper, zirconium, etc. Since the RE metals are highly reactive, alloying has to be performed in a vacuum induction furnace. The melting cycle needs careful optimization in order to minimize chemical reactions with the crucible and to prevent oxidation by residual atmospheric gases. The melted alloy is cast into ingots which have a polycrystalline microstructure (see top of Fig. 1).

An alternative alloying route is the calciothermic reduction diffusion (RD) process (Herget 1985). RE oxides, TM powder, and the required additions are mixed with calcium-granulate as a reducing agent. The compacted powders are heated up to 1100 °C in a vacuum, so that the calcium vapor reduces the RE oxide to RE metal. The RE metal diffuses into the TM powder and the RE–TM alloy results, mixed with calcium oxides. After cooling to room temperature the calcium oxides are leached by aqueous solutions. Since the calciothermic RD process uses RE oxides, the materials are more economic, but the final RE–TM alloy-powder contains more impurities than an alloy melted in a vacuum induction furnace.

A recently developed alloying process is *strip casting*. The molten alloy is cast onto a rotating copper-roll and is cooled at cooling rates of about $30\,\mathrm{K\,min^{-1}}$ to approximately 0.3 mm thick flakes (Hirose *et al.* 1998).

The cast ingots, alloy powder particles, or strip cast flakes have a polycrystalline microstructure resulting in a random distribution of the easy-axes of the crystals and hence of the magnetic moments. For achieving a well-defined texture or easy-axis, respectively, powder metallurgy is applied (Fig. 1). The alloys are crushed and milled mechanically or by hydrogen decrepitation to a fine alloy powder (Harris *et al.* 1994). In order to get a perfect alignment in a magnetic field, the powder particles must consist of single crystals. In general alloy powders with a particle size in the range of 3–5 μm meet this condition well. For the production of anisotropic magnets there exists different processing routes that determine the magnetic properties, dimensional tolerances, and processing costs.

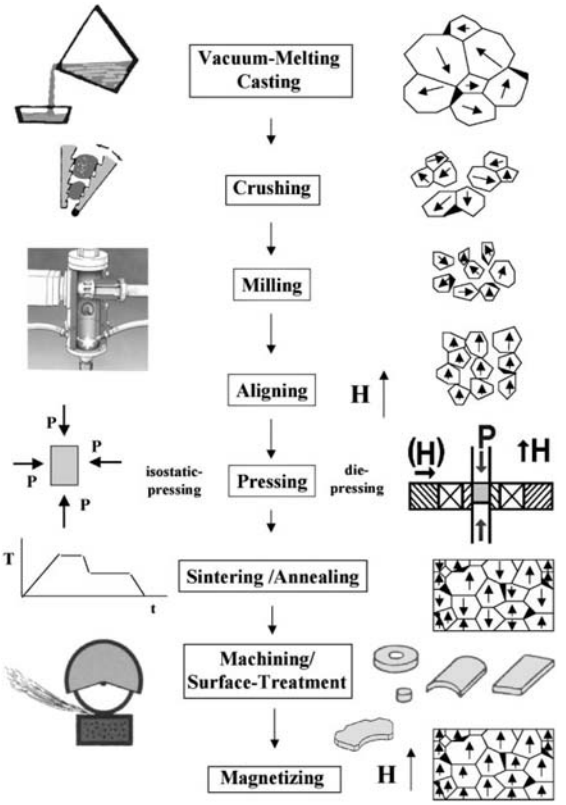

***Figure 1***
Principles of the different processing routes of sintered RE–TM magnets by powder metallurgy.

## 2. Compaction Methods

### 2.1 Cold Isostatically Pressed (CIP) Magnet Blocks

For the production of big blocks the alloy powder is sealed in a rubber mold, aligned in a magnetic field, and pressed isostatically. Since the pressure increases homogeneously from all directions, the alignment of the powder particles is not disturbed significantly during compaction (Fig. 1, left-hand side). The isostatically pressed blocks are sintered to more than 98% of the theoretical density and annealed in order to optimize the magnetic properties.

Hence, isostatically pressed blocks have an excellent texture. The alignment coefficient amounts to about 98% (Rodewald *et al.* 2000). Due to the proper alignment of all magnetic moments, sintered Nd–Fe–B magnets with a remanent polarization of 1.47 T and a coercivity of $9.6\,\mathrm{kA\,cm^{-1}}$ (12 kOe) can be produced resulting in a maximum energy density of $420\,\mathrm{kJ\,m^{-3}}$ (53 M GOe). Figure 2 presents the demagnetization curves $J(H)$ and $B(H)$ of such sintered Nd–Fe–B magnets at different temperatures. The temperature coefficients (TC) of the remanent polarization and of the coercivity amount to $-0.11\%\,\mathrm{K^{-1}}$ and $-0.77\%\,\mathrm{K^{-1}}$ in the temperature range of 20–100 °C.

### 2.2 Axial Field Die-pressed (AP) Net-shape Parts

The manufacturing of parts from isostatically pressed RE magnet blocks needs a lot of machining, which

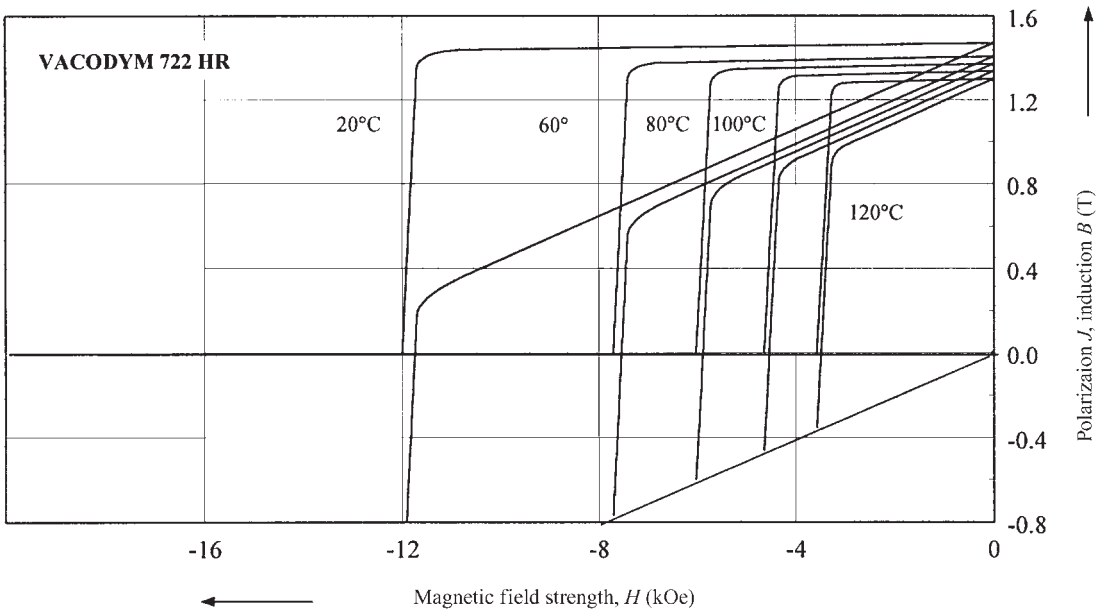

***Figure 2***
Demagnetization curves $J(H)$ and $B(H)$ at different temperatures of sintered Nd–Fe–B magnets, grade Vacodym 722 HR, with a maximum energy density of 420 kJ m$^{-3}$ (53 M GOe), manufactured by cold isostatic or rubber isostatic pressing, respectively.

increases the processing costs. An alternative route is the production of net-shape parts by die-pressing. The alloy powder is filled into the cavity of a die, aligned by an axial magnetic field and compacted (see Fig. 1, right-hand side). Since the easy-axes of the powder-particles are aligned parallel to the pressing direction, the alignment is disturbed during the compaction. Hence, the remanent polarization of axial field die-pressed magnets is in general about 8% lower in comparison to isostatically pressed magnet blocks.

By axial field die pressing a large variety of dimensions and shapes can be manufactured economically. For instance, net-shape Nd–Fe–B magnets for motor applications achieve a remanent polarization of 1.08 T and a coercivity $H_{cJ}$ (20 °C) of 28.7 kA cm$^{-1}$ (36 kOe) and a maximum energy density of 225 kJ m$^{-3}$ (28 M GOe). At 150 °C, the $H_{cJ}$ of such magnets amount to 12 kA cm$^{-1}$ (15 kOe). The TCs of the remanent polarization and of the coercivity amount to $-0.08\%\,K^{-1}$ and $-0.51\%\,K^{-1}$ in the temperature range of 20–100 °C. At room temperature such Nd–Fe–B magnet grades exceed sintered $Sm_2(Co, Cu, Fe, Zr)_{17}$ magnets, but at 200 °C the temperature stability of $Sm_2(Co, Cu, Fe, Zr)_{17}$ magnets is superior.

### *2.3 Transverse Field Die-pressed (TP) Near Net-shape Parts*

Another compaction technology is pressing of parts in a transverse magnetic field (Fig. 1, right-hand side). In this case the alignment of the powder particles is not disturbed so strongly during compaction resulting in a remanent polarization similar to isostatically pressed magnet blocks. The alignment coefficients range from 94% to 98% for rectangular blocks and from 93% to 97% for near net-shape parts.

By transverse field die pressing mainly rectangular blocks or near net-shape parts can be manufactured. After sintering, the blocks are cut into thin magnet plates according to customer specifications. However, near net-shape parts will need some contour grinding before cutting. Hence the machining costs increase in comparison to axial field die-pressed magnets.

### *2.4 Rubber Isostatic Pressing (RIP)*

Near net-shape magnet blocks with an excellent texture, i.e., an alignment coefficient similar to that of isostatically pressed blocks, are now manufactured by rubber isostatic pressing (Sagawa *et al.* 2000). The alignment of the precompacted alloy-powder particles in an elastic rubber mold is performed by a set of d.c. and a.c. field pulses with a maximum field strength of 24 kA cm$^{-1}$ (30 kOe) for instance. Afterwards the aligned alloy powder is compacted by axial pressing. But the axial pressing forces are diverted homogeneously by the elastic rubber mold, so that the compaction occurs almost isostatically.

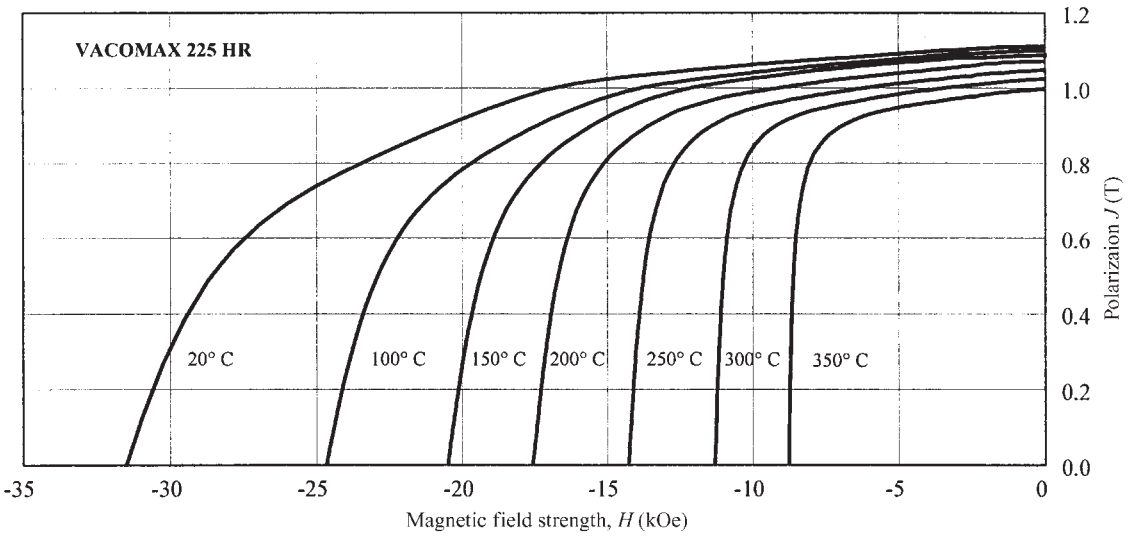

***Figure 3***
Demagnetization curves $J(H)$ at different temperatures of sintered $Sm_2(Co, Cu, Fe, Zr)_{17}$ magnets, grade Vacomax 225 HR, with a maximum energy density of 225 kJ m$^{-3}$ (28 M GOe), manufactured by cold isostatic pressing.

Optimization of the alloy composition, alloy powder milling, aligning and compaction technology, and sintering and annealing treatments now enables the commercial production of near net shape Nd–Fe–B parts with a maximum energy density of 420 kJ m$^{-3}$ (53 M GOe). Hence, sintered Nd–Fe–B magnets exploit the magnetic properties of the $Nd_2Fe_{14}B$ compound, $J_s = 1.6$ T, theoretical $(BH)_m = 509$ kJ m$^{-3}$ (63 M GOe), to more than 80% and have gained a similar maturity as Sm–Co magnets.

## 3. Samarium–Cobalt Magnets

Although the temperature stability and the corrosion behavior of sintered Nd–Fe–B magnets can be improved by increasing the coercivity and by small additions of aluminum, copper, cobalt, etc., the temperature and corrosion stability of sintered $Sm_2(Co, Cu, Fe, Zr)_{17}$ magnets remains superior at temperatures above 200 °C. The demagnetization curves $J(H)$ at different temperatures of isostatically pressed magnets demonstrate, that at 20 °C the remanent polarization and the coercivity amount to 1.11 T and 25.3 kA cm$^{-1}$ (31.6 kOe) resulting in a maximum energy density of 225 kJ m$^{-3}$ (28 M GOe, Fig. 3). At 200 °C, $Sm_2(Co, Cu, Fe, Zr)_{17}$ magnets still achieve a coercivity $H_{cJ}$ (200 °C) of 14 kA cm$^{-1}$ (17.5 kOe). Maximum continuous operating temperatures up to 350 °C are possible for such magnets. Recently developed $Sm_2(Co, Cu, Fe, Zr)_{17}$ magnets even achieve a straight demagnetization curve $B(H)$ at 550 °C (Walmer *et al.* 2000, see *Magnets: High-temperature*).

## 4. Concluding Remarks

Powder metallurgy enables the production of sintered net-shape RE–TM magnets for applications in motors, electronic devices, speakers, microphones, a large variety of sensors, bearings, couplings, NMR analysis equipment, MRI tomography, beam guidance devices, magnetic separation, switches, and relays (see *Magnetic Materials: Domestic Applications*).

In order to decrease the processing costs and improve the magnetic performance, the powder processing, aligning and compaction technologies, sintering and annealing treatments, as well as machining and coating processes need continuous optimization. Sintered Nd–Fe–B magnets with a maximum energy density of 420 kJ m$^{-3}$ (53 M GOe) have now come into commercial production, while by laboratory facilities a maximum energy density of 444 kJ m$^{-3}$ (55 M GOe) has been achieved (Kaneko 2000). In the year 2000, in total about 16000 t of sintered Nd–Fe–B magnets and 1000 t of sintered Sm–Co magnets were produced (Luo 2000).

Besides the production of anisotropic RE–TM magnets by sintering, some alternative processing routes have been developed and evaluated. These include: hot-pressing and hot-deformation of rapidly solidified flakes (Croat *et al.* 1984, Panchanathan 1995), hot-backward extrusion of radially aligned ring-magnets (Yoshikawa *et al.* 1994), hot-rolling (Shimoda *et al.* 1989, Yuri and Ohki 1994, see *Textured Magnets: Deformation-induced*), and vacuum plasma spraying (Overfelt 1986, Rieger *et al.* 2000). But the sintering technologies still meet the technical requirements very efficiently and economically.

## Metal Evaporated Tape

The first generation of commercial Metal-Evaporated (ME) tapes was introduced in 1989 for the Hi-8 video system (Chiba *et al.* 1989, Hokkyo *et al.* 1993) and consisted of an oblique-deposited Co–Ni–O thin film tape. This was followed by the scoopman digital recorder with a stamp-sized cassette (Hinemo and Katahu 1994). In 1993, a new digital video system was proposed (Digital Video Cassette (DVC)) (Yamamitsu *et al.* 1995). This system uses an improved ME tape with a 4 dB higher C/N (Futamoto and Honda 1994). Besides Co–Ni–O-deposited tapes, Co–O films with oblique anisotropy appeared on the market as the tape for DVC (Kawana *et al.* 1995). It is also planned that this type is used for large-capacity data storage tape for computer systems. More than 1 $Gbin^{-2}$ is being developed (Ishida *et al.* 2000) in a helical scanning tape storage system based on Co–O thin film material.

Important in system design is the trade-off between the amount of data reduction, playing time, and cassette size. For both the Hi8 and DVC systems, equivalent metal particle tapes (MP tapes) have been developed which meet these requirements. There is an ongoing competition between MP and ME tapes. In general, ME tape gives a promising signal-to-noise ratio and is a potential candidate for future applications if much smaller tracks will be written (Draaisma *et al.* 1999).

Another advantage of ME tape is that the recording layer thickness can be reduced below 100 nm without changing the magnetic properties too much. Moreover, the properties can be tailored with the deposition parameters of the coating machine. ME tape also has a low noise because of the decreased film thickness (Kagawa *et al.* 1997). The need for extremely small sizes combined with long playing times requires a tape with a very high signal-to-noise ratio and very thin magnetic and total tape thickness. In 1998, a very important paper was published discussing the key issues in the design of magnetic tapes (Richards and Charrock 1998).

Although the paper is not specifically focused on ME tape, most of the issues discussed are directly applicable to it. In the next paragraphs, only the basic

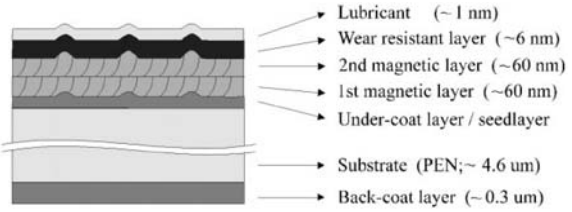

***Figure 1***
Schematic cross section of an ME tape

properties of the oblique-deposited magnetic layer, the related microstructure, and the magnetic behavior of ME tape will be discussed. Apart from the development of the magnetic layer, numerous other aspects have also to be considered such as tape mechanics, tape transport, friction and wear, head design, long term stability, etc.

In Fig. 1, a cross-section of an advanced ME tape is shown schematically.

In Fig. 1, two magnetic layers are presented. In recent years ME tape manufacturers have experimented with several magnetic coating layers. One of the reasons is an increased coercivity (by magnetic coupling) of so-called double layers. In Ashton and Thompson (1998), several possibilities are shown which can enhance the magnetic properties. Up to four magnetic sublayers were even reported in Kawana *et al.* (1995).

## *1. Oblique Evaporation and Columnar Separation*

When depositing a thin magnetic layer, by either sputtering or evaporation, a columnar morphology is usually observed (Smith 1995, Abelmann and Lodder 1997). Since these columns are in close contact with each other, a strong exchange coupling between adjacent columns is present resulting in an almost instant switching behavior of the film. This is highly unfavorable for a magnetic recording medium since it prevents writing a stable bit structure with sharp transitions in such a medium, so inducing a columnar separation is necessary to enable the recording of information in a thin magnetic film. One possibility for obtaining this columnar separation is to make use of the so-called shadowing effect as schematically presented in Fig. 2.

From Fig. 2(a) it is observed that due to the height of the initial nuclei, a ''shadow'' is thrown behind these nuclei and therefore the rest of the vapor flux can not reach the area directly behind them. Since this flux is deposited under an angle with respect to the normal of the substrate, subsequent stages of film growth will result in a tilted columnar morphology, which is schematically shown in Fig. 2(b). Here the columns make an angle $\beta$ with respect to the normal of the substrate. The relation between both angles is

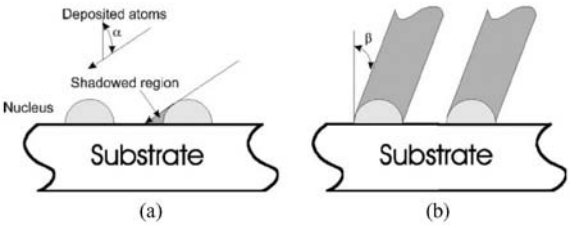

***Figure 2***
Physical principle of the shadowing effect. (a) shows the actual shadowing of the deposited atoms impinging under an angle $\alpha$ with the substrate. In (b) the columnar inclination angle $\beta$ is shown.

very much determined by the process conditions, i.e., substrate temperature, base pressure, energy of the arriving atoms, etc. (see, e.g., Abelmann and Lodder 1997). In principle, both sputtering (Bijker *et al.* 1997) as well as evaporation can be used in exploiting the effect of shadowing.

In general, atoms tend to migrate across the substrate surface once they have become adatoms. Therefore, the oblique incidence effect might be overcome by the transfer of thermal energy of the substrate to these adatoms, once the substrate temperature becomes high. Hence, low substrate temperatures are beneficial for this type of process. The thin-film morphology of an oblique-deposited magnetic layer with magnetically uncoupled grains can lead to relatively high coercivities. It is known from literature (Feuerstein *et al.* 1985) that the deposited materials iron, cobalt, and nickel show a remarkable increase in coercivity as a function of the angle of incidence ($\alpha$ in Fig. 2). Such an example is shown in Fig. 3. Similar results were reported in Kita *et al.* (1981) for $Co_{62.5}Fe_{37.5}$ and $Co_{30}Ni_{30}$ as well.

The sharp increase in longitudinal coercivity at a high angle of incidence is believed to arise from a strongly reduced exchange coupling between the columns.

## *2. Manufacturing Process*

To produce magnetic tapes, a mass-production equivalent of the mentioned static-angle experiments is schematically shown in Fig. 4.

In this figure, an unwinding and winding reel are shown, which guide the base film over the evaporation source. Therefore, the angle $\alpha$ (from Fig. 2) is changed from $90^\circ$ to $60^\circ$ (as indicated in Fig. 4). Thus, instead of making a fixed angle with the atom flux with respect to the substrate, a continuously varying angle of incidence (CVI) is introduced. The use of evaporation has led to the general term metal-evaporated tape or ME tape. The CVI method results in the typical morphology for ME tape, which is shown in Fig. 5.

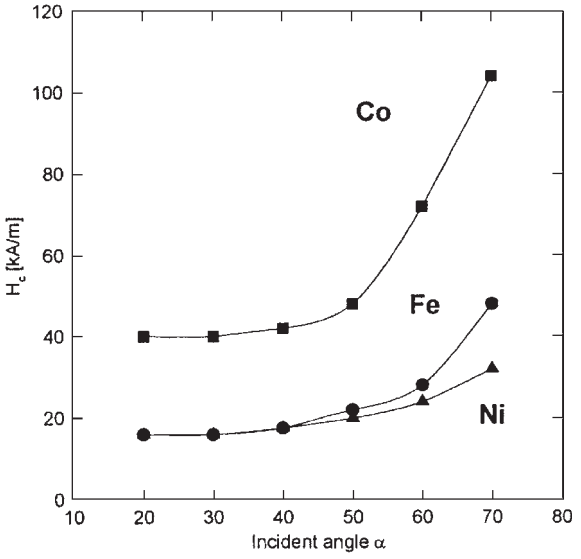

***Figure 3***
Effect of the angle of incidence of the vapor flux of the three ferromagnetic elements (after Feuerstein *et al.* 1985).

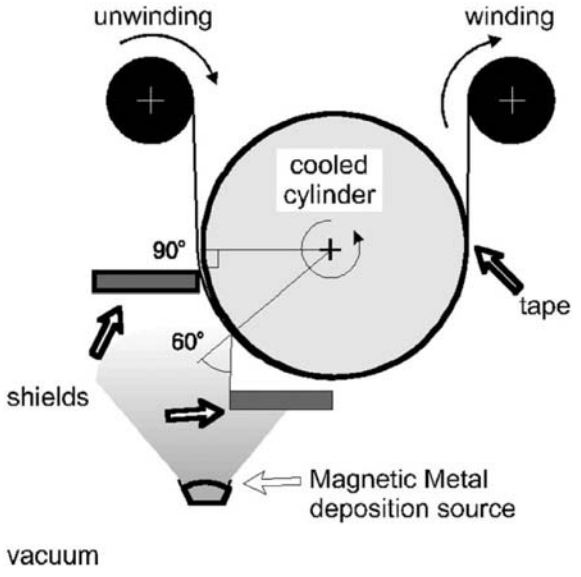

***Figure 4***
Principle of ME tape mass production.

Comparing the coating thickness and coercivity of ME and metal particle (MP) tapes, it can be concluded that thinner coatings can be achieved with usually better coercivities. Hence, according to the Williams and Compstock (1971) model, smaller values of the transition width (between two written bits) can be achieved. However, recently the particulate coatings have also been improved by developing better particles, which can be better aligned at smaller coating thickness, which have eventually resulted in comparable recording properties (see, e.g., Lalbahadoersing *et al.* 1997, Richter and Veitch 1995). Differences in easy-axis (MP (in-plane) and ME (tilted), and reversal mechanism of MP and ME tape might correspond with a smaller transition length, which results in a better overwrite behavior for ME tape (Lalbahadoersing *et al.* 1997). From the above, the principal process of making ME tapes was made clear.

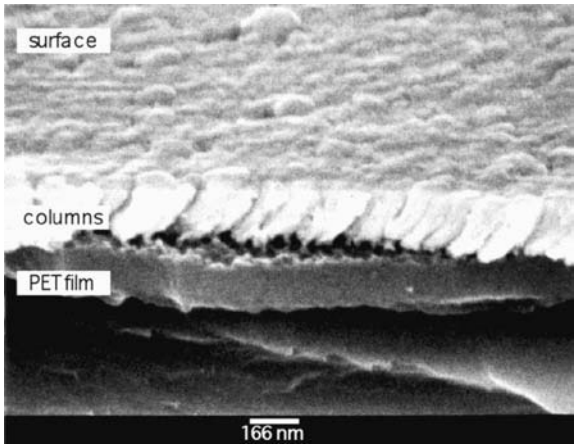

***Figure 5***
Scanning electron microscope image of an experimental ME tape showing the banana-shaped columnar structure (after Bijker 1998).

Many publications can be found about this subject and more detailed information of the subject can be acquired from Luitjens *et al.* (1996), Onodera *et al.* (1996), Kunieda *et al.* (1985), Richter (1993a). Apart from the development of the magnetic thin film or coating, numerous other aspects have also to be considered. These involve issues such as tape mechanics, tape transport, friction and wear, head design, long term stability, etc. When comparing ME tape with the more conventional particulate tape (e.g., $Cr_2O_3$ and $Fe_2O_3$), the manufacturing process is the most striking point of difference. As we explained above, ME tape is produced via an evaporation process. In Feuerstein and Mayer (1984), Feuerstein *et al.* (1985), and Wright (1987), several aspects of the vacuum deposition process are shown. In Fig. 6, a cross-section of a typical deposition machine is shown (taken from Feuerstein and Mayer 1984).

In Fig. 6, the base film is unwound from reel (a) via an intermediate coating station (b), towards the oblique deposition zone (c). Here the electron beam (e)

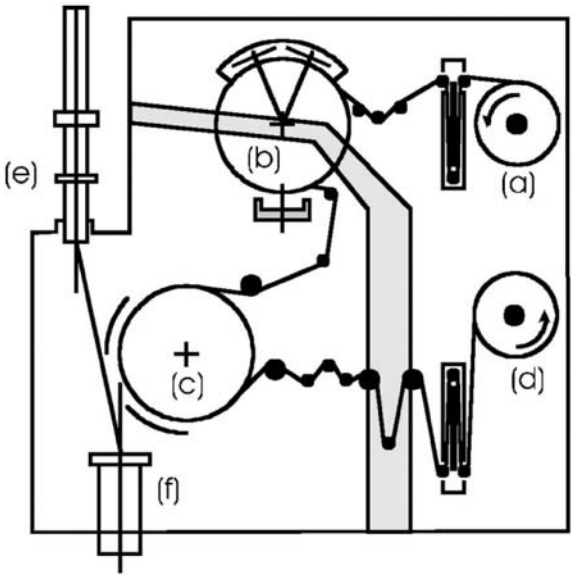

***Figure 6***
Schematic cross section of a production roll coater. See text for explanation of the items.

evaporates the magnetic material in the crucible (f). Finally, the tape is wound onto a reel (d). Furthermore, a separation between the unwinding zone and the deposition zone is necessary to sustain a reasonable pressure in the deposition zone. The separation is indicated in the figure by the grey area. Some simple calculations can be undertaken to calculate the necessary web speed and the deposition rate. The base material is typically supplied with a width of 1.20 m and a length of 10 km. For these base film lengths, a total coating time of around a few hours is applied. In total, about one hour is needed for pumping, accelerating the web to its full speed, heating up the evaporation source, etc. So, in approximately three hours, the total web length should be coated, which results in a web speed of around $1\,\mathrm{ms}^{-1}$ or $60\,\mathrm{m\,min}^{-1}$. Together with the drum diameter of one meter, and an opening angle of 30°, the necessary deposition rate can be calculated to be $\sim 0.5\,\mu\mathrm{m\,s}^{-1}$. In 1999, Maezawa *et al.* (1999) published data of Co–O tape prepared at deposition rates of 1 μm/s. Such deposition rates require e-beam evaporation sources with astronomically large power consumption.

Usually two e-beam guns are installed in a coater with a web width of 1.20 m (see Leybold 1992). These would be of around 0.5 MW each. The crucible also has a width of around 1.20 m, usually made of a $Al_2O_3$ ceramic. These large deposition rates require the coating material to be constantly replenished. In the early designs, a rod feed system was designed, but in later designs slugs of coating material were fed via a vibration system into the melt. This allows the use of a crucible, which can be parked in a separate vacuum chamber during charging of the vacuum machine. This eliminates a complete cooling down of the crucible and saves time. To obtain a homogeneous melt, the e-beams are swept over the melt with a frequency of about 400 Hz. Winding a thin polymer substrate in vacuum conditions is not trivial, let alone in a bi-directional manner. Base films do not necessarily have similar winding characteristics in air compared to vacuum conditions. As modern substrates tend to become thinner and thinner, more sophisticated winding systems are needed. Usually the drum and the winding and unwinding reels are controlled by measuring the torque exerted on the base film. To prevent wrinkling of the base film a slightly V-shaped roll, or capstan, is present in the winding system. Furthermore, when such large rolls of base film are unwound in a vacuum system, they tend to release considerable amounts of water vapor.

## 3. *Microstructure and Magnetic Structure*

From Fig. 3 it can be concluded that the necessary high coercivity can only be obtained by oblique deposition if the angle of incidence is very high. Consequently, that is also the area in which the deposition process becomes very inefficient. To overcome this problem depositions are made at smaller angles but with the addition of oxygen during deposition. The result is a very complicated microstructure (see Fig. 7) but with an increase of the coercivity.

The incorporation of the oxygen is hard to understand because companies do have their own specific processes, which are not published. However, in, e.g., Kunieda *et al.* (1985) and Hokkyo *et al.* (1993), the general trends are indicated: an increase in oxygen

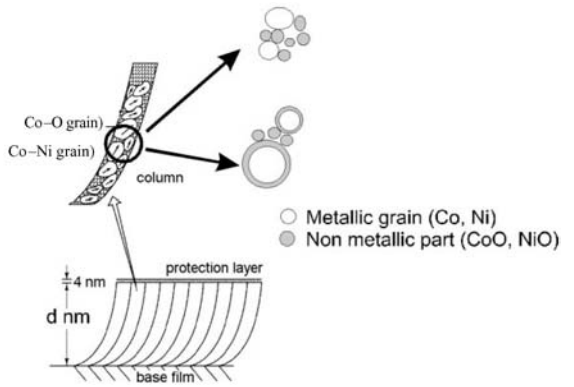

***Figure 7***
Banana-shaped columnar morphology of ME tape of thickness d. Two possible microstructures are also drawn.

flow, whilst keeping the deposition rate constant, will lead to an increase in longitudinal coercivity ($H_c$) and a decrease in apparent saturation magnetization ($M_s$). From Gau *et al.* (1986), a local optimum in $H_c$ as a function of the oxygen flow can be observed. A similar behavior has been observed by Bijker *et al.* (1999).

As can be seen in Fig. 7, apart from an oblique banana-shaped columnar morphology, which is due to the specific deposition geometry, the columns can either exist of ferromagnetic grains in close contact with the nonmetallic grains, or apart from the presence of nonmetallic grains, the ferromagnetic grains have a small oxide skin around them. The oxidation process is most likely diffusion limited (Mujumdar *et al.* 1986), and therefore could explain the correlation between the used deposition rate and the oxygen content in the upper part of the ME tapes which is accompanied by the larger grains sizes in this part of the film as well. This is also reflected by the $H_c$ of the films, which become larger with increasing oxide-shell thickness, thereby reducing the magnetic coupling between the ferromagnetic grains (Bijker 1998). In general, it is not straightforward to relate the microstructure of ME tapes to the switching behavior of the layer. Another distinct property of ME tape is the oblique easy axis of the tape. The easy axis of magnetization is known to exhibit a strong correlation with both the oxygen flow and the deposition geometry. More oxygen leads to increased columnar inclination angles (Nagao *et al.* 1991, Bijker 1998).

The strong relation on the deposition geometry was shown in, e.g., Ogawa *et al.* (1994) and Yano *et al.* (1994). The magnetic anisotropy (see *Magnetic Films: Anisotropy*) is found to be largely due to the shape anisotropy of the columns (see, e.g., Richter and Hibst 1991), although some contribution from the crystal anisotropy may be expected in view of the presence of small h.c.p. cobalt crystallites. The question remains, however, of whether the crystal anisotropy can contribute significantly since all the observed crystals seem to be very small ($\sim 5$ nm) and randomly oriented. No clear texture was observed from the microstructural analysis. From the Auger depth-profiling experiments, it becomes clear that an effective magnetization distribution over the film thickness must exist. When the packing density distribution is known as a function of the film thickness, the effective magnetization profile could be calculated. However, judging from the oxygen profile alone, a maximum magnetization is reached in the center section of the tape. A similar conclusion was made in Richter (1993b), although assessed with a combination of recording and VSM measurements. Apart from a distribution of the saturation magnetization, the longitudinal coercivity should also have a distribution over the thickness of the tape, since the columns are better separated in the lower parts of the tape by the geometry of the deposition process. The aid of oxygen leads to a better lateral decoupling of the columns in the upper parts of the tape.

## 4. *Anisotropy and Recording*

The anisotropy is strongly related to the morphology and microstructure of the deposited film. The extreme uniaxial anisotropy associated with the mesoscopic columnar structure in ME tapes gives rise to an oblique recording process which is close to one-dimensional in nature (Nouchi *et al.* 1986).

An oblique easy-axis angle gives rise to asymmetric pulse shapes. Since the columnar structure of ME tape is asymmetrical with respect to the recording head field, it might be expected that the recording behavior is somewhat different in both recording directions. The output spectrum of the Hi8 ME tape is shown in Fig. 8, where indeed a difference in output between the two recording directions is observed.

Similarly, the good and bad recording directions can be understood by considering the projection of the head fields to the oblique medium easy axis in the write process. If writing is assumed to occur at the trailing edge of the head where the field is equal to $H_c$, in the good direction of head-to-tape motion, the magnitude of the projected total field gradient is larger, leading to sharper transitions (and thus larger output) than the bad direction. The effect of recording in the good and bad direction on the recorded bits can be studied with magnetic force microscopy (MFM) observations.

In Fig. 9, written bits are shown for recording in both directions (see also Luitjens *et al.* 1996, Porthun *et al.* 1998). The same current is used for writing the bits. The distance between transitions ($=$ bit length) is about 0.33 um. The good direction shows sharp bits and track edges (Fig. 9, left). In the less favorable

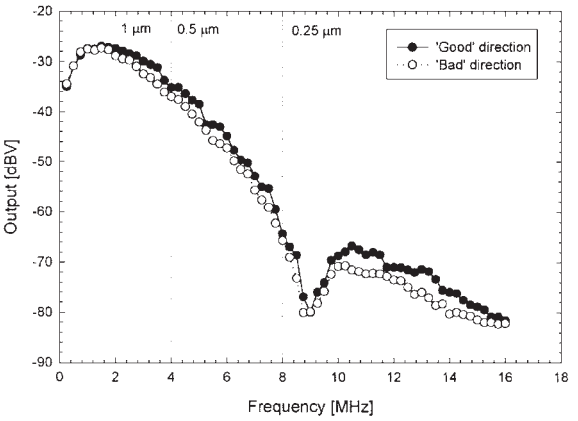

***Figure 8***
Difference in recording output depending on the recording direction of the Hi8 ME tape.

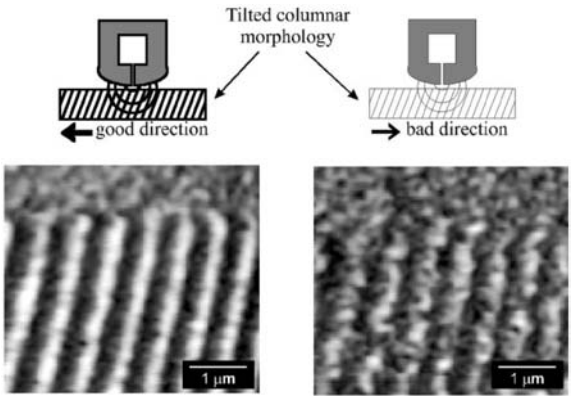

***Figure 9***
MFM measurements of the recorded magnetization pattern of the Hi8 ME sample in both recording directions. On the left are the bit transitions in the good recording direction; the right hand side shows the transitions in the bad recording direction.

direction, less sharp transitions and interrupted bits are visible (Fig. 9, right). The intrinsic magnetic structures beside the tracks have more or less the same dimensions as the written bits.

The direction, which leads to a higher output, is generally referred to as the good direction. Subsequently the other direction is called the bad direction. The difference is about 4.2 dBV (see Fig. 8). Apart from the effect on output, the read-back pulses are also known to be asymmetric (Krijnen *et al*. 1988).

From Fig. 9 it becomes clear that the transition regions of the bits written in the good direction are far less irregular compared to the image on the right hand side where the bits are written in the bad recording direction. On the right hand side, some subdomains are visible within the written bit structure and the bits are connected to the outside domain pattern. These irregularities contribute to the lower read-back voltage in the bad recording direction.

Various microscopic models have been developed, e.g., Richter *et al*. (1993). Most macroscopic models of the magnetic reversal process give rise to inverse cosine dependence. Incoherent reversal can be incorporated in a Stoner-Wohlfarth model by appropriate truncation of the switching asteroid (Cramer 1993, Lalbahadoersing 1999). In the limit of very strong interactions, mean-field models are not appropriate. This does not seem to be the case for ME. A key feature which needs to be incorporated, however, are the cooperative interactions (which give rise to very sharp transitions). The results of the different numerical simulations are in good agreement with each other and confirm the earlier-mentioned one-dimensional nature of the recording process in these materials. Both the one-dimensional and the more sophisticated models indicate that there is little or no improvement in the recorded output signal in ME tape associated with the transition from longitudinal to oblique recording (Stupp *et al*. 1994, Richter *et al*. 1993, Tagawa *et al*. 1991, Cramer 1993).

In Hokkyo *et al*. (1993), a clear relation was demonstrated between the noise level of an ME tape and the oxygen flow. When more oxygen is incorporated into the film, the cobalt grains become smaller and a simultaneous increase of the coercivity suggests a better decoupled structure. Thus, the more oxygen is incorporated, the more cobalt grains per unit of volume exist. From Mallinson (1993, p. 116), the signal-to-noise ratio (SNR) for thin film media is shown to be:

$$\mathrm{SNR} = \tfrac{1}{2} n W \delta \lambda \ (\mathrm{dB}) \qquad (1)$$

with $n$ being the number of particles per unit of volume, $W$ the track width, $\delta$ the medium thickness, and $\lambda$ the recording wavelength. From Eqn. (1) it becomes clear that increasing the number of particles per unit volume will lead to enhanced SNRs. Thus if the art of making fine decoupled cobalt particles is mastered, it will lead to an increase in SNRs.

Some authors have addressed the question of whether there exists exchange coupling over the length of the column, so over the thickness of the tape. Some clue is given by measurements of the activation volume (Richter 1993a, Suzuki and Tajiri 1997). Although care has to be taken with the use of a quantity like the activation volume, it might contribute in the discussion about the role of the exchange coupling. In both articles it was found that switching volumes are generally larger than the crystallites in the columns but smaller than the column size as a whole.

## 5. *Co–Ni(–O) and Co(–O) ME Tape*

In the early ME tape, Co–Ni–O is always used as the thin film material. The material is deposited using a continuously varying angle of vapor incidence in an oxygen environment, which leads to the mesoscopic banana-shaped column morphology as shown in Fig. 5. The dependence of the saturation magnetization $M_s$, coercivity $H_c$, signal, and noise on the process parameters is discussed in Hokkyo *et al*. (1993). There is a direct relationship between $H_c$ and the O content (due to the increased decoupling of grains) and an inverse relationship between $M_s$ and the O content (due to a reduction in the cobalt content and an increase in the CoO content). To further study the relation between deposition angle, oxygen concentration, magnetic properties, and recording performance, a mini roll coater has been developed (ten Berge *et al*. 1994) and basic experiments have been performed. Auger depth profiling showed that the Co/Ni ratio is constant over the total thickness of the film.

The general picture that emerges from the TEM and XRD analysis is that the ME tapes consist of a banana-shaped columnar structure where small crystallites are the building blocks of the entire column. This has also been established in literature (see, e.g., Hokkyo *et al.* 1993). A schematic representation is given in Fig. 7 as a result of combined TEM and XRD analysis. A similar sketch can be found in Kaneda (1997). In Fig. 10 a TEM cross section is given from a Hi8 Co–Ni(–O) ME tape. From the darkfield observation, the more-or-less homogenous distribution of the small crystals can be observed.

The O concentration is enhanced at the top (30 nm) and the bottom (10 nm). The relation between the deposition rate, the magnetic properties, and structural feature has been studied by ten Berge *et al.* (1994), Bijker (1998), Bijker *et al.* (1997), and Tohma *et al.* (1997). Between 1993 and 2001, not only Co–Ni–O tapes but also Co–O tapes have been prepared. The so-called advanced ME tape has been produced by oblique deposition of Co–O layers (Futamoto and Honda 1994, Yoshida *et al.* 1994, Sugita *et al.* 1999, Ishida *et al.* 2000). Experimental observations have shown that these films have a microstructure similar to the Co–Ni–O films: an hcp cobalt phase and Co–O crystals of about 5 nm are found. The easy axis of magnetization is about 50 degrees from the tape normal.

These tapes have shown sharp transitions at 100 kfrpi (kilo flux reversal per inch). The high recording densities are a result of the microstructure as well as the higher $M_s$ values (due to the higher cobalt

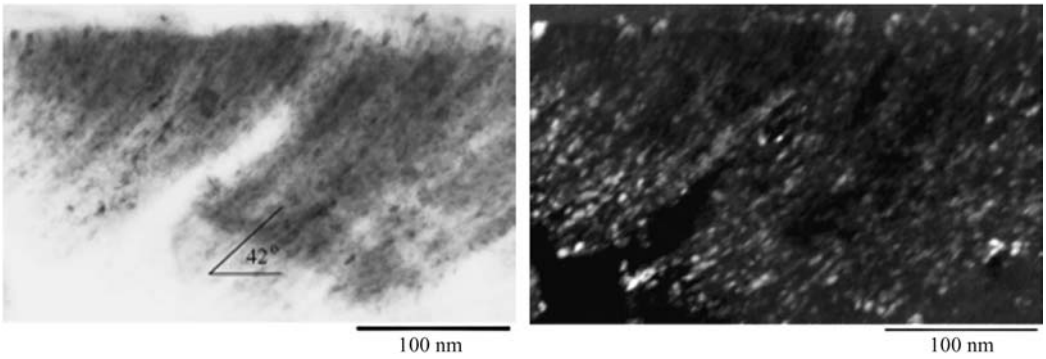

***Figure 10***
Cross sectional TEM views of a Hi8 ME tape. Both the brightfield (left) and the darkfield (right) are shown. In the brightfield view, the initial columnar inclination angle is also indicated.

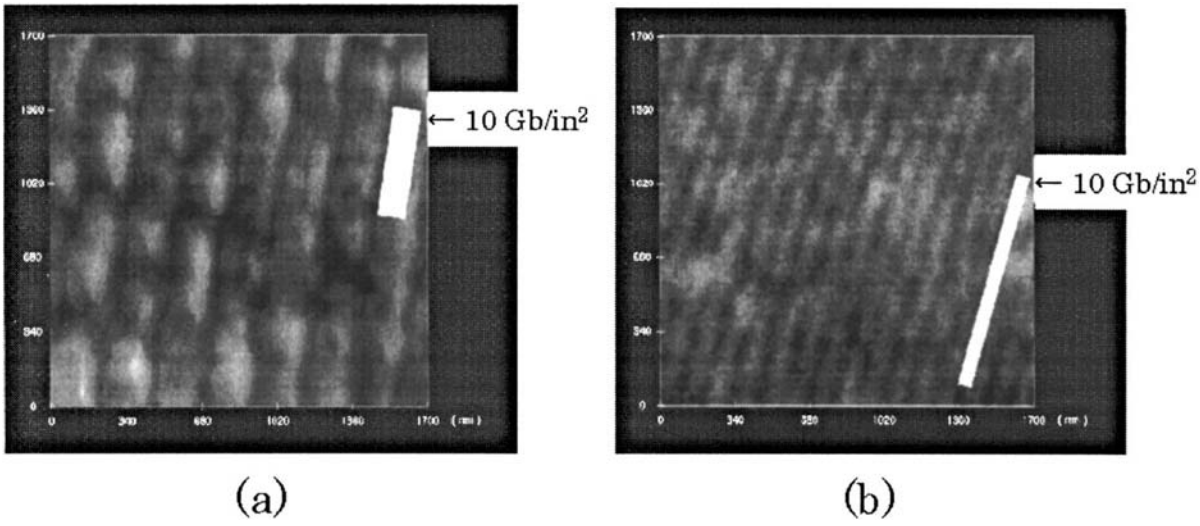

***Figure 11***
MFM images of the recorded magnetization at 200 kfrpi (a) and 400 kfrpi (b) (after Ishida *et al.* 2000).

content) in these media. In Fig. 11 MFM images are shown (Ishida *et al*. 2000) of the magnetization patterns taken at 200 and 400 kfrpi. The white rectangular regions indicate the bit size corresponding to an areal density of $10\,\mathrm{G\,b\,in^{-2}}$. Experimental work has been started (2000) by studying the effect of a CoO underlayer for the Co–O obliquely deposited films. The granular texture of the underlayer promotes separation between the obliquely grown columns and also decreases the size of the columns (Tohma *et al*. 1997).

The difference between Co–Ni–O and Co–O tape is that the latter has higher remanent magnetization and crystalline anisotropy (and thus coercivity). This results in better read/write characteristics and excellent recording performance. This is also due to the very thin DLC protective coatings, which can now be prepared (Yoshida *et al*. 1994, Yoshida *et al*. 1995, Shinohara 1994).

# Metal Hydrides: Electronic Band Structure

Metal–hydrogen systems have been continuously investigated ever since the ability of metallic palladium to absorb large amounts of hydrogen was discovered in 1866. Besides the importance of these systems in fundamental solid-state and materials science, the concern for energy and environmental problems has provided further motivation for studying hydrogen in intermetallic compounds such as $LaNi_5$ since the discovery of the exceptional hydriding properties of this intermetallic by van Vucht *et al.* (1970). Several aspects of the research on metal–hydrogen systems can be found in reviews and books by Mueller *et al.* (1968), Alefeld and Völkl (1978), Buschow *et al.* (1982), Schlapbach (1988, 1992), Fukai (1992), and Wipf (1997).

The insertion of hydrogen in metallic matrices leads to drastic changes in their electronic structure, due in part to structural effects (volume change often accompanied by crystal structure modifications), but mainly due to chemical effects. The presence of hydrogen perturbs the metal–metal bonds and creates new metal–hydrogen interactions, and the additional electrons of the hydrogen atoms modify the electron count and the electronic properties at the Fermi level. For good hydrogen absorbers, the hydrogen per metal atom ratio can vary in a wide range of non-stoichiometry from the solid solution limit to concentrated hydride phases, and the electronic properties at the Fermi level can thus be tuned in a continuous and fascinating way. Electronic band structure studies are useful in understanding, at a microscopic level, the changes in the important physical properties of the matrices on hydrogen uptake such as metal–semiconductor transitions, magnetism, and superconductivity, and thermodynamic properties such as stability, maximum hydrogen absorption capacity, and preferential H site occupancy. A review of the present status, achievements, and limits of the electronic band structure studies of binary transition and rare earth metal hydrides as well as of complex intermetallic hydrides follows, with a particular emphasis on compounds of potential importance for technological applications.

## *1. Methodologies*

The electronic structure problem for a solid involves the study of the light particles, the electrons which, in the Born–Oppenheimer approximation, are assumed to be moving in the electrostatic field of the fixed heavier particles, the nuclei. The energy of the electronic ground state obtained as a function of the fixed nuclei can then be used as a potential energy for the motion of the nuclei.

Since the Schrödinger equation of a system of $N$ interacting particles cannot be solved exactly, it is

usually replaced by an effective Schrödinger equation for one electron moving in the mean field of the other electrons and nuclei. The mean field used for solids is often based on the local density approximation (LDA) of the density functional theory (DFT) developed in the mid-1960s by Hohenberg and Kohn (1964). Besides the electrostatic interactions with the nuclei, this mean field is composed of the Coulomb repulsion due to the electron charge cloud and the exchange and correlation terms; it depends only on the electron density, $\rho(r)$.

In the LDA, the exchange and correlation term is obtained from the many-body theory applied to the electron gas having local density $\rho(r)$. The different *ab initio* techniques used in band structure calculations depend essentially on the approximations used for calculating the effective potential, and on the nature of the basis functions that can be fixed (plane waves, linear combination of atomic orbitals) or energy and potential dependent, as in the augmented plane waves (APW) method. The linear methods such as the linear muffin-tin orbital method (LMTO) and LAPW, use energy-independent basis functions derived from partial waves and combine the advantages of the two methods (see Skriver 1983 and Singh 1994 for reviews); they allow systems of complex structures to be studied using either approximate or full potential treatment. From these studies, total energies, attice parameters, elastic properties, and even fully relaxed structures can, in principle, be obtained. Using the spin-polarization techniques with spin-dependent electron densities, magnetic systems can also be studied.

Improvements beyond the LDA can be included using, for example, the generalized gradient approximation (GGA) and one can correct partly for correlation effects through the so-called GW approximation where G is the exact one-particle Green's function and W the screened Coulomb interaction.

## 2. *Binary Transition Metal Hydrides*

In most of the stable metal hydrides, a simple interpretation of the band structure can be obtained in the following way: since the hydrogen potential is more attractive than the metal atom potential, the lowest energy bands result from the hydrogen–metal bonding and H–H antibonding interactions. The number of corresponding bands is usually equal to the number of hydrogen atoms in the unit cell. The extent of the overlap of these states with higher energy metal states depends on a number of factors such as the energy difference between the metal and H orbitals, and the H–H distances; short H–H distances lead to an increase of the overlap due to a destabilization of the H–H antibonding states usually located at the top of the low-energy H-derived bands. The Fermi level position of the hydride depends crucially on the imbalance between the number of hydrogen-induced new states created below the Fermi level of the pure metal and the number of additional electrons per unit cell brought by the hydrogen atoms. This can either lead to a filling of the metal *d* bands as in the monohydrides, PdH and NiH, or to a depopulation of the pure metal *d* states in the early transition metal and rare-earth di- and trihydrides.

The electronic structure of rocksalt structure hydrides of transition metals of the end of the series such as palladium and nickel has been investigated since the early 1970s (see Switendick 1978 and Gupta and Schlapbach 1988 for reviews). It has been shown in great detail that the filling of the metal *d* bands in the stoichiometric hydride, leads to a drastic decrease of the densities of states at the Fermi level and the disappearance of ferromagnetism in nickel and of spin fluctuations of pure palladium. The Fermi surfaces of the monohydrides are topologically similar to those of noble metals; however, the protonic rigid band model is not quantitatively correct. Band structure calculations have been helpful in evaluating the electronic part of the electron–phonon coupling constant $\lambda$ that controls the superconducting critical temperature $T_c$ in normal superconductors. In PdH ($T_c =$ 9K), and its alloys with noble metals, it is the electron–optical phonon coupling that is responsible for the superconducting properties. The role played by the presence of hydrogen *s* states at the Fermi energy and the low frequencies of the optic modes has been stressed (Jena and Satterthwaite 1983).

Although metal–insulator transitions occurring in bulk yttrium and rare-earth hydrides for hydrogen/metal ratios approaching 3 have been thoroughly investigated (see Vajda 1995 for review), studies of the spectacular optical properties of switchable mirrors based on thin films of $YH_x$ and $LaH_x$ initiated by Huiberts *et al.* (1996) have renewed the interest in the fundamental understanding of the metal–insulator transition as a function of $x$. The metallic properties of dihydrides of trivalent transition metal are very well accounted for by self-consistent band structure calculations. In the dihydrides, the five valence electrons occupy the two low-energy bands associated with metal–hydrogen and hydrogen–hydrogen bonding and the Fermi level falls at bottom of the metal *d* bands that accommodate the remaining electron. This feature of the electronic structure of early transition metal hydrides has been often interpreted in terms of a depopulation of the metal *d* bands in favor of the bonding low energy bands. In fact, in these hydrides the proton is better screened than in PdH or NiH.

In trihydrides of trivalent rare earth, since three M–H and H–H bands are formed below the pure metal *d* states, a semiconducting or semimetallic behavior is expected for these 6 valence electron systems, depending on the existence of an energy

separation or an overlap of the two manifolds. However, band structure calculations within the LDA (Wang and Chou 1995) lead to a band overlap larger than 1 eV for $YH_3$ in the hexagonal $HoD_3$ structure and thus to a metallic state while an optical energy gap of about 2.8 eV is observed in reflection and transmission for $YH_3$. Although LDA is known to underestimate band gaps in other types of semiconductors or insulators, the discrepancy obtained for $YH_3$ seems particularly large and led to further interpretations involving broken symmetry structures and many-body effects beyond the LDA. Using parametrized model hamiltonians, Eder *et al.* (1997) showed that strong correlation effects associated with $H^-$ ions can open a substantial gap due to an energy lowering of the H-valence bands; the singlet formed by the two electrons on the $H^-$ ion bears some similarities with the Zhang–Rice singlet coupling two holes in the high-$T_c$ cuprate superconductors. Electromigration experiments of van der Molen *et al.* (2000) tend to be in support of this picture. Ng *et al.* (1999) also found that many-body effects result in a gap due to a narrowing rather than to an energy lowering of the H-derived bands. Other possible mechanisms such as symmetry-breaking distortions due to hydrogen displacements have been considered in particular by Kelly *et al.* (1997) on the basis of minimum energy structures. Although such symmetry breaking can lead to large gaps, these predictions have not been so far confirmed by the neutron diffraction experiments of Udovic *et al.* (1997).

The relevance of the comparison of gaps obtained from band structure calculations that probe only ground state properties and optical gaps that probe symmetry-allowed direct transitions has been questioned by van Gelderen *et al.* (2000). Parameter-free quasiparticle calculations in the GW approximation lead to a gap of 1 eV while inclusion of the electric dipole matrix elements give a larger optical gap of about 3 eV. According to another GW calculation by Miyake *et al.* (2000), the existence of a gap is due to many-body effects, and does not depend on the exact crystal structure; however, the gap is not due to a narrowing of the H-derived bands but rather to an upward shift of the unoccupied yttrium 4*d* states.

*Ab initio* calculations of the lattice dynamics of $YH_3$ in the $HoD_3$ and in symmetry-broken structures by van Gelderen *et al.* (2001), compared with the high-resolution neutron vibrational spectroscopy data of Udovic *et al.* (1997) support the existence of symmetry lowering in $YH_3$.

Thus, in spite of the most recent developments using state-of-the-art calculations, and experimental data such as neutron scattering and NMR electric field gradient (Zogal *et al.* 2001), the most stable crystal structure and the origin and value of the energy gap of $YH_3$ are still a matter of debate.

For h.c.p. yttrium, the hydrogen solid solution region has been investigated by Wang and Chou (1994) by total energy calculations using pseudopotentials (PP) and plane-wave (PW) basis within the LDA. From their total energy calculations, they found that the tetrahedral sites are more stable than the octahedral ones. A study of various pairings of the hydrogen atoms shows, in agreement with experimental data, that the linear ordering of pairs at the tetrahedral sites bridged by a metal atom is favored.

## 3. *Hydrides of Intermetallic Compounds*

ZrNi was the first intermetallic compound found to reversibly absorb hydrogen (Libowitz *et al.* 1958), thus opening a new field of investigation. A large amount of experimental research on $LaNi_5$ and related compounds was initiated by the work of van Vucht *et al.* (1970). The development of applications of intermetallics, in particular for energy storage (see Dantzer 1997 for a review), led to the search for new hydrogen-absorbing materials. The hydriding properties of AB-type compounds such as FeTi found by Reilly *et al.* (1974) as well as other intermetallic compounds such as Laves phases $AB_2$ have been thoroughly investigated. Band structure studies started only in 1982 (see Gupta and Schlapbach 1988 for review of the early work). An increasing number of *ab initio* investigations of these complex structure systems has become available since then. However, theoretical work on the fascinating role of hydrogen on the magnetic properties of intermetallic compounds (see Buschow *et al.* 1982 and Hilscher and Wiesinger 1991 for reviews) remains to be developed.

### 3.1 *Hydrides of AB Compounds*

#### (a) *Hydrides of ZrNi and ZrCo*

The maximum hydrogen absorption of ZrNi leads to the formation of $ZrNiH_3$ which crystallizes within the CrB-type orthorhombic structure, with a lattice expansion of about 20%. The total density of states (DOS) of the hydride, obtained by LMTO calculations (Gupta 1999) is plotted in Fig. 1. It is characterized as follows. (i) The presence of structure below –4 eV corresponds to metal–hydrogen bonding and H–H interactions. The energy position of this bonding structure agrees with photoemission and x-ray emission data. The contribution of the nickel 3*d* states to the metal–hydrogen bonding is sizeable although it is lower than that of the zirconium 4*d* states. This is due to the larger coordination number of hydrogen with zirconium in the pyramidal $Zr_3Ni_2$ and the tetrahedral $Zr_3Ni$ sites. (ii) The peak of the DOS centered around –3 eV is mostly due to nickel 3*d* states hybridized with zirconium 4*d*. (iii) The main zirconium 4*d* structure with a weak admixture of nickel 3*d* character is located above the Fermi energy.

The zirconium 4*d* DOS is considerably modified by the presence of hydrogen. The total DOS decreases

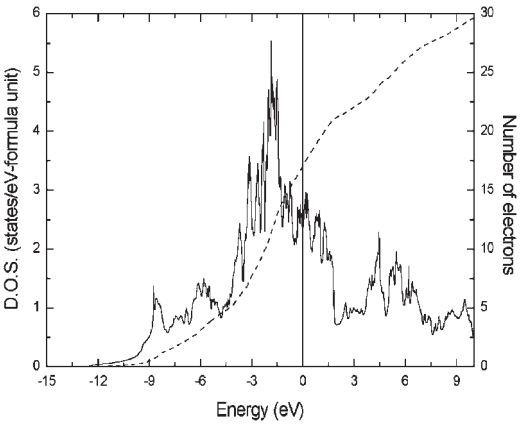

***Figure 1***
Total density of states of $ZrNiH_3$: solid line, left-hand-side scale; number of electrons, dashed line, right-hand-side scale. The origin of energies is the Fermi energy.

slightly from ZrNi to $ZrNiH_3$; the zirconium *d* contribution at $E_F$ decreases from 68% in the intermetallic to 62% in its hydride due to the broadening of the zirconium states and a slight lowering of $E_F$. This feature, which is important for the stability of the hydride, is due to the fact that the Zr–H interaction is strong enough to lower below $E_F$ empty zirconium states of the pure intermetallic compound. In contrast, the Ni–H interaction stabilizes in energy nickel *d* states already occupied in ZrNi, and thus does not contribute to the lowering of $E_F$.

A very unusual feature of the ZrNi-$H_2$ system is that the $Zr_4$ (4*c*) sites that are occupied in triclinic ZrNiH become empty in favor of the pyramidal $Zr_3Ni_2$ (4*c*) and tetrahedral $Zr_3Ni$ (8*f*) sites in $ZrNiH_3$. Total energy calculations were performed for ZrNiH for two possible occupancies of H sites, $Zr_4$ (4*c*) and $Zr_3Ni_2$ (4*c*). Both sites satisfy the usual geometric criteria of minimum hole size and minimum H–H distances. In agreement with neutron scattering data of Westlake *et al.* (1982), the chemical effect associated with the Zr–H interaction and the Fermi level position result in a greater stability of the $Zr_4$ sites. At higher hydrogen concentration, the repulsive H–H interaction at short distances leads to the site occupancy observed in $ZrNiH_3$.

ZrCo is also a good hydrogen absorber that has been considered since the late 1980s as a possible substitute for uranium for the storage of hydrogen and its radioactive isotope, tritium. $ZrCoH_3$ is isostructural to $ZrNiH_3$. The main differences in the DOS of the two hydrides can be summarized as follows: the cobalt 3*d* structure is broader and located at higher energy than the nickel 3*d* peak, leading to a larger overlap with the zirconium 4*d* states. Since the electron count decreases by one per formula unit from $ZrNiH_3$ to $ZrCoH_3$, the Fermi level is closer to the cobalt *d* peak and the total DOS of $ZrCoH_3$ is 30% larger than that of the CsCl structure ZrCo. This indicates a tendency towards magnetic ordering. In $ZrCoH_3$ the metal–hydrogen bonding states are centered around 7 eV below $E_F$, in agreement with photoemission data reported by Gupta and Schlapbach (1988).

*(b) Hydrides of FeTi and NiTi*

FeTi is a Pauli paramagnet of cubic CsCl-type ordered structure. As in isoelectronic and isostructural b.c.c. chromium, the Fermi level falls in the valley of the DOS between occupied *d*-like bonding states derived primarily from iron and empty *d*-like antibonding states derived mostly from titanium. In $\beta$-FeTiH, hydrogen occupies distorted octahedral $Fe_2Ti_4$ sites instead of the more usual tetrahedral sites characteristic of the b.c.c. metals. $\beta$-FeTiH has an orthorhombic structure. The analysis of APW band structure calculations shows that the metal–hydrogen bonding states, centered at 9 eV below $E_F$, are mainly due to the Fe–H interaction that lowers states already filled in the intermetallic. The Ti–H contribution to the bonding is not as large in spite of the greater affinity of hydrogen for titanium; however, this interaction brings new states below $E_F$. The Fermi level of $\beta$-FeTiH is found at higher energy than in FeTi, above the valley of the DOS; the calculated DOS at $E_F$ increases from the intermetallic to its hydride in agreement with the observed increase in the magnetic susceptibility and the electronic specific heat.

The electronic structure of $FeTiH_2$ has been studied ignoring the monoclinic distortion. The low-energy bonding structure grows in width and intensity upon increasing the hydrogen content. The contribution of Ti–H bonding is much larger than in FeTiH since one of the four hydrogen atoms in the unit cell is located closer to two titanium atoms rather than to the iron atoms. The Fermi level of $FeTiH_2$ falls above the valley of the DOS; it is, however, closer to the iron peak than in FeTiH due to the presence of a second H–H derived band at low energies.

Mössbauer isomer shift (IS) experiments reveal a systematic decrease of the *s* contact electron density at the metal site with hydrogen uptake that cannot be explained by a simple renormalization of the wavefunctions due to lattice expansion. Theoretical calculations show that the depletion of the 4*s* metal states at the iron site is due mostly to the Fe–H bonding contribution.

In the hydride of the shape memory alloy NiTi, the bonding properties are similar to those discussed for FeTi. The hydrogen absorption leads also to an upward shift of the Fermi level and the nesting features of the Fermi surface of NiTi disappear. The premartensitic phase transition of NiTi that arises from the condensation of a soft phonon is believed to be due to

strong electron–phonon coupling of nested electronic states at $E_F$. No martensitic transformation occurs in the hydride.

### *3.2 Hydrides of $AB_5$ (Haucke) Compounds*

#### *(a) $LaNi_5$–$H_2$ systems*

Several investigations of this system in the solid solution and concentrated hydride phases have been performed since the last review (Gupta and Schlapbach 1988) using the LMTO (Gupta 1998), the tight binding LMTO (Nakamura *et al.* 1998), and plane wave pseudopotential (PW-PP) methods within the GGA (Tatsumi *et al.* 2001).

$LaNi_5$ crystallizes in the hexagonal $CaCu_5$ structure, space group $P6/mmm$, in which the lanthanum atoms occupy the ($1a$) sites; there are two types of nickel atoms occupying respectively the ($2c$) sites in the basal lanthanum planes ($z = 0$), and the ($3g$) sites in the middle plane ($z = c/2$). The occupied part of the conduction band is dominated by the nickel $3d$ states with a non-negligible bonding contribution of lanthanum $5d$ states. The main part of the lanthanum $5d$ states is, however, located above the Fermi energy. The $4f$ states are empty; they are very localized at energies 3 eV above $E_F$. The nickel $d$ bands are not filled and the intermetallic is not a charge transfer compound as shown by core level photoemission spectroscopy, which does not indicate any significant shift in the lanthanum $3d$ and nickel $2p$ core states in $LaNi_5$.

The calculated total DOS is in agreement with XPS data concerning the width of the occupied states and the high emission observed at $E_F$. The DOS at $E_F$ is high and mostly composed of nickel $d$ states since the lanthanum $d$ contribution is only 4%. This result is in agreement with low-temperature heat capacity measurements which lead to large values of the electronic specific heat coefficient and with magnetic susceptibility data. In spite of the large value of the DOS $LaNi_5$ is found experimentally to be a Pauli paramagnet, although spin polarized band structure calculations (Nakamura *et al.* 1998) lead to a magnetic moment of about 0.6 $\mu_B$ per formula unit.

The crystal structure of $LaNi_5H_7$ has been repeatedly examined by neutron diffraction (see Percheron-Guégan 1995 for review). Although satisfactory refinements have been obtained in the $P6_3mc$ and the $P31c$ space groups, which differ by the presence of a mirror plane, total energy calculations of Tatsumi *et al.* (2001) favor the $P6_3mc$ structure by 0.34 eV per $LaNi_5$.

The DOS of $LaNi_5H_7$ obtained by the LMTO method is shown in Fig. 2. The low-energy structure, extending down to 10 eV below $E_F$, corresponds to seven bands associated with M–H and H–H interactions. The nickel contribution to the hydrogen bonding is larger than the lanthanum contribution. The

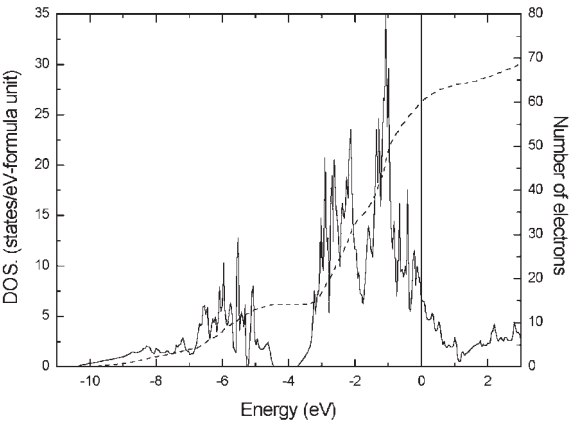

***Figure 2***
Total density of states of $LaNi_5H_7$: solid line, left-hand-side scale; number of electrons, dashed line, right-hand-side scale. The origin of energies is the Fermi energy.

nickel $d$ states are not entirely filled in the hydride, and thus the DOS at $E_F$ remains large in the hydride although a decrease is found from its value in the intermetallic in agreement with the trends observed in electronic specific heat and magnetic susceptibility data.

In the solid solution LaNi–H within the $P6/mmm$ space group, five non-equivalent interstices have been proposed as possible H sites. The total energy calculations of Tatsumi *et al.* (2001) for $La_2Ni_{10}H_1$ using the five possible H site occupancies and including geometry optimization indicate that the ($12n$) site appears to be the most energetically favorable, in agreement with neutron scattering data.

Experimental values of the heats of formation remain difficult to predict accurately from *ab initio* calculations since they result from the subtraction of very large values of total energies. Nevertheless, using full geometry optimization, Tatsumi *et al.* (2001) obtained a heat of formation of $-33$ kJ mol$^{-1}$ $H_2$ for the primary solid solution, in rough agreement with experimental data and a heat of formation of –45 kJ mol$^{-1}$ $H_2$ for $LaNi_5H_7$, a value that is 30–40% lower than the experimental one.

#### *(b) Effects of substitutions*

Substitutions at the lanthanum or nickel sites are used experimentally to modify the thermodynamic properties and play an important role in the selection of the alloys for specific technological applications, since they affect the stability and the maximum hydrogen content (for review see Takeshita *et al.* 1980 and Percheron-Guégan 1995). In order to optimize the choice of intermetallic compound, a better understanding of the role of each alloy constituent on

the electronic properties of the material is crucial. Several semiempirical models (see Griessen and Riesterer 1988 for review) have been proposed for the heat of formation and the heat of solution of metal hydrides and attempts have been made to justify the maximum hydrogen absorption capacity of the matrices. These models show that the energetics of the metal–hydrogen interaction depend both on geometric and electronic factors.

The effect of replacement of nickel by the 3*d* elements manganese, iron, or cobalt, by an *s-p* element of the 3*d* series such as copper, as well as by *s-p* elements such as aluminum and tin have been investigated by LMTO band structure calculations of ordered systems, thus ignoring the effect of disorder and the possible clustering of substituted elements. Neutron scattering data show that the nickel substitutions considered here occur predominantly at the nickel (3*g*) sites, in agreement with total energy calculations which indicate that substitutions at the nickel (3*g*) site are energetically preferred over nickel (2*c*) by several milliRydberg (mRy). Substitutions of nickel neighbors, M, on the left of the periodic table (M = Mn, Fe, Co) does not just lead to a simple depopulation of the nickel 3*d* bands. In all the substituted intermetallics a new narrow sub-band, associated with the 3*d* states of the substituting element M, appears slightly above the nickel *d* bands. The Fermi level of the substituted intermetallic falls in all cases in the narrow antibonding sub-band of the M element while the main nickel 3*d* structure is filled. As a consequence, the DOS at the Fermi level increases further from $LaNi_5$ to $LaNi_4M$ (M = Mn, Fe, Co) indicating the possibility of magnetic ordering as found in spin-polarized calculations by Yang *et al.* (2000). In contrast, for M = Cu, the copper 3*d* subband is centered below the main nickel *d* peak in agreement with photoemission data. The substitution of nickel by copper or by an *s*, *p* element such as aluminum or tin leads to a decrease of the DOS at $E_F$ associated with the progressive filling of the nickel *d* bands.

The heats of formation of the substituted alloys $LaNi_4M$ (M = Mn, Fe, Co, Cu) have been measured by calorimetric methods. In all cases, the substituted intermetallics are less stable than $LaNi_5$. Band structure calculations indicate that the effect of chemical substitution plays an important role in the observed decreased stability of $LaNi_4M$ compared to $LaNi_5$ since the lattice expansion alone accounts for less than 50% of the decohesion of the alloy.

The electronic structures of some hydrides of substituted intermetallic compounds have been studied. In $LaNi_4CoH_4$, the Fermi level corresponds to a filling of the main cobalt 3*d* peak. The maximum hydrogen content appears to be associated with the filling of the cobalt *d* peak: further shift of the Fermi energy in the lanthanum 4*d* bands would cost energy since the DOS is not too high.

### *3.3 Hydrides of $AB_2$ Laves Phases Compounds*

Amongst the intermetallic compounds, the Laves phases have been widely investigated in connection with their superconducting and magnetic properties (see Schlapbach 1988 for review), but also as structural materials due to their high melting temperature and high strength, and as hydrogen storage materials. Besides the rich field of potential applications of the Laves phase hydrides, the understanding of the modifications of the electronic and magnetic properties on hydrogen absorption is of fundamental interest. Although electronic structure studies of many cubic (C-15) and hexagonal (C-14 and C-16) intermetallic compounds are available, band structure calculations of the corresponding hydrides remain rather scarce.

#### *(a) Superconducting Laves phases*

In the superconducting $AB_2$ Laves phases (A = Zr, Hf, B = V) with superconducting critical temperatures $T_c = 8$ K for $ZrV_2$ and $T_c = 9$ K for $HfV_2$, the electron–phonon coupling is expected to be strongly affected by both the lattice expansion and by the change in the nature of the electronic states at $E_F$ on hydrogen absorption.

$ZrV_2$ crystallizes within the C-15 cubic phase above $T_m = 100$ K; below this temperature it undergoes a rhombohedral distortion (Moncton 1973). The interplay between structural and superconducting transitions also observed in the superconducting A-15 materials was widely discussed in the mid-1970s since they are both indicative of large electron–phonon coupling.

The total density of states of the cubic phase is plotted in Fig. 3. The Fermi energy falls in the transition metal (TM) *d* bonding bands close to a peak in the DOS. In agreement with previous work by Klein *et al.* (1983), the value of the DOS at $E_F$ is found to be large and dominated by the vanadium 3*d* contribution, which is about 50% larger than that of the zirconium 4*d* states. The large value of the DOS at $E_F$ is consistent with the large magnetic susceptibility above $T_m$, as well as with the value of the electronic specific heat coefficient obtained from low-temperature microcalorimetry. In the rhombohedral phase, due to the symmetry lowering, the Van Hove singularities of the DOS are considerably smoothed. The total DOS at $E_F$ is found to decrease by 35% from its value in the cubic phase, a result consistent with the sharp decrease of the magnetic susceptibility observed at $T_m$. It is interesting to point out in this connection that two distinct superconducting transitions differing by 1 K have been observed experimentally by Daümer *et al.* (1989) and it has been suggested that the two phases are superconducting, the higher $T_c$ value being attributed to small amounts of untransformed cubic C-15 phase.

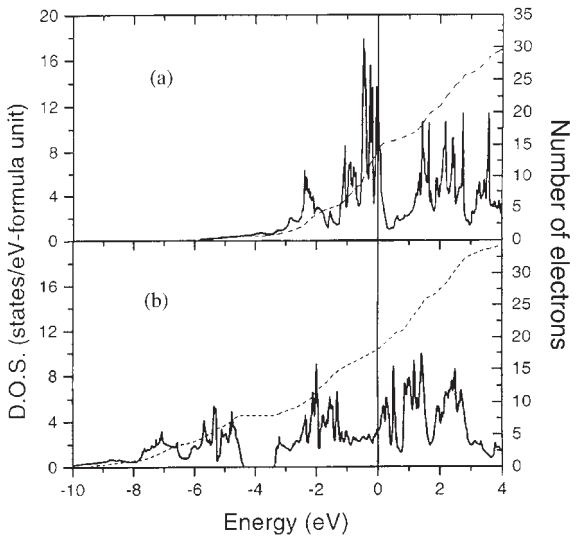

***Figure 3***
Total density of states: solid line, left-hand-side scale; number of electrons, dashed line, right-hand-side scale. (a) $ZrV_2$ C-15 cubic phase (b) $ZrV_2H_4$. The origin of energies is the Fermi energy.

The DOS of $ZrV_2H_4$ calculated using the structural data of Didisheim *et al.* (1981) in the low-temperature tetragonal phase in which the hydrogen atoms order at one of the $Zr_2V_2$ sites is plotted in Fig. 3. The metal–hydrogen bonding states form four bands per formula unit, extending from $-10.3$ eV and $-4.4$ eV below $E_F$. The hydrogen interaction with zirconium is slightly larger but of the same order of magnitude than that with the vanadium states. The DOS at $E_F$ is 72% lower than in the pure intermetallic. In the hydride, as in the pure intermetallic, the states at $E_F$ have mostly a vanadium *d* character. In contrast to the pure intermetallic, the vanadium *p* contribution at $E_F$ is much smaller since the vanadium *p* states are rather found to participate in the metal–hydrogen low-energy states.

The band width and structures obtained in the calculated DOS of $ZrV_2$ and $ZrV_2H_4$ are in good agreement with UV and x-ray photoemission data of Schlapbach *et al.* (1984) and x-ray emission spectroscopic results.

The results of electronic structure calculations can be used in conjunction with experimental data on the vibrational properties to estimate the electron–phonon coupling constant $\lambda$ which essentially determines the value of $T_c$.

Band structure calculations show that the electronic contribution of the electron–acoustic phonon coupling is drastically reduced from the intermetallic to the hydride due to a large decrease of the DOS at $E_F$ and to a reduced value of the vanadium *p* orbital character of the electronic states. The electronic contribution of the electron–optical phonon is very small because the Fermi level of the hydride falls into the metal *d* bands unlike in superconducting PdH. For these two reasons, hydrogen absorption leads to the disappearance of the superconducting properties.

*(b) Hydrides of magnetic Laves phases*

The influence of hydrogen absorption on the magnetic properties of Laves phase $AB_2$ compounds, where A is a transition or rare earth element and B a magnetic or nonmagnetic transition element, is a very vast and fascinating topic that has been experimentally investigated since the pioneering work of Buschow *et al.* (Buschow and van Diepen 1976, Buschow and Sherwood (1977). Due to the great complexity of the phase diagrams and crystal and magnetic structures observed, *ab initio* investigations of these hydrides remain scarce, particularly for systems involving 4*f* electrons of magnetic rare earths and 3*d* moments on the transition elements, which raise the controversy of the validity of localized versus band models.

The insertion of hydrogen in the matrix is expected to affect the magnetic properties via several factors: magnetism is strongly dependent on interatomic distances that increase by the negative pressure effect associated with hydrogen uptake; in addition, the metal hydrogen bonding and the change in the Fermi level position are expected to strongly modify the magnetic interactions betwen A and B atoms.

We shall discuss here band structure results only on magnetic cubic (C-15) $AB_2$ compounds (A = Y, B = Mn, Fe) and their hydrides.

$YMn_2$ is found to be an antiferromagnet: the moments obtained in spin-polarized LMTO calculations, 2.6 $\mu_B$ per manganese atom, are in satisfactory agreement with the experimental value of 2.7 $\mu_B$ found by (Nakamura *et al.* 1983) and previous LMTO (Pajda *et al.* 1996) and tight-binding Hartree–Fock calculations. The total energy of the antiferromagnetic state is 8 mRy lower than that of the paramagnetic phase and the calculated volume change at the antiferromagnetic–paramagnetic transition agrees with thermal expansion measurements. The hydrogen absorption has been investigated since the work of Buschow *et al.* (Buschow 1976). The band structure of $YMnH_x$ at low ($x = 0.5-1$) (Pajda *et al.* 1996) and high ($x = 4$) hydrogen concentrations has been investigated. Total energies performed for three different hydrogen positions in the low concentration limit favor the tetrahedral $A_2B_2$ sites, as observed experimentally. The hydrogenated compounds are found to be antiferromagnetic with a small ferrimagnetic component.

At all hydrogen concentrations, the volume expansion leads to an increase of the magnetic moments while the Mn–H bonding interaction tends to decrease the magnetic moment. The change in the magnetic

properties as a function of hydrogen concentration is rather complex (see Goncharenko *et al.* 1997, Latroche *et al.* 2000) and has not yet been fully studied theoretically.

The magnetic properties of $YFe_2$ obtained from band structure calculations show, in agreement with experimental data of Buschow and van Diepen (1976) and later work, that the intermetallic is ferromagnetic, with a calculated total magnetic moment of 2.86 $\mu_B$ compared to the experimental value of 2.9 $\mu_B$. The moment is essentially localized on the iron atoms; however a small ferrimagnetic contribution due to the more delocalized 4*d* orbitals appears on the yttrium sites. Two hydrides $YFe_2H_x$ have been investigated assuming a hydrogen ordering ($x = 3$) by an augmented spherical wave calculation (Paul-Boncour and Percheron-Guégan 1999 and references therein) and by the LMTO method for $x = 4$. For $YFe_2H_4$ it is found that the 20% lattice expansion leads to an increase of the moment up to 3.93 $\mu_B$ while the chemical metal–hydrogen interaction reduces this value as also observed for $YFe_2H_3$ and $YMn_2H_x$.

## 4. *Hydrides of Intermetallic Compounds with Transition and Alkali or Alkaline-earth Elements*

The search for new storage materials of light weight and good hydrogen absorption capacities, as well as the fundamental interest in hydrides of metals with unusual coordination number or valence, led to the synthesis and characterization of a number of ternary hydrides of general composition $A_xM_yH_z$ where A forms binary insulating hydrides and B forms rather metallic hydrides (see Yvon 1994, Bronger 1995 for reviews).

These hydrides present interesting features from a theoretical point of view due to (i) the possible coexistence of ionic, covalent, and metallic bonding of hydrogen with A and B, (ii) the electrical properties can vary from those of ionic insulators to metallic systems, and (iii) the possibility of finding superconductivity.

### 4.1 *$Mg_2NiH_4$, $Mg_2CoH_5$, $Mg_2FeH_6$ and Related Hydrides*

Hydrides of the series $A_2MH_6$ (A = Mg, Ca, Sr, M = Fe, Ru, Os) crystallize in the cubic $K_2PtCl_6$ structure while $Mg_2CoH_5$ and $Mg_2NiH_4$ are present above 500 K as a high-temperature cubic phase and low-temperature phases of lower symmetry. In the cubic phases the metal lattice is of antifluorite type with large M–M distances. The hydrogen atoms form octahedral cages around the M atom in $A_2MH_6$ with short M–H distances. The hydrogen positions of the high-temperature phases of $Mg_2NiH_4$ and $Mg_2CoH_5$ are believed to result from the thermal average of square planar or tetrahedral configurations around nickel and square pyramidal arrangement of hydrogen atoms around cobalt. These hydrides correspond to 18 valence electron compounds; the hydrogen content can be increased by a corresponding decrease of the transition metal valence.

The band structures (Gupta and Schlapbach 1988, Orgaz and Gupta 1993, Garcia *et al.* 1999) can be interpreted in terms of coordination chemistry since the M–H cages are weakly coupled. Two types of bonds coexist due to the covalent M–H interactions and the ionic character of the A element. The compounds are found to be insulating. In hydrides with octahedral coordination, $A_2MH_6$, the gap opens between the three M *d*-$t_{2g}$ nonbonding and the M *d*-$e_g$, hydrogen *s* antibonding states. In $Mg_2NiH_4$, with tetrahedral $NiH_4$ cages, the gap occurs between the five nickel *d* nonbonding and the Ni–H *s* antibonding states. In $Mg_2CoH_5$ with the square pyramidal configuration, the gap appears between the four nonbonding M *d* and the antibonding $d_{x2-y2}$ hydrogen *s* antibonding states as expected from coordination chemistry. The maximum hydrogen content in these hydrides corresponds to the complete filling of bonding M–H and nonbonding M states, a situation that is known to be energetically favorable. The values of the energy gaps obtained in the LDA calculations are in reasonable agreement with experimental observations although they are expected to be affected by correlation effects in systems with narrow *d* bands.

### 4.2 *Palladium-based Ternary Hydrides*

Since hydrides of palladium and its alloys with filled *d* bands are superconductors with moderate but sizeable critical temperatures (PdH ($T_c = 9$K), $Pd_{0.55}Cu_{0.45}H_{0.7}$ ($T_c = 16$K)), the synthesis of ternary hydrides of palladium with filled *d* bands and electronic properties at the Fermi level similar to those of PdH could result in an important electron optical phonon coupling and superconductivty.

$Li_2PdH_2$ and $Na_2PdH_2$ have been synthesized by Kadir *et al.* (1991). These hydrides are characterized by a body-centered tetragonal array of linear $PdH_2$ entities along the *c*-axis of the tetragonal unit cell, with short Pd–H distances. According to conventional valencies these compounds should be insulating; however, band structure calculations by Gupta (1993) and Switendick (1993) show that these 14 valence electron hydrides are rather semimetallic with a low DOS at $E_F$ associated to a weak overlap between the seven palladium *d*, hydrogen *s* derived bands and the eighth band mostly due to lithium or sodium *p* states.

The crystal structure of $K_2PdH_4$ is characterized by a b.c.t. array of square planar $PdH_4$ units with short Pd–H distances; this 16 valence electron hydride is found to be insulating with a gap of 1.8 eV. Its electronic structure can be interpreted in terms of

coordination chemistry of $(PdH_4)^{-4}$ entities, with square planar $D_{4h}$ point group, interacting only weakly, the alkali counterion neutralizing the structure.

Platinum-based compounds such as $K_2PtH_4$ and $Na_2PtH_4$ have also been synthesized and characterized. In these hydrides, the $PtH_4$ units have different orientations than in the palladium-based compounds. These quasimolecular complexes are all found to be insulating (Orgaz and Gupta 2000).

The electronic structure of the palladium-based cubic perovskite structure $APdH_3$ (A = Sr, Eu, Yb) and the complex hydride $PdSr_2LiH_5$ has been investigated in connection with the possible occurrence of superconductivity. In the hydrides $APdH_3$ the electrons of the divalent element are essentially transferred to the Pd–H states, the main part of the *d* bands of palladium are essentially filled, and the Fermi level falls in the antibonding Pd–H states. These hydrides are metallic with DOSs at $E_F$ as in PdH and noble metals. The crystal structure of the complex $PdSr_2LiH_5$ hydride can be understood from the stacking of cubic perovskite insulating $SrLiH_3$ subunits and defective perovskite $SrPdH_2$. A metallic behavior is found for $PdSr_2LiH_5$. As in $APdH_3$, the essential part of the palladium *d* states are filled and a non-negligible contribution of the hydrogen *s* states is found at $E_F$. A study of the electronic part of the electron–phonon coupling shows that the hydrogen contribution is non-negligible, although it is always smaller than in superconducting PdH. If the optical phonon modes, not yet known, are not too high, hydrides of this family could be potential candidates for superconductivity. Experimentally only $NaPd_3H_2$, which can be viewed as a distorted sodium-substituted palladium hydride, has been found to be superconducting below 2 K, while $CaPd_3H$ is metallic but not superconducting as shown by Rönnebro *et al.* (2000).

## 5. Perspective

Band structure calculations have greatly improved, at a microscopic level, our understanding of the electronic properties of metal–hydrogen systems. In the near future, further progress needs to be made in the study of compounds of greater structural complexity, in the areas of the thermodynamic and elastic properties, and especially in the rich field of magnetism.

## Metal Hydrides: Magnetic Properties

Magnetism in the solid state covers a wide range of phenomena, which are intimately correlated with the localized/delocalized nature of the electrons, the crystal structure, the electronic structure, and the metallurgy

of a given metal or compound. The absorption of hydrogen in a metal or intermetallic compound leads to drastic changes of the electronic structure not only due to volume and structural changes but also due to chemical effects (see *Metal Hydrides: Electronic Band Structure*). In a simplified view the effect of hydrogen absorption upon the magnetic properties in transition metals and their intermetallics is twofold: First, the presence of hydrogen perturbs the metal–metal bonds by creation of metal–hydrogen interactions, and hydrogen contributes two electronic states but only one electron which changes the Fermi level and hence modifies the transition metal moment in the band picture. Second, hydrogen absorption commonly results in a volume expansion (i.e., negative pressure), which influences not only the strength of the magnetic exchange interaction between localized/delocalized electrons but increases also the extent of localization of their associated magnetic moments. In other words, a larger volume implies narrower bands which, on the one hand, gives rise to more localized moments and, on the other hand, may reduce the hybridization of different electronic states present in the host compound. Accordingly, the ground-state properties such as the type of magnetic order (e.g., ferro-, ferri-, antiferromagnetism, etc.), Pauli- or Van Vleck paramagnetism or superconductivity as well as their temperature dependences are significantly changed upon hydrogenation. For experimental and theoretical details, we refer to the comprehensive review articles of Buschow *et al.* (1982), Buschow (1984), Wiesinger and Hilscher (1988, 1991), Vajda (1995), and Pourarian (2002).

For the description of magnetic properties particularly the localized/delocalized nature of the electrons appears to be an important factor. One has to consider two extreme limits.

- The localized limit for which the magnetic moments and their fluctuations are localized in real space (delocalized in reciprocal space). For these systems the Heisenberg model, at least as a prototype, is appropriate where the phenomenological Weiss molecular field is just the exchange interaction which tends to align spins parallel (or antiparallel) when the exchange integral is negative (or positive). Here the carrier of magnetism is a spin and/or an angular momentum yielding localized moments, and the magnetization vanishes at $T_C$ because of disorder between the local moments due to thermal fluctuations. Nevertheless, their absolute value (or amplitude) remains almost independent of temperature. Typical examples are 3*d*-transition metal oxides that are insulators. In these materials, the exchange interaction proceeds via oxygen, which is called superexchange. Another type of compounds with strongly localized moments are rare-earth intermetallics where the localized moment arises from the 4*f*-electrons that are well localized in space and also well screened from the surrounding by 5*s*- and 5*p*-electrons. The magnetic interaction between the 4*f*-moments is mediated by the oscillatory polarized conduction electrons and is called Ruderman–Kittel–Kasuya–Yosida (RKKY) exchange.
- The itinerant limit for which the moments and their fluctuations are delocalized in real space (localized in reciprocal space) with their amplitudes (or magnitude) being strongly temperature dependent. The simplest approach is the Stoner–Wohlfarth itinerant electron model where the magnetic moment is determined by the number of unpaired electrons in the exchange-split spin-up and spin-down bands. With growing temperature the thermal excitations of electron–hole pairs (single-particle excitations) reduce the exchange splitting and thus favor the paramagnetic state at elevated temperature. Consequently, the magnetization disappears if the absolute value of the magnetic moment goes to zero, which happens if the exchange splitting is zero. This model sufficiently describes magnetism in metals at 0 K. Unfortunately, it predicts Curie temperatures ($T_C$) which are 5–10 times larger than those observed experimentally, because single-particle excitations are not (or only to a reduced extent) responsible for metallic magnetism at elevated temperatures. Accordingly, for quite a long time 3*d*-magnetism has been a controversial topic, where still some problems are not completely settled. The reason for this controversy is the absence of a general agreement upon the microscopic nature of the magnetic excitations at finite temperatures in particular above and below $T_C$.

To solve these inconsistencies, thermally induced collective excitations of the spin system—as they are well known for localized spins—are included by Moriya to formulate a unified picture of magnetism. A similar and very promising approach by Murata and Doniach was to introduce local and random classical fluctuations of the spin system being excited thermally which are called spin fluctuations. Both models become equivalent at high temperatures and lead to a Curie–Weiss law above $T_C$ and allow the calculation of realistic *ab initio* Curie temperatures (for details see, e.g., Mohn (2003) and references therein).

## 1. Binary Hydrides of d-metals

Most transition metals form hydrides at sufficiently high pressures of hydrogen. The difficult high-pressure preparation technique and the rather limited hydrogen solubility of *d*-metals constrain the available results, which are reviewed by Antonow (2002). The following binary hydrides were found to exhibit magnetic order: $\alpha$-$MnH_x$, $\gamma$-$MnH_x$ and $\varepsilon$-$MnH_x$ order antiferromagnetically, the latter two with a collinear spin structure ($T_N \gg 300$ K for $\gamma$-$MnH_x$ and $T_N \approx 360$ K for $\varepsilon$-$MnH_x$). *Double h.c.p.* $\varepsilon'$-$FeH_x$ ($x \approx 1$) is a ferromagnet with $T_C$ exceeding room temperature, while h.c.p. $\varepsilon$-$FeH_{0.42}$ is

paramagnetic down to 4 K. Hydrides of Co are ferromagnets where, in the $\varepsilon$-hydrides, the moments are aligned along the $c$-axis and decrease with increasing hydrogen content at a rate of $0.36\mu_B$ per H atom. $\gamma_1$-Ni hydride is ferromagnetic and $T_C$ decreases with hydrogen content. The interpretation of the drastic changes of the magnetic properties mainly involves phenomenological and rather qualitative arguments based on the rigid band model. Exceptions are binary and ternary Pd-hydrides where superconductivity is induced by hydrogen absorption (see *Metal Hydrides: Electronic Band Structure*).

## 2. Binary Hydrides of Rare Earth and Actinides (4f- and 5f-metals)

Contrary to $d$-metals the rare earths absorb hydrogen readily and form solid solutions and binary hydrides ($RH_x$) with stoichiometries $x = 2$ and $x = 3$. The generic phase diagram according to Vajda (1995) is displayed in Fig. 1. It consists of three basic parts: (i) the metallic solid solution ($\alpha$-$RH_\delta$) with H inserted into the tetrahedral interstices of the host metal; (ii) the metallic dihydride $\beta$-$RH_{2\delta}$ crystallizing in the f.c.c. fluorite system where two hydrogen atoms occupy the two available tetrahedral sites; (iii) the insulating h.c.p. trihydride $\gamma$-$RH_{3-\delta}$ where both tetrahedral sites and one octahedral site are filled up with H. In the case of $x$ approaching 3, metallic

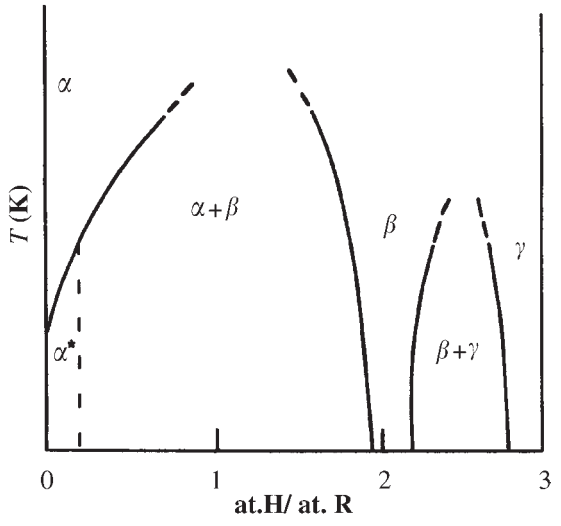

*Figure 1*
Schematic phase diagram for R–H systems: α, solid solution, α*, ordered H-sublattice in some R–H solutions; $\beta$, dihydride; $\gamma$, trihydride (reproduced by permission of Vajda (1995) from *Handbook on the Physics and Chemistry of Rare Earths*, Vol. 20, pp. 207–29; © Elsevier).

conductivity disappears, which has been attributed to the formation of a low-lying $s$-band with the capacity to hold six valence electrons which has been confirmed to a great extent by band structure calculations. In fact, in this simple view, the number of electrons supplied to the conduction band by one R-atom and three H-atoms is equal at $x = 3$. Since this low-lying bonding band is completely filled up with electrons, in $RH_3$ conduction electrons are no longer present, prohibiting interactions occurring via the RKKY mechanism. This accounts for the suppression of magnetic interactions to below 3–5 K, where magnetic dipole–dipole interactions become important, which is fairly generally observed, indeed.

Considerable progress has been achieved with respect to the details in off-stoichiometric $\beta$- and $\gamma$-phases since the discovery of the metal–insulator transitions by Vajda (1995) and the associated optical properties applicable to switchable mirrors (Huiberts *et al.* 1996). The magnetic properties in the rather extended solid solution ($\alpha$-$RH_\delta$) and dihydride ($\beta$-$RH_{2\pm\delta}$) are significantly affected by ordering interactions between the $\delta$-hydrogens. In the case of magnetic rare earths, this gives rise to various fascinating phenomena caused by the competition between magnetic anisotropy and RKKY interactions on the one hand and the hydrogen sublattice via crystal field interactions on the other. The peculiar quasilinear H–R–H ordering along the $c$-axis in the $\alpha$-phase of some h.c.p. rare earth (as well as in Sc and Y) gives rise to the low-temperature ordered $\alpha^*$–phase which affect the modulated magnetic structures (i.e., sinusoidal or conical) via Fermi surface topology (Vajda 2000). In the $\beta$-$RH_{2+\delta}$ phase, the excess $\delta$-hydrogens occupying the octahedral sites in the $CaF_2$ structure frequently order in a tetragonal hydrogen sublattice corresponding to an $RH_{2.25}$ stoichiometry which modifies the various commensurate and incommensurate magnetic structures, sometimes leading to the appearance of short-range magnetic order or even yielding a breakdown of magnetism.

From the early actinides (Th, Pa, and U), only $\alpha$- and $\beta$-$UH_3$ order ferromagnetically below $\sim$ 180 K (for a summary, see Wiesinger and Hilscher 1991), while the heavier rare-earth-like actinide hydrides crystallize in the $CaF_2$ structure. Rather similar behavior is observed for $AH_{2+\delta}$ systems (A = Np, Pu, Am) as for the isostructural $\beta$-$RH_{2+\delta}$ (Vajda 2000).

## 3. Hydrides of Intermetallics Containing d-transition Metals and Rare-earth Metals

When a transition metal (TM) is alloyed to a rare earth (R) or a related metal as Y, Sc, and Zr, the R–*3d* exchange interaction (*3d–5d* overlap) leads to a significant reduction of the TM moment. The strong hydrogen affinity of the R-metals brings about a

decrease of the *3d–5d* overlap in the hydrides. Thus, the absorption of hydrogen frequently cancels this moment depression to a certain degree. This partial restoration of the *3d*-moment is interpreted as a hydrogen-induced screening effect. In R–*3d* intermetallics and their hydrides, where both the R- and the *3d*-elements carry a magnetic moment, we can distinguish between three main types of magnetic interactions which are quite different in nature: (i) between the localized 4*f*-moments; (ii) between the more itinerant 3*d*-moments; and (iii) between 3*d*- and 4*f*-moments. Generally, it is observed that these interactions decrease in the following sequence: $3d-3d > 4f-3d > 4f-4f$.

In contrast to binary 4*f*-hydrides, for ternary R−3*d* hydrides no similar straightforward arguments can be given about the hydrogen-induced change of the magnetic order. The only statement being generally valid is that upon hydrogen absorption the magnetic order of R–Co and R–Ni compounds is considerably weakened. However, this is only rarely observed in the case of R–Fe compounds. Thus, hydrogen absorption usually weakens the magnetic coupling between 4*f*- and the 3*d*-moments via the reduction of the $4f-3d$ exchange interaction that can lead to substantial changes of the 3*d*-transition metal moment in either way. This is explained by a reduced overlap of the 3*d*-electron wave functions with the 5*d*-like ones due to the narrower bandwidth as a consequence of the hydrogen-induced increase in volume. Furthermore, concentration fluctuations of H-atoms over a few atomic distances may frequently occur leading to a difference in electron concentration between one site and another. This can therefore lead to a varying coupling strength and/or to competing interactions, giving rise to frustration and freezing phenomena at low temperatures. Additionally, a disturbance of the lattice periodicity takes place in the hydrides, reducing the mean free path of the conduction electrons. This leads to a damping of the RKKY conduction electron polarization, which in turn decreases the magnetic coupling strength.

If the magnetic order in R-intermetallics is dominated by 4*f*-moments, the concept of an R–H charge transfer by analogy with binary rare-earth hydrides has proved to be a reasonable first approach for explanations of hydrogen-induced changes in magnetism.

In the case where 3*d*-magnetism is dominant in the R–3*d* compounds, no general rule can be given. Commonly, hydrogen absorption leads to a loss in 3*d*-moment in Ni- and Co-based intermetallics, but to an enhancement of the Fe-moment. For Mn-intermetallics both changes from paramagnetism to ferromagnetism and vice versa are obtained. In Fe-containing intermetallic hydrides the 3*d*-states are localized to a greater extent compared to the parent compound. This leads to an enhancement of the molecular field, which, however, is opposed by the influence of the increased Fe–Fe distance, tending to reduce it. As it is observed experimentally, the former mechanism is apparently the dominating one, yielding an increased or at least an unchanged molecular field constant $n_{RFe}$ upon hydrogenation.

When discussing the hydrogen-induced change of the magnetic properties, one is, among other things, faced with the problem of finding reliable moment data. Frequently, one has to rely on magnetization measurements. The latter may lead to wrong results in those cases, where for experimental reasons (lack of a high field facility), only incomplete saturation has been achieved. Particularly in the case of ternary hydrides, magnetic saturation is difficult to obtain. An alternative way is offered by Mössbauer measurements. However, the problem of correlating the hyperfine field unambiguously with the magnetic moment (particularly in the case of the hydrides) still remains. Only in few cases one can refer to reliable data from neutron diffraction experiments. For a detailed summary of the experimental data in this field, we refer to Yvon and Fischer (1988).

Subsequent to the availability of synchrotron radiation (see *Magnetism: Applications of Synchrotron Radiation*), x-ray absorption (XAS), and x-ray circular magnetic dichroism (XCMD), several studies were devoted to investigations of the electronic states in hydrides. The former simplified approach, where changes of magnetic properties upon hydrogenation were frequently attributed to the influence of hydrogen on the 3*d*-sublattice only, has to be modified. On the contrary, an important role is played by the rare earth sublattice through the R(*5d*)–TM(*3d*) hybridization, which is weakened upon hydrogen uptake. XCMD experiments at the $L_{2,3}$ edges of a rare-earth element and K-edge of a 3*d*-transition element are particularly suitable to study hydrogen-induced changes of the magnetic properties, since they allow to probe directly the local states of the transition and the rare-earth element. Furthermore, the valence of the latter species can be determined, which in the case of Ce and Yb compounds is of essential importance. x-ray absorption near edge structure (XANES) studies are capable for probing both the electronic unoccupied states and the local structure at a selected site. In particular, $L_{III}$ absorption spectroscopy yields information on inner shell properties, 4*f*-occupation numbers, and valence shell properties of rare-earth systems that is related to the magnetic properties of the system. Due to an unstable valence, Ce and Yb compounds are of particular interest in metal hydrogen studies.

## 4. *Hydrides of Mn Compounds*

Particularly for Mn-containing ternary hydrides—where mainly $RMn_2$ and $R_6Mn_{23}$ have been investigated—no general prediction can be made for the changes in magnetic properties upon hydrogen

uptake. Onset and complete loss of magnetic order after hydrogen absorption are found, as well a substantial reduction of $T_C$ and the magnetization. Moreover, spin glass behavior is frequently obtained for Mn-rich ternary hydrides, which most probably has to be related to the presence of Mn segregations. The reason for these heterogeneous results probably lies in the specific sensitivity of the magnetic properties of Mn compounds upon interatomic distances. Particularly in Mn compounds a critical Mn–Mn distance is of essential importance for the occurrence of magnetic order. In contrast to parent $RMn_2$ compounds, in the corresponding hydrides the Mn–Mn magnetic interaction dominates and imposes magnetic order in the rare-earth sublattice, with the result that both the R- and Mn-sublattices order at the same temperature. To completely understand the complex process of magnetic ordering present in these compounds, band structure calculations have to be performed and considered.

The Laves-phase compounds $RMn_2$ have been intensively studied because of their peculiar structural and magnetic properties. Two magnetic sublattices are present: the first one is built up from well-localized 4*f*-moments of the rare earth, whereas the second one consists of unstable 3*d* Mn-moments, strongly dependent on the Mn–Mn distance. The topological frustration present in the parent compounds is released when hydrogen is absorbed by forming changes of the local symmetry of the magnetic ions. The hydrogen-induced lattice expansion stabilizes the Mn-moments (Goncharenko *et al.* 1999). Large increases of $T_C$ are observed upon hydrogen uptake. The spin orientation in the hydrides commonly, differs from that observed in the parent compounds and cannot be explained by a unique set of crystal field parameters. This leads to the suggestion that the hydrogen superstructure significantly influences the anisotropy (Cadavez-Peres *et al.* 2001). $CeMn_{1.8}Al_{0.2}$ absorbs more than 4.4 H atoms/f.u., thereby undergoing a volume expansion ($\Delta V/V = 42.5\%$, which is the largest known among metal hydrides). Concomitantly, a metal atom site exchange occurs over a distance of 2.7 Å at room temperature, which is the first of that type observed in Laves phases. The exceptional high mobility of the metal atom substructure is presumably related to the valence transition $Ce^{+4}$ to $Ce^{+3}$, which is accompanied by a change from Pauli paramagnetism to antiferromagnetic order below 75 K and Curie–Weiss susceptibility above; see Fig. 2 (Filinchuk *et al.* 2003).

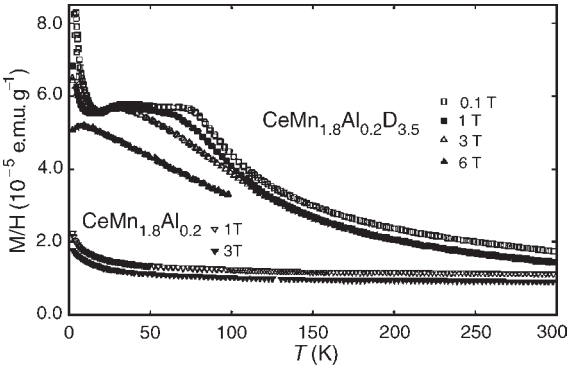

***Figure 2***
Zero-field cooled susceptibility (M/H) as a function of temperature for $CeMn_{1.8}Al_{0.2}$ and $CeMn_{1.8}Al_{0.2}D_{3.5}$; the antiferromagnetic order of $CeMn_{1.8}Al_{0.2}D_{3.5}$ at about 75 K is shifted to below 10 K at 6 T.

## 5. *Hydrides of Fe Compounds*

In this case the hydrogen-induced influence on the magnetic properties is less pronounced than in Mn-compounds. Predominantly, the following stoichiometries were studied: $R_2Fe_{17}$, $RFe_{11}X$, $R_2Fe_{14}B$, $R_6Fe_{23}$, $R_6Fe_{13}X$, $RFe_3$, $RFe_2$, and $Zr_3Fe$. Various neutron diffraction experiments proved that there is an increase of the Fe-sublattice moment after hydrogenation, whereas the rare-earth sublattice moment is generally reduced. The Curie temperature can show changes in either direction; the behavior depends on the amount of Fe in the compound. Compensation points, whenever present in the parent material, are lowered upon the absorption of hydrogen, thus reflecting the reduced rare-earth sublattice contribution to the total magnetic order. In several cases spin reorientations upon hydrogen insertion were found. When the R–Fe exchange is comparable to the local anisotropy energy of the rare earth, the R-moment is strongly coupled to the crystal field axis randomized by the presence of hydrogen. This may lead to a fanning of the R-moments at low temperatures. In that case a hydrogen-induced rise in moment is observed; it only takes place up to a certain hydrogen concentration, beyond which a complete loss of any magnetic order is found, frequently accompanied by complete damage of the lattice periodicity.

A systematic study of almost the whole series $R_2Fe_{17}H_x$ was performed (see, e.g., Grandjean *et al.* 2002). Hydrogen uptake commonly increases the magnetic ordering temperature as well as the saturation magnetization. Spin reorientations present in the parent compound are suppressed by the insertion of hydrogen, an exception being $Pr_2Fe_{17}H_x$. There, hydrogen uptake leads to a slight decrease of the $^{57}Fe$ hyperfine field. In $Ce_2Fe_{17}$, on the other hand, the absorption of hydrogen changes the helical magnetic structure into ferromagnetic alignment of the magnetic moments within the basal plane.

While in the context of metal hydrides predominantly polycrystalline materials (mainly powder) are studied, in rare cases (as for $RH_x$) single crystals of hydrides could be prepared that allow us to study, for

example, the magnetocrystalline anisotropy in $R_2Fe_{17}H_x$ ($x = 0, 3$) crystals (Tereshina *et al.* 2003). In one case (R = Ho) hydrogen induces an FOMP-type transition; for R = Er this transition disappears after the absorption of hydrogen. For R = Tb an easy cone transition is observed upon H-uptake. The experimental results are interpreted on the basis of the orientation of the 4*f*-shell quadrupolar moment with respect to the direction of the electric field gradient due to the charges of the surrounding ions.

Ce exhibits intermediate valence behavior ($v = 3.3$) in $CeFe_{14}BH_x$, $CeFe_{11}H_x$, and $Ce_2Fe_{17}H_x$; this behavior is essentially unaffected by the absorption of hydrogen. This is in contrast to the usual finding that upon hydrogen absorption the significant volume expansion is associated with a change of tetravalent to trivalent Ce. In this case, the increase of the magnetization upon hydriding is not due to a significant Ce 4*f*-contribution via localization of the Ce 4*f*-moment. From XCMD signals a complete 4*f*-delocalized band is obvious, confirming that the itinerant character of the Ce 4*f*-states is also retained in the hydrides. This has to be attributed to the variation of the *3d*(Fe)–*5d*(Ce) hybridization. It appears that although the hydrogen uptake is due to the H–Ce interatomic chemical attraction, the effect on the physical properties is rather due to a change of the Fe sublattice. The magnetism on the Fe-sites is enhanced upon hydrogen uptake, even if hydrogen is not attracted by Fe-atoms. The large-hydrogen-induced volume increase cannot be attributed to a significant change in the Ce valence; it is mainly due to a relaxation of the stressed Fe–Fe interatomic distances (Isnard *et al.* 1994).

In recent investigations on the high-performance Nd–Fe–B magnets, a group of compounds with the stoichiometry $R_6Fe_{13}X$ was found as an intergranular phase in sintered magnets. Since the Nd–Fe–B magnets are frequently produced via the hydrogen decrepitation (HDDP) process, $R_6Fe_{13}X$ hydrides became a matter of interest. Despite their large Fe-content, the parent compounds exhibit a low net magnetic moment below 1 $\mu_B$/f.u. due to a ferrimagnetic coupling of the moments. Upon hydrogen uptake, these compounds behave as ferromagnetic, exhibiting moments above 25 $\mu_B$/f.u. at room temperature (Leithe-Jasper *et al.* 1996). In the case of X = Sn, it was demonstrated by $^{119}$Sn Mössbauer spectroscopy that a small hyperfine field, being absent in the parent compound, develops at the Mössbauer nuclei upon hydrogenation (Leithe-Jasper *et al.* 1997).

The itinerant metamagnetic transition associated with large magnetocaloric effects in $La(Fe_xSi_{1-x})_{13}$ triggered the investigation of the corresponding hydrides (Fujita *et al.* 2003). Hydrogen absorption increases both $T_C$ and the metamagnetic transition significantly and thus makes $La(Fe_xSi_{1-x})_{13}H_y$ as one of the most promising magnetic refrigerants working in a wide temperature range around room temperature and in fairly low magnetic fields (see *Magnetic Refrigeration at Room Temperature*).

## 6. *Hydrides of Co Compounds*

Compounds with various stoichiometries ($R_2Co_{17}$, $R_2Co_{14}B$, $RCo_5$, $R_2Co_7$, $RCo_3$, $RCo_2$) were studied extensively in the past, the results being treated in the reviews cited. In contrast to the corresponding Fe-systems, in all the Co-based systems hydrogen uptake reduces the magnetic order of the Co-sublattice. Values obtained for Curie temperatures and magnetic moments (R as well as Co moments) in the hydride are lower compared to those in their parent counterparts. The hydrides generally show a pronounced resistance against magnetic saturation. With ultra-high fields (up to 110 T) and high-pressure experiments ($P = 12$ kbar), it was possible to estimate the effects of lattice expansion and changes of the electronic structure in $YCo_3H_{1.8}$ and $Y(Co_{0.88}Fe_{0.12})_3H_x$ where itinerant metamagnetic transitions occur from the low-moment to the high-moment state. Upon hydrogen uptake the critical field $B_c$ is substantially reduced (see Fig. 3), whereas upon applying pressure the critical field $B_c$ increases at the rate of $dB/dP = 1.46\,T\,\text{kbar}^{-1}$. From these data it was concluded that both contributions—the lattice expansion and changes of the electronic structure—are of similar magnitude (Bartashevich 2001), which should be proved by band structure calculations.

Yamamoto *et al.* (2002) reported on an increase of the equilibrium hydrogen pressure as a function of magnetic fields in $RCo_5H_x$ (R = La, Pr, Sm) according to the relation $\ln(P^*/P_0) = 2B\Delta M_S/RT$, where

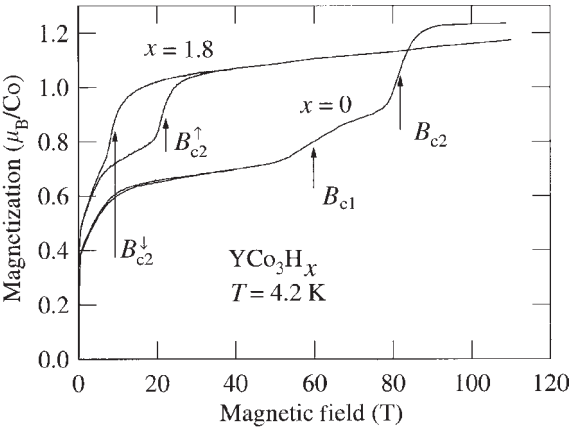

***Figure 3***
Magnetization as a function of external field for $YCo_3$ and $YCo_3H_{1.8}$; the arrows indicate the different critical field for the metamagnetic transition (reproduced by permission of Bartashevich *et al.* (2001) from *Physica B* **294–295**, 186–9; © Elsevier).

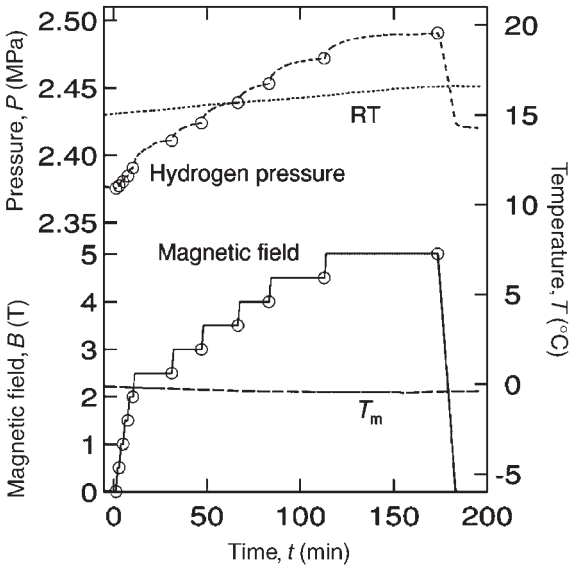

***Figure 4***
Time variation of magnetic field and hydrogen pressure, sample temperature (dashed line), and room temperature (dotted line) for $PrCo_5H_{4.42}$; the circles indicate the equilibria (reproduced by permission of Yamamoto (2002) from *J. Alloys Compnds.* **330–332**, 56–8; © Elsevier).

$P^*$ and $P_0$ are the equilibrium hydrogen pressures under a magnetic field $B$, $R$ is the gas constant is and $\Delta M_S$ is the change of the saturation magnetization per desorbed mole of hydrogen. Figure 4 demonstrates the correspondence between the field variation and changes of the hydrogen pressure, the effect of field being largest for the $\beta + \gamma$ region in $PrCo_5H_{4.4}$. In this context, it is worth noting that the magnetic-field-induced change in the heat of reaction was calculated and experimentally proved for some $RCo_5H_x$ systems by the same group (see, e.g., Yamaguchi *et al.* 2002). For a chemical reaction the magnetic field contributes to the chemical potential, yielding magnetothermodynamic effects: as a result, when a magnetic field is applied, the heat of reaction increases in the $\alpha + \beta$ region, whereas it decreases in the $\beta + \gamma$ region for $LaCo_5H_x$.

## 7. *Hydrides of Ni Compounds*

In nearly all cases ($RNi_5$, $R_2Ni_7$, $RNi_3$, $RNi_2$, $R_7Ni_3$, with R being mainly La and Y) a strong reduction of the magnetic order after hydrogen absorption is obtained, which frequently leads to a complete loss of long-range order. Particularly in these Ni-containing hydrides the precipitation of f.c.c. Ni clusters can be observed. If the parent compound is paramagnetic (as, e.g., $LaNi_5$), the Ni cluster formation is readily observed in an enhanced susceptibility or even by the onset of magnetic order. The origin of the hydrogen-induced ferromagnetism appears to be the exchange between Ni clusters mediated by the metal–H matrix (Blach and Gray 1997). In the case of Ce-containing intermetallics, the insertion of hydrogen can lead to a change from Kondo- to ferromagnetic behavior as, for example, in $CeNiInH_x$ (Chevalier *et al.* 2002). This is caused by the change of the Ce valence from intermediate in the parent compound to trivalent in the hydride, which is governed by the hydrogen-induced decrease of the hybridization between the Ce 4*f*-electrons and the conduction electrons due to the large rise in volume.

# Metal Particle versus Metal Evaporated Tape

Magnetic recording media make up a special class of permanent magnets. Storing information involves switching between different energy states so just as in conventional magnets a high-energy product is desirable. In addition, the need for a high storage density imposes the requirement for media with fine microstructure capable of supporting magnetization patterns on the submicrometer scale. A second, related, special requirement is for an extremely smooth surface finish. This is because spatially varying magnetic fields decay rapidly with distance and therefore the magnetic recording transducer must be kept close to the medium. The design philosophy for finely structured recording media is to take very small magnetic particles having a uniaxial magnetic anisotropy. The particles are too small to support a domain wall (*single-domain particles*) and essentially their rest magnetization can be in only one of two distinct states.

There are two very different commercial approaches to producing media for tape recording. In the first approach, a nonmagnetic base film is coated with an ink containing the magnetic particles and other ingredients. This type of medium is called "*particulate*" and can be found as tape or as floppy disk. The magnetic particles in use are (i) $\gamma$-$Fe_2O_3$, (ii) $CrO_2$ and cobalt-doped $\gamma$-$Fe_2O_3$, and (iii) metal particle (MP). It is the general consensus that metallic particles are the only particulate media that can sustain very high recording densities.

In the second approach, the recording layer is produced by thin-film deposition techniques, such as evaporation. (Sputtering is not considered a viable alternative because the achievable coating speed is too low.) Metal evaporated (ME) tape is produced by oblique evaporation in an oxygen atmosphere. ME tape is the only thin-film tape commercially available. When ME tape first appeared on the market at the beginning of the 1990s, it greatly outperformed MP tape and appeared to be the only tape medium that could sustain a very high recording density.

## 1. Recording Potential of ME and MP Tape

Magnetic recording media of either particulate or thin-film type are granular in nature. Fundamentally, the recording potential of a granular medium is related to the number of grains that fit into a bit. Mallinson (1969) pointed out that the maximum signal-to-noise ratio (SNR) is proportional to the particle density in a tape. At read-back, the average magnetization of all magnetic particles in the volume sensed by the read-back head determines the signal, while the deviation from the mean magnetization is noise. Tape media—including ME tape—have a relatively small volumetric packing fraction, typically smaller than 50%. (Even ME tape has a rather low packing fraction (Richter 1993a).) According to Mallinson (1991) the wide-band SNR ratio is given by

$$\mathrm{SNR} \approx \frac{\bar{m}^2 n W \lambda^2}{2\pi(1 - p\bar{m}^2)}, \quad \bar{m} = \frac{\bar{M}}{M_r} \tag{1}$$

where $\lambda$ is the minimum wavelength occurring in the recording system, $\bar{M}$ is the mean magnetization sensed by the head, $p$ is the volumetric packing fraction of the particles in the tape, and $n$ is the number of particles per unit volume. The tape volume sensed by the head is proportional to $W\lambda^2$, which directly appears in Eqn. (1).

Therefore, it is desirable to prepare media with very small particles. Magnetically, extremely small particles—although magnetically ordered—lose their hysteresis, because the energy barriers, $\Delta E$, separating the magnetization states are too small to withstand the thermal energy, $k_B T$ ($k_B = 1.38 \times 10^{-23}\,\mathrm{J\,K^{-1}}$ (Boltzmann's constant) and $T$ is the temperature in kelvin). This leads to a thermally activated process with a relaxation rate, $r$, given by

$$r = f_0 \exp\left(-\frac{\Delta E}{k_B T}\right) \tag{2}$$

where $f_0$ is the "attempt" frequency $\sim 10^{10}\,\mathrm{Hz}$. At zero applied field, the energy barrier, $\Delta E$, is

$$\Delta E = K_1 V \tag{3}$$

here $K_1$ is an anisotropy constant and $V$ is the particle volume.

Table 1 gives some material data for ME and MP tape. The main constituent of MP tape particles is iron. The most advanced MP particles are made of an Fe–Co alloy rather than pure iron, because Fe–Co has a somewhat higher saturation magnetization. Moreover, alloying with cobalt improves the corrosion resistance of the metallic particles. MP particles are made needle-like and thus possess shape anisotropy. Since iron and Fe–Co alloys have cubic elementary cells the magnetocrystalline anisotropy can be neglected and is close to zero anyway for the higher cobalt-content Fe–Co alloys. The shape anisotropy fields in Table 1 are calculated assuming elongated ellipsoids of revolution with a ratio of the axes of five. Using the resulting anisotropy constant, $K_1 = \frac{1}{2}(\mu_0 M_s H_A)$, the minimum volume required to achieve a stable magnetization can be calculated. In the product $\mu_0 M_s H_A$ we see the analogy with the energy product used to characterize permanent magnets. For a lifetime of $\sim 10$ years, Eqn. (2) yields a required energy barrier of $40\,k_B T$. The magnetic volume given in Table 1 yields an energy barrier of $80\,k_B T$, which provides an adequate margin to tolerate demagnetizing fields and elevated temperatures. Since pure metallic particles are pyrophoric, the particles are surface oxidized. The oxide shell is nonmagnetic and has a thickness of only 3 nm. Therefore, the required (physical) particle volume is significantly larger than the required magnetic volume.

A similar consideration applies to ME tape. Since there is not much information available about the shape of the magnetic subunits, the shape anisotropy contribution has been set to zero. Since ME tape is manufactured in the presence of oxygen, a part of the magnetic layers is oxidized. In contrast to MP tape, the oxidized volume fraction is considerably smaller. The magnetic particle volumes for both types of tape are rather similar, but the physical particle volumes are considerably larger for MP tape. Evidently, the balance between ME and MP tape shifts if the amount of oxygen in either tape can be reduced.

The foregoing analysis is highly simplified and implies that the magnetization reversal process follows the Stoner–Wohlfarth model (Stoner and Wohlfarth 1948). In reality, the magnetization in MP tape switches at lower fields, typically between $150\,\mathrm{kAm^{-1}}$ and $200\,\mathrm{kAm^{-1}}$, which can be because of incoherent switching processes such as curling (Aharoni 1986), or deviations from the ellipsoidal shape (Seberino and Bertram 1999). It has also been reported that the metallic core of MP can consist of several crystallites (Veitch *et al.* 1994), which leads to incoherent magnetization reversal and to a reduced thermal stability. It should also be noted that the coercivity measured in a magnetometer is lower than that at writing. This is an effect of thermally activated magnetization processes and can be derived from Eqn. (2) (Sharrock and McKinney 1981). ME tape does not follow the model of coherent rotation either. Thin films containing

***Table 1***
Magnetic properties of iron and Fe–Co as used for MP tape, and cobalt and $Co_{0.8}Ni_{0.2}$ as used for ME tape. The shape anisotropy values are calculated assuming an aspect ratio for the particle of five. The magnetic volume represents the minimum volume of the magnetic material to achieve an energy barrier of $80\,k_B T$. For MP tape, a nonmagnetic oxide shell of thickness 3 nm is assumed, for ME tape the volume of the oxide is assumed to be 45% that of the metallic core.

| Material | $M_s$ ($\mathrm{kA\,m^{-1}}$) | $H_A^{\mathrm{shape}}$ ($k\mathrm{Am^{-1}}$) | $H_A^{\mathrm{crystaline}}$ ($k\mathrm{Am^{-1}}$) | $V_{\mathrm{mag}}$ ($\mathrm{nm^3}$) | $V_{\mathrm{tot}}$($\mathrm{nm^3}$) | $l_{\mathrm{tot}}$ (nm) |
|---|---|---|---|---|---|---|
| Fe | 1710 | 712 | | 433 | 3971 | 33 |
| $Fe_{0.7}Co_{0.3}$ | 1926 | 802 | | 341 | 3552 | 31 |
| $Co_{80}Ni_{0.2}$ | 1170 | | 584 | 770 | 1117 | |
| Co | 1436 | | 584 | 627 | 910 | |

cobalt generally contain stacking faults, which reduce the anisotropy and, in particular, the switching field down to values of 100–150 $kAm^{-1}$. Unlike particulate tape, magnetic exchange interaction between the magnetic subunits cannot be entirely excluded.

Since neither of the two tape materials can be described by the model of coherent rotation, the values for the critical volumes given in Table 1 do not—strictly speaking—apply. Nonetheless, the critical volume for the ME tape "particles" can be expected to be smaller owing to the lesser amount of oxygen built into the tape. This gives ME tape an advantage over MP tape, with an estimated factor of two in critical volume. Applying Eqn. (1), one would therefore expect an advantage of 6 dB in SNR for ME tape over MP tape. The potential gain of ME tape over MP tape is therefore rather moderate (see also Richter and Veitch (1995)).

## 2. *Structure and Manufacture of MP and ME Tapes*

### *2.1 MP Tape*

Figure 1 shows a schematic view of the cross-section of standard MP tape. The tape consists of a base film, a back coating, and the magnetic layer. In standard MP tape, the magnetic powder accounts for roughly 40% of the volume of the magnetic layer. In addition to the metal powder, the magnetic layer contains carbon black, abrasive particles of $Al_2O_3$, dispersants, and lubricants, all held in a plastic binder system. It is essential that the magnetic particles are well dispersed in the coating ink. Very fine MP particles can be better dispersed if a high shear premix or kneading stage is added to the process. Shortly after the coating process, the still wet coating is magnetically oriented. After the alignment, the coating has to dry until the chemical reactions in the binder system are complete. The next step is to "calander" the tape. A calander presses the tape between polished rollers at a high temperature. This treatment results in a compressed magnetic film and, most importantly, in a very smooth surface finish.

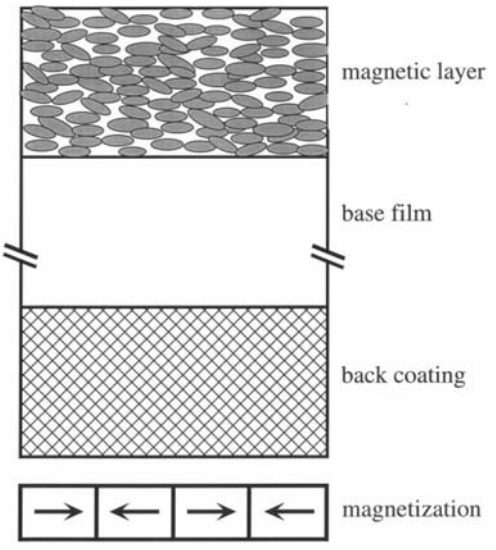

***Figure 1***
Cross-sectional view of MP tape. The magnetic particles are needle-shaped. The bottom sketch indicates that particulate tapes are magnetized longitudinally.

### *2.2 Double-layer Coating of MP Tape*

Although double, or even multiple, coating is an old idea, the exciting and reinvigorating developments are more recent. Double-layer MP media have a very thin magnetic layer and a nonmagnetic underlayer that contains very small $TiO_2$ or $\alpha$-$Fe_2O_3$ particles (Inaba *et al.* 1993). The two layers are coated simultaneously. The first commercial product made on this principle was a Hi-8 videotape with considerably improved recording performance. It is not the thinness of the magnetic layer itself—which is about 400 nm for this tape—but the improved surface smoothness that provides the additional output. It has been demonstrated that magnetic layers as thin as 120 nm (Saitoh *et al.* 1995, Richter and Veitch 1995) or even 100 nm (Inaba *et al.* 1998) can be achieved. MP tapes can now virtually match the performance of advanced metal evaporated (AME) tapes of the kind used in the consumer Digital Video system (Inaba *et al.* 1998).

### *2.3 ME Tape*

Figure 2 shows a schematic cross-section of ME tape. The obvious difference between MP and ME tape is the magnetic storage layer. ME tape is manufactured by oblique evaporation of cobalt or $Co_{0.8}Ni_{0.2}$ in an oxygen atmosphere. At the beginning of the evaporation of the layer, the vapor arrives at the substrate at grazing incidence. A film grown at grazing incidence shows uniaxial anisotropy in an oblique direction. These films are porous and it has been found that finished ME tapes can contain as much as 50% voids (Richter 1993a). Roll-coaters operate in a wide range of evaporation angles (continuously varying incidence, CVI (Shinohara *et al.* 1984)), whereby deposition is started at grazing incidence to preserve oblique anisotropy. A CVI process leads to a curved columnar microstructure. The magnetically easy axis is tilted out of the film plane with a tilt angle roughly coinciding with the angle at which the columns start to grow on the base film, typically around 35°. For improvement of particle separation and material yield, the evaporation is performed in the presence

of oxygen. The oxidation of the magnetic material largely removes exchange coupling in ME tape.

Apart from the magnetic layer, there are other differences between ME and MP tape:

(i) For mechanical protection, ME tape typically has a carbon overcoat, which is reactively sputtered. This carbon layer is of the diamond-like carbon (DLC) type and is 5–10 nm thick.

(ii) The lubricant has to be applied as a separate layer on top of the thin-film medium. In MP tape, the pores in the coating serve as reservoirs for the lubricant.

(iii) The surface of the base film, onto which the magnetic layer is deposited in ME tape, carries a thin coating with very small particles. After deposition of the magnetic film, the surface of the magnetic layer then shows "nodules." These nodules are about 10–20 nm high and have a density of 10–50 $\mu m^{-2}$. The invention of the nodules has been the technological breakthrough for ME tape. The nodules improve tribology at the expense of an additional spacing loss that sacrifices a small amount of the recording performance.

From a manufacturing point of view, MP tape is very attractive because existing coating technology can be used, whereas ME tape requires a switch to vacuum technology, which is associated with a big investment. Clearly, MP tape is much more economical, and many tape makers have opposed a technology switch to ME tape.

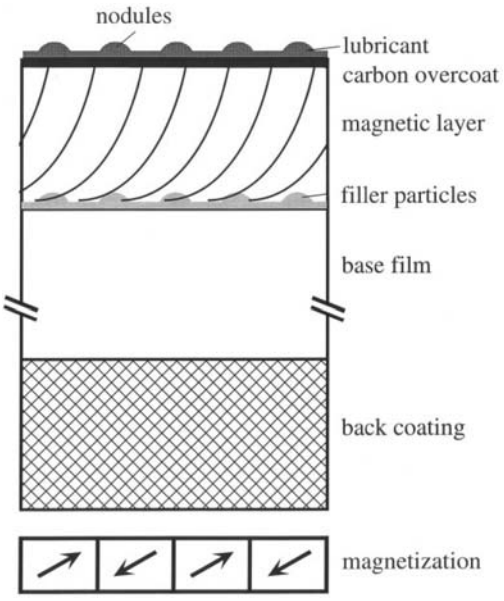

***Figure 2***
Cross-sectional view of ME tape. The filler particles underneath the magnetic layer give rise to nodules sticking out of the film plane. The easy axis of magnetization is tilted out of the film plane.

## *3. Magnetic Properties of MP and ME Tape*

Some magnetic parameters of ME and MP tape are summarized in Table 2. Owing to the inclination of the easy axis out of the film plane, the magnetization of the tape is tilted out of the film plane. Initially, little attention was paid to the demagnetization effects present in simple measurements of the magnetic properties. Magnetic properties of regular particulate tapes are measured in the longitudinal direction, which coincides with the alignment direction (i.e., the easy axis of the tape). For ME tape, this standard procedure yields low values for the squareness (ratio of remanent magnetization and saturation magnetization) and large values for the switching field distribution (SFD). The SFD is related to the normalized slope of the hysteresis curve:

$$\mathrm{SFD} = 1 - \left.\frac{H_C\, dM}{M_r\, dH}\right|_{\text{at } H=H_C}$$

Magnetically, ME tapes did not seem to be very attractive.

If the tape magnetization has a perpendicular component, there is a perpendicular demagnetization field that has to be added *vectorially* to the applied field. The magnetic "particles" in the tape therefore do not "see" the external field alone, rather the vectorial sum of the external field, $\vec{H}_a$, and the film-demagnetizing field, $\vec{H}_d$:

$$\vec{H}_i = \vec{H}_a + \vec{H}_d \qquad (4)$$

***Table 2***
Magnetic parameters of ME and MP tapes.

| Application | Type | $M_r$ (kAm$^{-1}$) | $H_c$ (kAm$^{-1}$) | Coating (μm) | $n$ (1000 μm$^{-3}$) |
|---|---|---|---|---|---|
| Hi8 tape | MP | 200 | 120–135 | 2–3 | 8 |
| | ME[a] | 350 | 90 | 0.2 | ~125 |
| DVC tape | MP | >300 | 180 | 0.15 | 50 |
| | ME[a] | 450 | 135 | 0.15 | ~125 |

a Intrinsic properties.

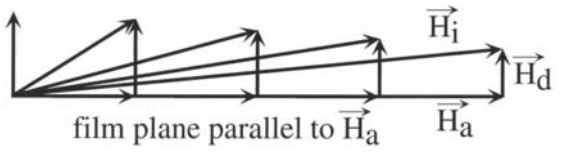

***Figure 3***
Evolution of internal field during a hysteresis loop measurement of ME tape.

The demagnetizing field is always directed perpendicular to the film plane with $H_d = -M_\perp$, where $M_\perp$ is the perpendicular magnetization of the film. A careful examination shows that during the course of a conventional hysteresis loop measurement in the film plane, the internal field *rotates* when the direction of the external field is held fixed (see Fig. 3). Since a proper hysteresis measurement implies that the applied field direction is not changed, results from a conventional hysteresis loop measurement are highly misleading. Keeping the internal field direction fixed therefore requires that the direction of the external field be continuously adjusted during the measurement. These compensated measurements have been done (Bernards and Cramer 1992, Richter 1993a) and they indicate that the intrinsic properties of ME are excellent: a very square loop with a high squareness and a narrow SFD has been observed.

## *4. Recording Properties*

The ultimate recording potential of ME and MP tape was estimated in Sect. 1. The considerations there imply that the dominant noise source in a recorder is the particle noise of the magnetic medium. In a recorder, however, there are other noise sources present and the absolute output signal of the medium becomes important, especially for inductive readout. This favors high-magnetization media, such as ME and MP tape, and consequently none of the older particulate media are considered for high-density tape recording. The introduction of magnetoresistive (MR) heads, which are more sensitive than inductive heads, de-emphasizes the output requirements.

The most critical parameter in a recording system is the head-to-medium spacing. At read-back, the flux decreases exponentially with distance to the tape surface:

$$\phi \propto \exp(-kz) \Leftrightarrow -55z/\lambda \text{ dB} \qquad (5)$$

where $z$ is the distance from the top surface of the medium, $k = 2\pi/\lambda$, and $\lambda$ is the recorded wavelength of a sinusoidal magnetization.

Equation (5) is called "spacing loss" and is an inevitable consequence of the Laplace equation in two dimensions (Mallinson 1993, Bertram 1994). The derivation assumes that the track width is much larger than the other dimensions of the recording system, which is the case in all practical recorders. In addition to the reading spacing loss, there is a writing spacing loss. The writing spacing loss is of the order of $45z/\lambda$ dB (Bertram and Niedermeyer 1982), such that the total spacing loss amounts to roughly $100z/\lambda$ dB. In order to reduce head-to-medium spacing, it is therefore required to create a very smooth tape surface. Unfortunately, adhesion occurs between excessively smooth surfaces, so that one has to strike a delicate balance between electrical and mechanical performance.

To achieve a high output, the width of a magnetization transition between regions magnetized in opposite directions needs to be kept as small as possible. To first order, the effect of transition width on the recording output is the same as that of a spacing loss (Bertram 1994). The width of a transition is determined by the following factors:

(i) *Demagnetization*. This occurs at the instant of writing and is proportional to the ratio of remanent magnetization and coercivity of the medium. The first paper to recognize this was that of Williams and Comstock (1971).

(ii) *Particle length ("length loss")*. The transition width cannot be smaller than the length of a particle (Richter and Veitch 1996). Early MP tapes had particle lengths of 150 nm or even longer which affected recording of very short wavelength. Modern MP tapes have particle lengths down to 100 nm and lower such that the length loss effect is small. In addition, smaller particles potentially allow smoother tape surfaces. Shorter lengths will be necessary if the linear recording density is to be increased. Particles of about 60 nm have been made (Hisano and Saito 1998) but they suffer from a poorer SFD.

(iii) *Switching field distribution*. This would determine the transition width if no demagnetization and no limitation by the particle length were present. For ME tape, the SFD can considered to be very small; for MP tape the narrowest values achieved are about 0.2.

(iv) *Coating thickness*. This obviously determines the output of the tape. However, thicker coatings generally produce wider transitions, either caused by greater demagnetization or by geometrical effects (Richter 1997). Examples for some transitions are given in Fig. 4. For many tapes, however, the total thickness of the coating is not at all relevant. The depth of recording is roughly equal to the gap length of the writing head such that the particles at the bottom of a thick magnetic coating remain untouched (partial penetration recording). In addition, spacing loss effects attenuate the contributions from the deeper layers of the tape, especially for short wavelengths. ME tape coatings are 150–200 nm thick, but even those are not fully recorded throughout their depth. It has been shown experimentally and theoretically that thin-film MP tapes do not have a higher

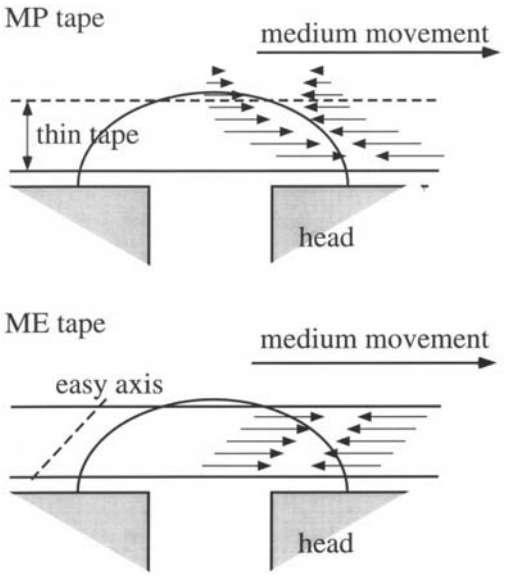

***Figure 4***
Schematics of recorded transitions for MP and ME tape. In MP tape, the top layers of the tape are recorded further downstream, while the opposite is true for ME tape. The dashed line in the upper figure indicates how thick is a "thin" MP tape coating.

output at short wavelength than thick tapes (Richter and Veitch 1995, Richter 1997). On the contrary, thinner tapes show a lower output for long-wavelength recording. Thin magnetic coatings are advantageous for overwrite behavior (Richter and Veitch 1995, Veitch *et al.* 1999). For identical coating thickness, ME tape is found to have a much improved overwrite over MP tape owing to its superior intrinsic properties and the tilt of the easy axis.

(v) *Direction of the easy axis.* It has been discovered that ME tape exhibits a recording anisotropy: the recording output in the two directions differs by about 6 dB. The high output is observed when the recording head runs over the medium as shown in Fig. 4. Modeling results indicate that the optimum tilt of the easy axis is between 20° and 30° out of the film plane and that the output increase over an easy axis in the tape plane is only moderate (Richter 1993b, Stupp *et al.* 1994). The oblique recording inherent to ME tape also reduces nonlinear intersymbol interference (Mallinson 1989, Cumpson and Stupp 1997).

## 5. The Future: ME or MP Tape?

As discussed in Sect. 2, ME tape has a higher recording potential and some other advantages in recording behavior. Apart from the improved recording performance, ME tape can also be made thinner. If the base film, for example, has a thickness of 5 μm, the total thickness of the tape is roughly 5.2 μm. This has to be contrasted with MP tape, where the total tape thickness is roughly 6 μm. The MP tape is thicker because any particulate coating (double layer, single layer) cannot yet be made thinner than roughly 1 μm, and thus more ME tape than MP tape can be wound into a given cassette.

However, ME tape can be recorded in only one direction, which effectively limits its use to helical scan systems, whereas the major new data storage systems (Digital Linear Tape and Linear Tape Open) use serpentine linear recording, reversing direction at the end of the tape. While ME is simply ruled out for these systems, it may seem surprising that it has not been adopted for the latest helical scan data system DD4. We can conclude that the advantages of ME tape over MP tape are too small to justify moving to a new technology. It should not be forgotten that a technology switch is also associated with risks, and—although tremendous progress in ME tape has been made—the tribological properties of particulate tape still have to be regarded as superior to those of ME tape. It is therefore likely that MP tape will be the dominant tape recording medium in the future.

# Metamagnetism: Itinerant Electrons

Itinerant electron metamagnetism (IEM) is a first-order field-induced transition from the paramagnetic state to the ferromagnetic one in itinerant electron systems. This phenomenon is closely related to the instability of ferromagnetism (see *Itinerant Electron Systems: Magnetism (Ferromagnetism)*). Since this phenomenon was predicted to occur by Wohlfarth and Rhodes (1962), many experimental studies using ultrahigh magnetic fields have been done to observe it. Now, many metamagnetic compounds such as pyrites $Co(S_{1-x}Se_x)_2$, Laves phase compounds such as $YCo_2$, $Y(Co_{1-x}Al_x)_2$, $LuCo_2$, and $Lu(Co_{1-x}Ga_x)_2$ are found. This article first outlines theoretical concepts of IEM and then presents experimental results on the magnetic and electrical properties and magnetovolume effects of these compounds together with alloying and pressure effects on the metamagnetic transition.

## 1. Theoretical Background

Wohlfarth and Rhodes (1962) first discussed IEM using a Landau-type expression for the free energy of the itinerant electron system based on the Stoner model. They pointed out that IEM is expected to occur in a strongly exchange-enhanced paramagnet with a broad maximum in the temperature dependence of the susceptibility. More detailed conditions for the appearance of IEM at $T=0$ were given by Shimizu (1982). Later, a theory of IEM at finite temperature, based on the spin fluctuation model, was developed by Moriya (1986) and Yamada (1993).

The magnetic behavior of itinerant electron paramagnets in magnetic fields depends on the shape of the density of states (DOS) near the Fermi level (see *Itinerant Electron Systems: Magnetism (Ferromagnetism)*). The paramagnet does not satisfy the Stoner condition for the appearance of ferromagnetism, $I\rho(\varepsilon_F)>1$, where $I$ is the exchange energy of electrons and $\rho(\varepsilon_F)$ $(=\rho_\uparrow(\varepsilon_F)+\rho_\downarrow(\varepsilon_F))$ is DOS at the Fermi level $\varepsilon_F$. If $\rho(\varepsilon_F)$ increases with field in a strongly exchange-enhanced paramagnet, however, the Stoner condition will be satisfied in a high magnetic field and a ferromagnetic state will appear. When the function of $\rho(\varepsilon)$ has a positive curvature near $\varepsilon_F$, $\rho(\varepsilon_F)$ increases with field. This is one of the conditions for IEM, as discussed below.

The equation of state for the itinerant electron system at $T=0$ is written as

$$B = aM + bM^3 + cM^5 \tag{1}$$

where $B$ is the magnetic field, $M$ the magnetic moment, and $a$ the inverse susceptibility $\chi^{-1}$ (Shimizu 1982). The coefficients $a$, $b$, and $c$ are functions of DOS and its derivatives at $\varepsilon_F$. At a temperature $T>0$, the coefficients in Eqn. (1) are renormalized by thermal spin fluctuations and the equation is rewritten as

$$B = A(T)M + B(T)M^3 + C(T)M^5 \tag{2}$$

where $A(T)$ is the inverse susceptibility $\chi(T)^{-1}$ (Moriya 1986, Yamada 1993). The coefficients $A(T)$, $B(T)$, and $C(T)$ are functions of $a$, $b$, $c$, and the square of the amplitude of thermally fluctuating moment $\xi(T)^2$. $\xi(T)^2$ is an increasing function of $T$ and proportional to $T^2$ at low $T$.

Moriya (1986) determined the magnetic phase diagram for $a>0$, $b<0$, and $c>0$. The negative value of $b$ indicates that the DOS curve has a positive

curvature near the Fermi level. The ground state is paramagnetic for $ac/b^2 > 3/16$. IEM appears under the condition

$$\frac{3}{16} < \frac{ac}{b^2} < \frac{9}{20} \tag{3}$$

However, IEM does not occur for $ac/b^2 \geqslant 9/20$. For $0 < ac/b^2 < 3/16$, the ground state becomes ferromagnetic even in zero field although the Stoner condition ($a < 0$) is not satisfied. Figure 1 shows the theoretical phase diagram for $a > 0$, $b < 0$, $c > 0$ in the narrow region $0.16 \leqslant ac/b^2 \leqslant 0.21$ near the appearance of ferromagnetism. Since the value of $c\xi(T)^2/|b|$ increases monotonically with increasing $T$, the ordinate is considered as the $T$ axis. The ferromagnetic transition (FT) occurs on the $T_C$ curve. FT is second order for $0 < ac/b^2 < 5/28$ and first order for $5/28 < ac/b^2 < 3/16$, where the value of $T_C$ abruptly decreases with increasing $ac/b^2$. The type of FT changes at point $T_t$ on the $T_C$ curve. Note that IEM appears also just above $T_C$ in $5/28 < ac/b^2 < 3/16$. The $T_0$ line merges into the $T_C$ line at $T_t$.

The inverse susceptibility is given by the relation (Yamada 1993)

$$\chi^{-1} = a + \frac{5}{3}b\xi(T)^2 + \frac{35}{9}c\xi(T)^4 \tag{4}$$

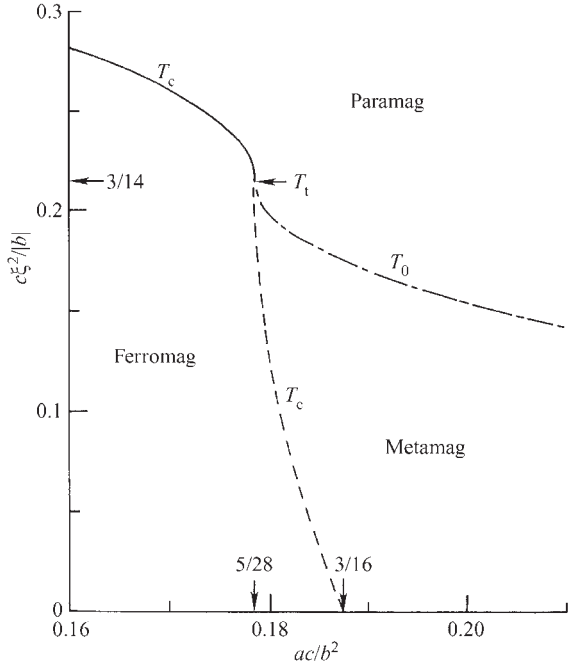

***Figure 1***
Theoretical phase diagram for $a > 0$, $b < 0$, $c > 0$ in the narrow region $0.16 \leqslant ac/b^2 \leqslant 0.21$ near the appearance of ferromagnetism.

Under the condition $ac/b^2 > 5/28$, $\chi$ becomes maximum at a temperature $T_{max}$. Thus, the paramagnetic system with IEM has a broad maximum in $\chi(T)$, which increases in proportion to $T^2$ at low $T$. The system with the first-order FT also has a broad maximum in $\chi(T)$ above $T_C$.

The temperature dependence of the average critical field for IEM is given by

$$B_c(T) = B_c(0) + \frac{1}{16}\sqrt{|b|/3c}\,|b|\,\xi(T)^2 \tag{5}$$

Therefore, the critical field increases with $T$ as $T^2$ at low $T$ (Yamada 1993).

## 2. *Observations of Itinerant Electron Metamagnetism*

### *2.1 Laves Phase Compounds $MCo_2$ (M: Y and Lu)*

The Laves phase compounds $YCo_2$ and $LuCo_2$ are typical *3d* systems with IEM. $ScCo_2$ is believed to exhibit IEM. These compounds are strongly exchange-enhanced paramagnets. The susceptibility $\chi(T)$ increases with $T$ at low $T$ followed by a maximum at a temperature $T_{max}$. At high $T$, $\chi(T)$ obeys the Curie–Weiss law. $\chi(T)$ in the low $T$ region increases in proportion to $T^2$. The $T^2$ dependence is caused by the excitation of spin fluctuations and can be explained with Eqn. (4) (Yamada 1993).

Goto *et al.* (1989, 1990) observed IEM in $YCo_2$ and $LuCo_2$ around 70 T. The magnetization curve of $LuCo_2$ is shown in Fig. 2 (see Fig. 3 for that of $YCo_2$). In $ScCo_2$, however, IEM does not occur in ultrahigh magnetic fields up to 120 T. The high-field susceptibility of $YCo_2$ and $LuCo_2$ is very large above

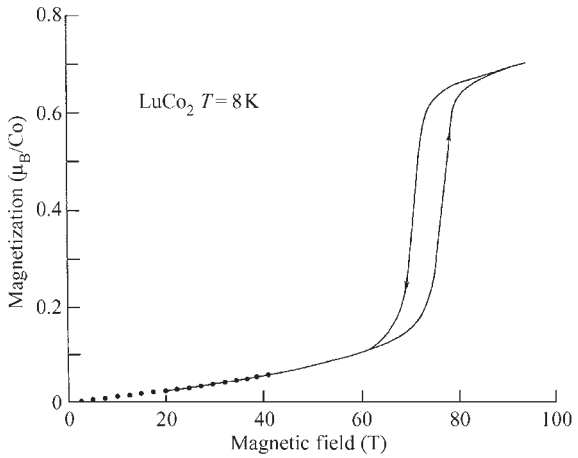

***Figure 2***
Magnetization curve of $LuCo_2$. The metamagnetic transition can clearly be seen.

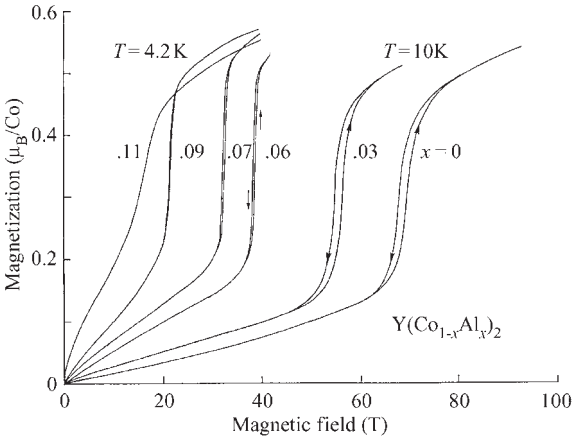

***Figure 3***
Magnetization curves of paramagnetic $Y(Co_{1-x}Al_x)_2$ with $x \geqslant 0.11$ at low $T$.

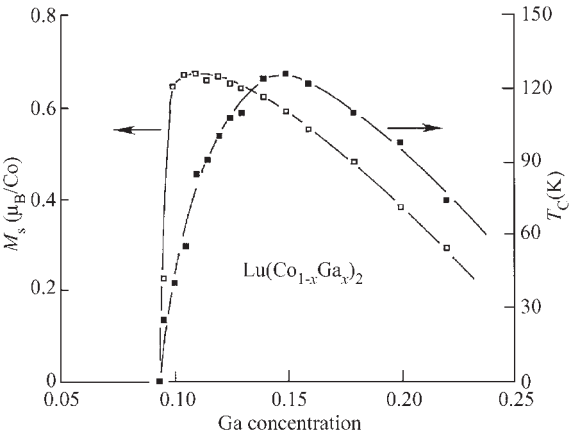

***Figure 4***
Spontaneous magnetization $M_s$ and the Curie temperature $T_C$ of $Lu(Co_{1-x}Ga_x)_2$.

$B_c$, which indicates that the magnetization is not completely saturated by the metamagnetic transition (MT). MT is very sharp at low $T$, but becomes broad with increasing $T$. The critical temperature for the disappearance of the first-order MT is determined to be $T_0 = 100 \pm 10$ K for $YCo_2$ (Goto *et al.* 1994).

According to the band model of IEM, the critical field is expected to change sensitively by shifting the position of the Fermi level in the DOS curve. This phenomenon has been examined using samples of $Y(Co_{1-x}M_x)_2$ (M = Fe, Ni, and $Fe_{0.5}Ni_{0.5}$) (Goto *et al.* 1994). Iron substitution shifts the Fermi level to the lower energy side, while nickel substitution shifts it to the higher energy side. With increasing $x$, $B_c$ decreases in $Y(Co_{1-x}Fe_x)_2$, but increases in $Y(Co_{1-x}Ni_x)_2$. The change of $B_c$ can easily be understood by considering the band structure. Since iron substitution increases the DOS at the Fermi level, the parameter $a$ in Eqn. (1) decreases. This causes the reduction of $B_c$. However, an increase in $B_c$ is expected by nickel substitution. In the case of doping with equal amount of iron and nickel, no change of $B_c$ is expected. In fact, the observed change of $B_c$ is very small for the doping.

The substitution of aluminum for cobalt in $YCo_2$ expands the lattice and enhances the susceptibility $\chi$ (Yoshimura *et al.* 1985). The position of $T_{max}$ shifts to the low $T$ side and a weak ferromagnetism appears in $Y(Co_{1-x}Al_x)_2$ with $0.12 \leqslant x \leqslant 0.19$. Figure 3 shows the magnetization curves of paramagnetic $Y(Co_{1-x}Al_x)_2$ with $x \geqslant 0.11$ at low $T$ (Goto *et al.* 1994). These compounds exhibit IEM. The average critical field $B_c$ decreases nearly linearly with increasing $x$ and is found to be proportional to $T_{max}$, $B_c/T_{max} = 0.29$ [T/K] (Goto *et al.* 1994).

The field $B_c$ of $LuCo_2$ also decreases and a ferromagnetic state becomes stable by replacing cobalt with gallium (Murata *et al.* 1993). The critical concentration of $Lu(Co_{1-x}Ga_x)_2$ for the onset of ferromagnetism is $x_c \approx 0.095$ (Saito *et al.* 1997). The field-induced moment in the paramagnetic compound is consistent with the spontaneous moment $M_s$ of the ferromagnetic one. Figure 4 shows the value of $M_s$ and $T_C$ as a function of $x$, which increases abruptly at $x_c$, where $B_c$ becomes zero (Saito *et al.* 1997). These results imply that the appearance of IEM is related to the instability of ferromagnetism.

When the nonmagnetic M atom in $MCo_2$ is replaced with magnetic rare earth R, the cobalt moment is induced by the effective field from the R site. The effective field can be evaluated using the relation $B_{eff} = 84(g_J - 1)J$ [T], where $g_J$ is the g-factor of R and $J$ the total angular momentum (Goto *et al.* 1989). The induced cobalt moment is found to increase rapidly at about 70 T, indicating that the effective field produces MT. This value corresponds to the critical field of $YCo_2$.

### *2.2 Pyrites $Co(S_{1-x}Se_x)_2$*

The $CoS_2$ compound with the pyrite structure is an itinerant ferromagnet with $T_C \cong 120$ K. The substitution of selenium for sulfur in $CoS_2$ makes the 3*d* band wider and changes the second-order FT to the first-order one accompanied by a rapid decrease of $T_C$. The $Co(S_{1-x}Se_x)_2$ compounds with $x \geqslant 0.12$ are paramagnetic and exhibit a broad maximum in $\chi(T)$.

IEM was first observed in paramagnetic $Co(S_{1-x}Se_x)_2$ by Adachi *et al.* (1979). Later, detailed studies were done by Goto *et al.* (1997). Figure 5 shows the magnetization curves of $Co(S_{1-x}Se_x)_2$ for 4.2 K (Goto *et al.* 1997). The average critical field $B_c$ increases linearly with $x$. The magnetization in the induced ferromagnetic state is consistent with the spontaneous

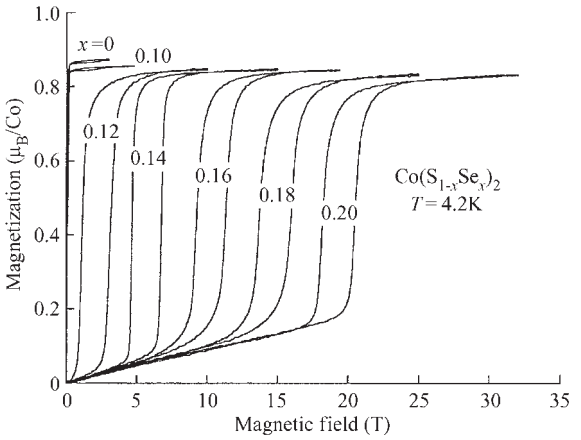

***Figure 5***
Magnetization curves of $Co(S_{1-x}Se_x)_2$ with $0 \leqslant x \leqslant 0.2$ for 4.2 K.

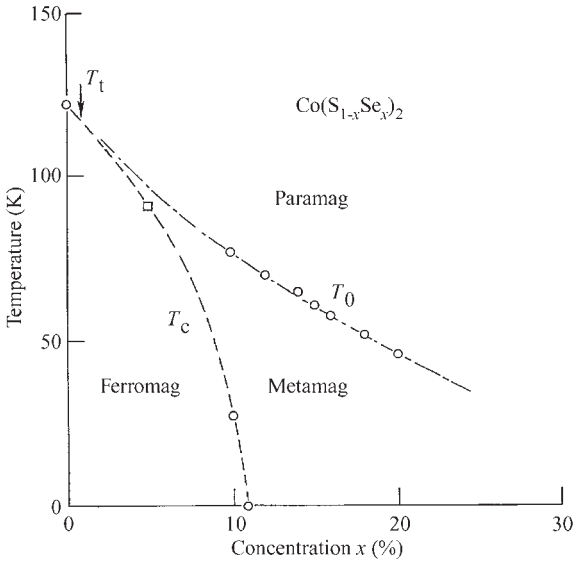

***Figure 6***
Magnetic phase diagram of $Co(S_{1-x}Se_x)_2$ in the $x$–$T$ plane.

moment of the ferromagnet. In $Co(S_{0.9}Se_{0.1})_2$ with a first-order FT at 27 K, a metamagnetic transition (MT) is found to appear just above $T_C$. However, $CoS_2$ with a second-order FT does not exhibit MT above $T_C$. The critical field for $0.1 \leqslant x$ shifts in proportion to $T^2$ as $B_c(x,T) = B_c(x,0) + T^2$ in the low $T$ region $T < 70$ K. The $T^2$ dependence can be explained by the theory of IEM.

Figure 6 shows the magnetic phase diagram of $Co(S_{1-x}Se_x)_2$ in the $x$–$T$ plane, where $T_0$ is the critical

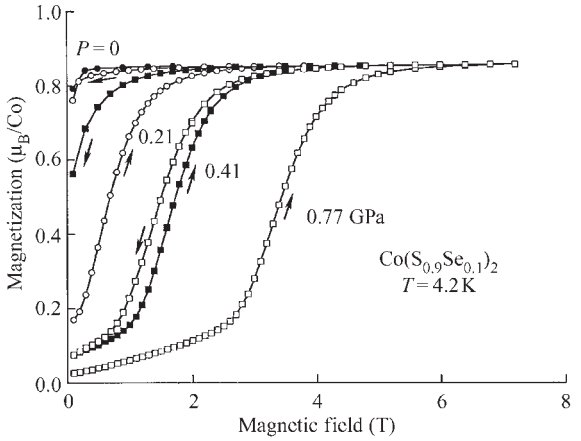

***Figure 7***
Magnetization curve of ferromagnetic $Co(S_{0.9}Se_{0.1})_2$ for 4.2 K at various pressures.

temperature for the disappearance of IEM (Goto *et al.* 1997). The type of FT changes from second-order to first-order at $T_t$ on the $T_c$ curve. The position of $T_t$ can be determined from the critical concentration $x_t$ ($=1\%$) at which $\chi(T_{max})^{-1}$ becomes zero. FT is second-order for $0 \leqslant x < 1\%$, but first-order for $1\% < x < 11\%$. The value of $T_C$ on the first-order phase boundary decreases abruptly with increasing $x$. MT appears between the $T_C$ and $T_0$ curves. The experimental phase diagram can be compared with the theoretical one shown in Fig. 1. Since $ac/b^2$ for $Co(S_{1-x}Se_x)_2$ increases with $x$, the abscissa of the theoretical phase diagram is considered as the $x$ axis. On the other hand, the ordinate corresponds to the $T$ axis of the phase diagram of $Co(S_{1-x}Se_x)_2$. The theoretical phase diagram reproduces well the experimental one.

## 3. *Pressure Effects*

The theoretical phase diagram suggests that the application of high pressure rapidly decreases the value of $T_C$ of the ferromagnet with the first-order transition because $ac/b^2$ increases with pressure. Figure 7 shows the magnetization curve of ferromagnetic $Co(S_{0.9}Se_{0.1})_2$ for 4.2 K at various pressures (Goto *et al.* 1997). The compound becomes paramagnetic at $P > 0.21$ GPa and exhibits IEM. Similar phenomena were also found in ferromagnetic $Lu(Co_{1-x}Ga_x)_2$ by Goto *et al.* (1994). The critical pressure for the disappearance of ferromagnetism in $Co(S_{0.9}Se_{0.1})_2$ is estimated to be $P_c = 0.25$ GPa from the relation $B_c(P_c) = 0$ at $T = 0$. Since $T_C$ is 27 K at 0 GPa, the pressure effect on $T_C$ is evaluated to be $dT_C/dP = -108$ K/GPa, which is extremely large compared with usual itinerant ferromagnets. The increase of $B_c$ comes mainly from the suppression of the

Stoner enhancement factor. However, the second-order FT is expected to change to the first-order one by the application of pressure. In fact, the FT of $CoS_2$ changes into the first-order one at 0.4 GPa and MT is found just above $T_C$ for $P > 0.4$ GPa. The application of pressure also affects the susceptibility $\chi$. In $Lu(Co_{0.92}Ga_{0.08})_2$, $\chi$ is found to decrease and is accompanied by an increase of $T_{max}$ with increasing $P$, which is also caused by the suppression of the enhancement factor (Goto *et al*. 1994).

## 4. Magnetovolume Effects

In the itinerant electron system, the appearance of a magnetic moment $M$ produces a volume magnetostriction $\omega(=\Delta V/V)$, which is related to $M$, $\omega = nM^2$, where $\Delta V$ is the volume change and $n$ is the magnetoelastic coupling constant (see also *Magnetoelastic Phenomena*). Figure 8 shows the magnetostriction curve of $Lu(Co_{0.94}Ga_{0.06})_2$ at 4.2K in high magnetic fields up to 40 T (Goto and Bartachevich 1998). The volume expands by MT. The estimated value of $n$ is $10.1 \times 10^{-3}$ $(\mu_B/Co)^2$ in the paramagnetic state and $5.0 \times 10^{-3}$ $(\mu_B/Co)^2$ in the induced ferromagnetic one. The reduction of $n$ is also found in the $Lu(Co_{1-x}Ga_x)_2$ and $Y(Co_{1-x}Al_x)_2$ systems, originating from the change in the electronic structure of the d electron system caused by MT.

## 5. Electrical Properties

The spin fluctuation contribution to the electrical resistivity $\rho_{sp}(T)$ has been estimated by subtracting the resistivity of $YAl_2$ from those of $YCo_2$, $LuCo_2$, and $ScCo_2$ (Gratz *et al*. 1995). The $\rho_{sp}(T)$ curves increase steeply at low $T$ followed by a maximum. At high $T$, $\rho_{sp}(T)$ decreases nearly linearly with increasing $T$. $\rho_{sp}(T)$ in the low $T$ region is proportional to $T^2$, $\rho_{sp}(T) = AT^2$. The $A/\gamma$ ratios (where $\gamma$ is the coefficient of the electronic specific heat) for these compounds satisfy the Kadowaki–Woods relation, $A/\gamma = 1.0 \times 10^{-5}$ μΩcm $(KmolmJ^{-1})^2$, as well as heavy fermion compounds. This relation can be explained in terms of a spin fluctuation theory (Wada *et al*. 1993). The longitudinal magnetoresistance of $Lu(Co_{0.91}Ga_{0.09})_2$ has been measured at 4.2 K in high magnetic fields (K Murata, unpublished data). Initially the resistance $R$ decreases gradually with increasing field. At MT of 5 T, a large reduction of $R$ by 13% has been observed, which is caused mainly by the suppression of spin fluctuations (see also *Intermetallic Compounds: Electrical Resistivity*).

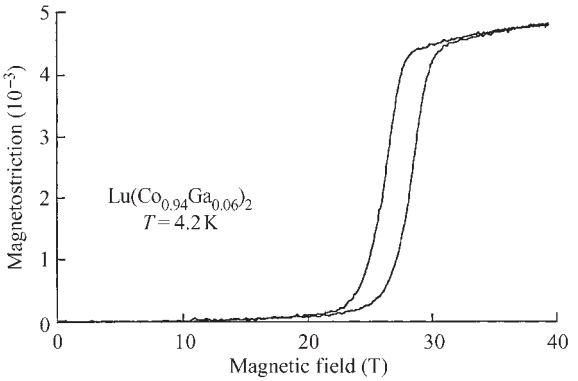

***Figure 8***

## 6. Conclusion

IEM observed in cobalt-based Laves phase compounds and cobalt pyrites originates from a special shape of the DOS curve near the Fermi level, which enhances spin fluctuations at finite temperature. The unusual magnetic properties of these compounds can be explained well with the theory of IEM based on the spin fluctuation model. The metamagnetic transition and the susceptibility are sensitively changed by pressure. Magnetostriction measurements suggest that the electronic structure of the field-induced ferromagnetic state is quite different from that of the paramagnetic state. The electrical resistivity is largely affected by the spin fluctuations.

## Metrology: Superconducting Cryogenic Current Comparators

The superconducting current comparator (SCC) is a development of the magnetic d.c. comparator (DCC), introduced in 1964 and which operates at room temperature. Initial attempts (Harvey 1972) to develop a superconducting version included enclosing the high $\mu$ magnetic core of the DCC in a superconducting shield, but it was soon realized (Sullivan and Dziuba 1974, Grohman *et al.* 1974) that this was unnecessary, the superconducting shield alone was sufficient; in fact the magnetic core could contribute excessive noise to the detector.

The basic operating principle of the SCC relies on the Meissner effect (see *Electrodynamics of Superconductors: Flux Properties*) and can be understood by imagining a very long superconducting tube, open at both ends, and having a thickness greater than the penetration depth of the superconductor. Two separate wires (they need not themselves be superconducting) thread the cylinder. Currents $I_1$ and $I_2$ flowing in the wires induce a circulating current $I_s = -(I_1 + I_2)$ in the wall parallel to $I_1 + I_2$ on the inside surface of the cylinder. $I_s$ completes a path round the cylinder creating a magnetic field that is measured with a suitable detector on the outside of the cylinder. If $I_1 = -I_2$ then $I_s = 0$ and, assuming that magnetic field contributions to the detector due to end effects (insufficient length of cylinder) or direct interference from $I_1$ and $I_2$ outside the cylinder can be eliminated, the device is a perfect comparator and can be used to compare currents with a sensitivity that depends on the minimum resolution of the detector relative to the magnitude of $I_1$.

Two versions of the SCC designed to satisfy the criteria outlined above have been described: type I (Sullivan and Dziuba 1974) is the most common so far in the metrology community, and is often described as the "snake swallowing its own tail" comparator; and type II (Grohman *et al.* 1974), a toroidal version of type I, which is more difficult to fabricate but is under development for very high current ($\leqslant 100$ A) and a.c. applications.

### 1. Type I SCC

The SCC (Fig. 1) comprises a torus (made from Tufnol or machinable glass–ceramic) on which a coil, with as many separate windings as necessary for the intended purpose (e.g., in a typical SCC to be used in an $n$:1 ($n \leqslant 10$) resistance ratio bridge, there are $n+2$ windings each having 64 turns), is wound. The windings are NbTi, copper-clad, single-core, insulated superconducting wire with an overall diameter of $\sim 65$ μm, and impregnated with epoxy glue or

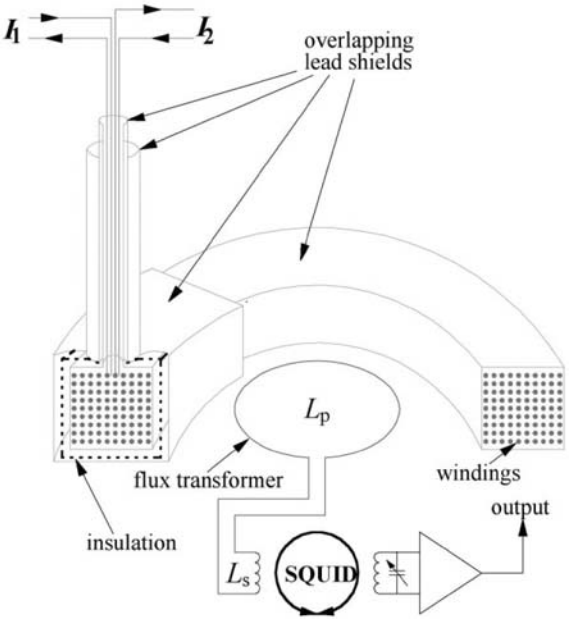

***Figure 1***
Type I SCC.

otherwise tightly wrapped to prevent movement. The coil is covered with a toroidal superconducting lead shield (0.15 mm thick lead foil carefully soft-soldered to prevent pinholes), with each overlapped turn insulated by thin tape (0.1 mm Kapton). The ends of the windings are brought to the exterior inside 10 cm long, insulated, coaxial lead tubes joined to each turn of the shield. Typically 2.5 overlapped turns are sufficient to meet the requirements set out in the introduction and to obtain the desired accuracy.

The detector coil, with inductance $L_p$, is wound with superconducting (niobium or NbTi) wire on a Tufnol or machinable glass–ceramic former and inserted coaxially into the middle of the shield. It is connected as a flux transformer to the input coil, inductance $L_s$, of a d.c. or radio-frequency (RF) superconducting quantum interference device (SQUID). The whole construction, SCC and SQUID, is enclosed in a superconducting shield surrounded by cryoperm, a low-temperature, high $\mu$ magnetic shield and lowered into a cryostat containing liquid helium. Optimum flux transfer from the SCC to the SQUID occurs for $L_p \approx L_s$ and a typical sensitivity for a single winding in the SCC is $4.5\,\mu A/\varphi_0$, where $\varphi_0$ is the flux quantum. Since an RF SQUID may have a noise sensitivity of $10^{-4}\varphi_0\,Hz^{-1/2}$, the sensitivity of a 64-turn single winding is approximately $7\,pAHz^{-1/2}$ and it is relatively easy to detect current inbalances to $\leqslant 1$ part in $10^9$.

To check the ratio accuracy of the SCC, equivalent windings are connected in series-opposition and energized with a current large enough to resolve any inbalances. By using a ''binary buildup'' procedure it is possible to determine the accuracy of any integer ratio. The highest accuracy, reported in 1991 for a 2:1 ratio derived from $10^4$ turns per winding, is a few parts in $10^{12}$.

## 2. Type II SCC

In the type I SCC the ratio windings are on the inside of the overlapping superconducting shield and the detector coil sensing flux inbalance on the outside. The topology of the type II SCC is exactly reversed from this, with the detector coil wound toroidally on a former located on the inside of a toroidally shaped superconducting shield with an insulated, overlapped gap region. The ratio windings are also wound toroidally on the outside of the shield and for this reason it is possible for them to carry more current than the type I SCC, without the risk of driving part of the superconducting shield into its normal state. When the detector coil is connected to a SQUID similar to that used for the type I described above, the current sensitivity of a single turn is somewhat less, but since one reason for choosing this design is to compare currents up to 100 A, this is not relevant.

## 3. SCCs in Resistance Ratio Bridges

The main application of the SCC in metrology is in the measurement of the ratio of two standard resistors $R_1$ and $R_2$, which are maintained at precisely controlled temperatures in suitable enclosures. For the most accurate measurements four terminal resistors and an SCC are connected in a bridge arrangement (Delahaye 1978). A fully automated version (Williams and Hartland 1991) is shown in Fig. 2.

Current $I_1$ from a primary electronic constant current source $S_1$ flows through resistance $R_1$ and an in-series primary winding $N_1$ of a type I SCC. A secondary current $I_2 \approx (N_1/N_2)I_1$, from source $S_2$, derived from a voltage generated by $I_1$, is arranged to flow in resistance $R_2$ and a secondary winding of $N_2$ turns of the SCC. The two windings of the SCC are connected in opposite senses to produce approximately zero flux, sensed by an RF SQUID closely coupled by a flux transformer to the SCC. Since the relative accuracy of the winding ratio $N_1/N_2$ is typically smaller than 1 part in $10^{10}$ any departure in the current ratio $I_2/I_1$ from that in the winding ratio is corrected by feedback of the SQUID out-of-balance signal to $S_2$. The ratio $R_1/R_2$ is determined from the output of the null detector D. This output can also be used to generate a balance current $I_b$, which flows in

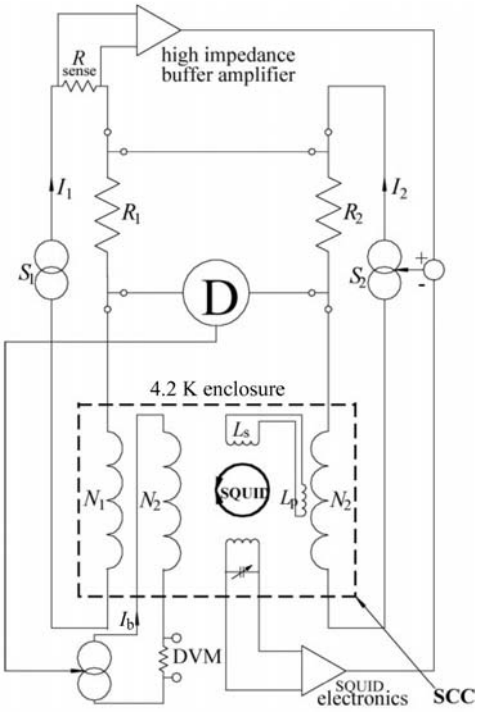

***Figure 2***
SCC resistance ratio bridge.

an auxiliary winding of $N_2$ turns of the SCC and brings the detector D to zero balance, so ensuring that the gain stability and linearity of the detector are not significant. Combining the expressions for the detector balance, $R_1I_1-R_2I_2=0$, and for the SCC balance, $(N_1/N_2)I_1+I_b-I_2=0$, one obtains

$$\frac{R_1}{R_2}\cong\frac{N_1}{N_2}\left(1+\frac{I_b}{I_2}\right)$$

if $I_b$ is small. The current $I_b$ is measured using a resistor and digital voltmeter (DVM), and a large value, accurately known resistor shunting $R_2$ is used to calibrate $I_2$. Attention must be paid to the elimination of unwanted leakage currents and that offset currents from the high-impedance buffer amplifier have no significance in the potential circuit.

The operation of the bridge is controlled by a computer, which reverses the direction of $I_1$ (and $I_2$) to eliminate the effect of thermal e.m.f.s in the potential circuit, and takes readings of the DVM. For low power dissipation ($\leqslant 1$ mW) in $R_2$, relative random uncertainties (type A) of $R_1/R_2$ of $\sim 1$ part in $10^9$ can be achieved for measurement times of about 10 minutes.

The SCC bridge is widely used by national laboratories to determine the value of standard resistors in terms of the quantum standard of resistance $R_K$ ($\equiv 25812.807\Omega$); to compare quantized Hall resistances fabricated from different materials; and to compare the standard resistors of different national laboratories, with accuracies of a few parts in $10^9$. Since 1996 the SCC resistance-ratio bridge has been produced commercially by two companies located in the UK.

## Micromagnetics: Basic Principles

A small class of materials exhibit the important property of long range magnetic order. Fundamentally, this arises because of the so-called ''exchange energy'' which can, under certain circumstances, lead to parallel alignment of neighboring atomic spins. Given the link between the atomic spin and magnetic moment, the spin order gives rise to the observed long range magnetic order. The origin of the long range magnetic order is a fundamental scientific problem which has been studied extensively, both theoretically and experimentally and is now understood in some depth. However, within magnetism there is a major problem when relating fundamental atomic properties to magnetization structures and magnetization reversal mechanisms in bulk materials.

The problem was described vividly by Aharoni (1996) in his discussion of magnetostatic effects. The essential idea is that the material properties are determined by the exchange energy, which in principle is effective on a length scale of subnanometers, and the magnetostatic energy, which has contribution from the boundaries of the material itself and which introduce a different length scale entirely. The challenge of micromagnetics is to develop a formalism in which the macroscopic properties of a material can be simulated including the best approximations to the fundamental atomic behavior of the material.

In brief, the classical approach to micromagnetics replaces the spin by classical vector field which initially allows the determination of magnetostatic fields within the system. In addition to this a different approach to the exchange interaction much be formulated which can replace the quantum mechanical exchange interaction with a formalism appropriate for the limit of continuous material. This, coupled with an energy minimization approach, forms the basis of classical micromagnetics which will be outlined in a later section.

The history of micromagnetics starts with a 1935 paper of Landau and Lifshitz on the structure of a wall between two antiparallel domains, and several papers by Brown around 1940. A detailed treatment of micromagnetism is given by Brown in his 1963 book (Brown 1963).

For many years micromagnetics was limited to the use of standard energy minimization approaches to determine domain structures and classical nucleation theory to determine magnetization reversal mechanisms in systems with ideal geometry. Arguably, the current interest in micromagnetics arises from the availability, from about the mid-1980s onward, of large-scale computing power which enabled the study of more realistic problems which were more amenable to comparison with experimental data.

One important realization during this period was the fact that energy minimization approaches in

principle only determine nucleation fields for the system, and do not predict necessarily correctly the state of the system after magnetization reversal. Consequently, a lot of work has gone into the development of dynamic approaches which use simulations based on the Landau–Lifshitz equation of motion. This is probably the technique in most common use today.

The other area in which considerable development has taken place during the 1990s is that of the calculation of magnetostatic fields, which because of its complexity forms the largest part of most micromagnetic calculations. A number of techniques are available and it is the intention in this review to outline each technique and give consideration to the circumstances under which each one is most applicable.

## 1. Energy Terms

### 1.1 Exchange Energy

Exchange energy forms an important part of the covalent bond of many solids and is also responsible for ferromagnetic coupling. The exchange energy is given by

$$E_{exch} = -2J\mathbf{S}_1 \cdot \mathbf{S}_2 \tag{1}$$

where $J$ is referred to as the exchange integral. $\mathbf{S}_1$ and $\mathbf{S}_2$ are the atomic spins. Clearly for ferromagnetic ordering $J$ must be positive. This so-called direct exchange coupling is somewhat idealized and applicable to only a few materials rigorously.

A number of other models exist, including itinerant electron ferromagnetism and indirect exchange interaction or Ruderman–Kittel–Kasuya–Yoshida (RKKY) interaction. Generally speaking, however, Eqn. (1) is the form usually taken for the exchange interaction with the value of $J$ dependent on the detailed atomic properties of the material.

### 1.2 Anisotropy

The term anisotropy refers to the fact that the properties of a magnetic material are dependent on the directions in which they are measured. Anisotropy makes an important contribution to hysteresis in magnetic materials and is therefore of considerable practical importance. The anisotropy has a number of possible origins.

*(a) Crystal or magnetocrystalline anisotropy*

This is the only contribution intrinsic to the material. It has its origins at the atomic level. First, in materials with a large anisotropy there is a strong coupling between the spin and orbital angular momenta within an atom. In addition, the atomic orbitals are generally nonspherical.

Because of their shape the orbits prefer to lie in certain crystallographic directions. The spin–orbit coupling then assures a preferred direction for the magnetization—called the *easy direction*. To rotate the magnetization away from the easy direction costs energy— and *anisotropy energy*. As might be expected the anisotropy energy depends on the lattice structure.

(i) Uniaxial anisotropy occurs in hexagonal crystals such as cobalt.

$$E = KV\sin^2\theta + \text{higher terms} \tag{2}$$

Here $\theta$ is the angle between the easy direction and the magnetization, $K$ is the anisotropy constant, and $V$ the volume of the sample. The higher order terms are small and usually neglected. This has one "easy axis" with two energy minima, separated by energy maxima. This energy barrier leads to hysteresis.

(ii) Cubic anisotropy; for example, iron, nickel

$$E/V = K_0 + K_1(\alpha_1^2\alpha_2^2 + \alpha_2^2\alpha_3^2 + \alpha_1^2\alpha_3^2) \tag{3}$$

Here $\alpha$ gives the direction cosine, i.e., the cosine of the angle between the magnetization direction and the crystal axis.

*(b) Shape anisotropy*

Consider a uniformly magnetized body. By analogy with dielectric materials we can refer to the magnetization (magnetic polarization) creating fictitious "free poles" at the surface.

These lead to a "demagnetizing field" $H_d$ which acts in opposition to $\mathbf{H}$. Figure 1 shows a sample with an anisotropic shape with a magnetic field applied in two perpendicular directions. The energy increases as $H_d$ increases. For an ellipsoid of revolution it can be shown that

$$E = -K_{eff}V\sin^2\theta \tag{4}$$

i.e., the same form as for uniaxial anisotropy. $\theta$ is the angle between the long axis of the sample and the magnetization direction. Also,

$$K_{eff} = \tfrac{1}{2}(N_b - N_a)M^2 \tag{5}$$

where $\boldsymbol{M}$ is the magnetization and $N_b$ and $N_a$ are "demagnetizing factors" in the short axis and long axis directions. $N_b$ and $N_a$ depend on the geometry so that $K_{eff} = 0$ for a sphere and $K_{eff} = M^2/2$ for a needle-like sample.

*(c) Stress anisotropy*

This arises from the change in atomic structures as a material is deformed. It is related to the phenomenon of "magnetostriction' which is important for sensor applications.

*(d) Magnetostatic effects and domain formation*

Magnetostatic fields are a natural consequence arising from any magnetization distribution. The

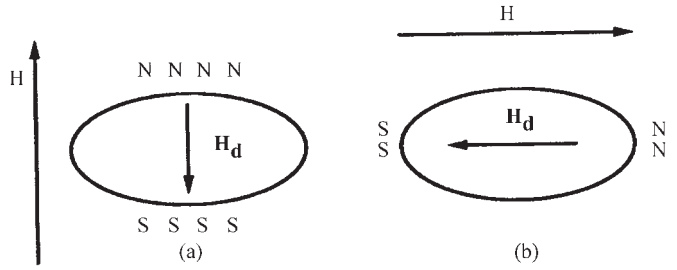

***Figure 1***
Sample with an anisotropic shape with a magnetic field applied in two perpendicular directions: (a) parallel to the short axis; here the "free poles" are separated by a relatively short distance, leading to a large $H_d$, (b) parallel to the long axis; poles separated by a smaller distance, which leads to a small value of $H_d$.

magnetostatic fields are fundamental to the micromagnetic problem and, importantly, introduce another length scale. Magnetostatic effects give rise to magnetization structures on a length scale orders of magnitude greater than atomic spacings. Consequently it is impossible to deal with both magnetostatic and exchange effects rigorously in micromagnetic calculations at least with the current computer facilities. The formulation of the magnetostatic interaction field problem will be given in detail later but for the moment it is simply necessary to introduce the fact that because of magnetostatic fields a magnetized body has a magnetostatic self energy given by

$$E_{mag} = \tfrac{1}{2} N_d M^2 \tag{6}$$

where $N_d$ is a factor depending on the shape of the sample.

This is, of course, related to the statement (Aharoni 1996) that the energy of a system depends on the boundary of the material. Clearly the energy given by Eqn. (6) can be reduced if the magnetization **M** is reduced. As a result of this the material has a tendency to break into domains in which the magnetization remains at the spontaneous magnetization appropriate for a given material at a given temperature with the domains oriented in such a way as to minimize the overall magnetization and hence the magnetostatic self energy.

However, creating a boundary between two domains also requires energy and the actual domain structure depends on a minimization of the total exchange *and* magnetostatic self-energy. This in a sense was the first application of micromagnetics.

It is interesting to note that as the size of a system reduces the magnetostatic self energy reduces and at some point it becomes energetically unfavorable to form a domain structure since the lowering of the magnetostatic energy is not sufficient to compensate for the energy necessary to create the domain wall. Below this size a sample is referred to as single domain and here the magnetization processes are dominated by the rotation of the magnetic moment against the anisotropy energy barrier.

## 2. *Foundations of Micromagnetics*

It is not possible to neglect any of the three major energy terms, exchange, anisotropy, and magnetostatic. The detailed magnetic behavior of a given material depends on the detailed balance between these energy terms. It is not even possible to add the magnetostatic and anisotropy terms as a perturbation to the exchange energy term and use a quantum mechanical solution of this problem. Currently the only realistic approach is to ignore the atomic nature of matter, to neglect quantum effects, and to use classical physics in a continuum description of a magnetic material.

Essentially, we assume the magnetization to be a continuous vector field $\mathbf{M}(\mathbf{r})$, with $\mathbf{r}$ the position vector. Thus we write

$$\mathbf{M}(\mathbf{r}) = M_s \mathbf{m}(\mathbf{r}); \quad \mathbf{m} \cdot \mathbf{m} = 1 \tag{7}$$

where $M_s$ is the saturation magnetization of the material. The basic micromagnetic approach is to formulate the energy in terms of the continuous magnetization vector field and to minimize this energy in order to determine static magnetization structures. Classical nucleation theory can be used to study modes of magnetization reversal and nucleation fields. The energy terms are formulated as follows.

### 2.1 *Anisotropy Energy*

This remains a local calculation and is straightforward to carry out using the expressions for either cubic or uniaxial symmetry given earlier.

### 2.2 *Exchange Energy*

The exchange energy is essentially short ranged and involves a summation over the nearest neighbors.

Assuming a slowly spatially varying magnetization the exchange energy can be written

$$E_{exch} = JS^2 \sum \phi_{ij}^2 \tag{8}$$

the summation being carried out over nearest neighbors only. The $\phi_{ij}$ represents the angle between two neighboring spins $i$ and $j$. It should be noted that in Eqn. (8) the energy of the state in which all spins are aligned has been subtracted and used as a reference state. This is legitimate as long as it is done consistently. For small angles, $|\phi_{ij}| \approx |\mathbf{m}_i - \mathbf{m}_j|$, a first-order expansion in a Taylor series is

$$|\mathbf{m}_i - \mathbf{m}_j| = |(\mathbf{s}_i \cdot \nabla)\mathbf{m}_j| \tag{9}$$

where $\mathbf{s}$ is a position vector joining lattice points $i$ and $j$.

Substituting, Eqn. (9) into Eqn. (10) gives

$$E_{exch} = JS^2 \sum_i \sum_{\mathbf{s}_i} |(\mathbf{s}_i \cdot \nabla)\mathbf{m}_j|^2 \tag{10}$$

where the second summation is over nearest neighbors. Changing the first summation to an integral over the whole body, the result is that for cubic crystals

$$E_{exch} = \int_V W_e \mathrm{d}V; \quad W_e = A(\nabla \mathbf{M})^2 \tag{11}$$

where

$$(\nabla \mathbf{M})^2 = (\nabla M_x)^2 + (\nabla M_y)^2 + (\nabla M_z)^2 \tag{12}$$

The material constant $A = JS^2/a$ for a simple cubic lattice with lattice constant $a$. This represents a major step in the formulation of micromagnetism: we have related the fundamental atomic properties to the spatial derivatives of the magnetization in the continuum approximation. The atomic properties are included via the exchange integral $J$ which in micromagnetic terms is essentially a phenomenological constant which can be determined from experimental data.

### 2.3 Magnetostatic Fields

Here we consider only the magnetostatic field arising from the magnetization distribution itself and not any externally applied field which is trivial to add to the overall energy. The magnetostatic or demagnetizing field $\mathbf{H}_d$ is governed by Eqns. (13) and (14)

$$\nabla \times \mathbf{H}_d = 0 \tag{13}$$

$$\nabla(\mathbf{H}_d + 4\pi\mathbf{M}) = 0 \tag{14}$$

Eqns. (13) and (14) are written in cgs units, i.e., $\mathbf{B} = \mathbf{H} + 4\pi\mathbf{M}$. Since the curl of $\mathbf{H}_d$ is 0, the demagnetizing field can be derived from a scalar potential,

$$\mathbf{H}_d = -\nabla\phi \tag{15}$$

Substitution of Eqn. (15) into Eqn. (14) yields

$$\nabla^2\phi = -4\pi\nabla \cdot \mathbf{M} \tag{16}$$

which because of its analogy with Poisson's equation in electrostatics leads to the definition of a volume magnetic charge density given by

$$\rho = -4\pi\nabla \cdot \mathbf{M} \tag{17}$$

Thus we can solve for the magnetostatic field by solving for the potential using Eqn. (16) subject to boundary conditions which determine the continuity of the normal component of $\mathbf{B}$ and of the tangential component of $\mathbf{H}_d$.

$$\mathbf{n} \cdot (\mathbf{B}_{ext} - \mathbf{B}_{int}) = 0 \tag{18}$$

$$\mathbf{n} \times (\mathbf{H}_{d;ext} - \mathbf{H}_{d;int}) = 0 \tag{19}$$

where $\mathbf{n}$ is a unit vector pointing outward from the surface.

In terms of the scalar potential the equivalent conditions are

$$\phi_{ext} = \phi_{int} \tag{20}$$

$$\left.\frac{\partial\phi}{\partial n}\right|_{ext} . - \left.\frac{\partial\phi}{\partial n}\right|_{int} = -4\pi\mathbf{M} \cdot \mathbf{n} \tag{21}$$

Thus again the surface of a bulk magnetized body is determining the overall response of a phenomenon having its origins at the atomic level. Finally we can write expressions for the potential and demagnetizing field as follows:

$$\phi(\mathbf{r}) = -\int_V \frac{\nabla \cdot \mathbf{M}(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|}\,\mathrm{d}V' + \int_S \frac{\mathbf{M}(\mathbf{r}') \cdot \mathbf{n}}{|\mathbf{r} - \mathbf{r}'|}\,\mathrm{d}S' \tag{22}$$

$$\mathbf{H}_d = -\int_V \frac{(\mathbf{r} - \mathbf{r}')\nabla \cdot \mathbf{M}(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|^3}\,\mathrm{d}V' + \int_S \frac{(\mathbf{r} - \mathbf{r}')\mathbf{M}(\mathbf{r}') \cdot \mathbf{n}}{|\mathbf{r} - \mathbf{r}'|^3}\,\mathrm{d}S' \tag{23}$$

The integrals in Eqn. (23) can be interpreted as fields arising from volume and surface change densities $\rho = -4\pi\nabla \cdot \mathbf{M}$ and $\sigma = 4\pi\mathbf{M}(\mathbf{r}) \cdot \mathbf{n}$, respectively.

Although Eqns. (22) and (23) represent elegant closed form solutions for the potential and demagnetizing field, they are not the best form for numerical computation. Essentially, the total energy of the system involves an integral over the volume as follows:

$$E_{mag} = \frac{1}{2}\int_V \mathbf{H}_d \cdot \mathbf{M}\mathrm{d}V \tag{24}$$

which because of Eqn. (23) involves a six-fold integration. In terms of the numerical problem this involves a scaling with $N^2$, where $N$ is the number of elements into which the body is discretized. This of course leads to rapid degradation of computational speed with system size and in practice an alternative solution must be found for the calculation of $\mathbf{H}_d$. The techniques involved will be described in detail later.

### 2.4 Brown's Equations

The final step in the formulation of classical micromagnetics is to minimize the total energy which can be written as follows

$$E_{tot} = \int_V \left[ A(\nabla \mathbf{M})^2 + E_{anis} - M_s \mathbf{m} \cdot \left( \mathbf{H}_a + \frac{\mathbf{H}_d}{2} \right) \right] \mathrm{d}V \quad (25)$$

where $\mathbf{H}_a$ is the externally applied field. Here, $E_{anis}$ is the anisotropy energy density.

The approach uses standard variational principles but the derivation is somewhat protracted. Essentially, setting the first variation of the total energy to zero leads to two equations. The first is a surface equation

$$2A \left[ \mathbf{m} \times \frac{\partial \mathbf{m}}{\partial n} \right] = 0 \Rightarrow \frac{\partial \mathbf{m}}{\partial n} = 0 \quad (26)$$

since $\mathbf{m} \cdot \partial \mathbf{m} / \partial \mathrm{n} = 0$ by virtue of $\mathbf{m} \cdot \mathbf{m} = 1$. The second is a volume equation,

$$\mathbf{m} \times \left[ \frac{2A}{M_s} \nabla^2 \mathbf{m} + \mathbf{H}_d + \mathbf{H}_a + \mathbf{H}_K \right] = 0 \quad (27)$$

where the anisotropy field $\mathbf{H}_K$ is defined as

$$\mathbf{H}_K = -\frac{1}{M_s} \frac{\partial E_{anis}}{\partial \mathbf{m}} \quad (28)$$

Eqn. (27) can be written

$$\mathbf{m} \times \mathbf{H}_{eff} = 0 \quad (29)$$

where the effective field $\mathrm{H}_{eff}$ is

$$\mathbf{H}_{eff} = \frac{2A}{M_s} \nabla^2 \mathbf{m} + \mathbf{H}_d + \mathbf{H}_a + \mathbf{H}_K \quad (30)$$

Eqn. (27) states that the equilibrium solution is found by making the magnetization lie parallel to the local field. Eqns. (26)–(30) are referred to as Brown's equations and form the basis of the classical micromagnetic approach for the solution of stationary problems.

## 3. Analytical Solutions

### 3.1 Stoner–Wohlfarth Theory

Stoner–Wohlfarth (SW) theory is the simplest micromagnetic model since it is assumed that all spins remain collinear thus removing the exchange term. Consider a particle with uniaxial anisotropy and easy axis at some angle $\psi$ to the applied field. The magnetization of the particle has an angle $\theta$ to the easy axis and $\theta - \psi$ to the applied field. The magnetic moment of the particle is $MV$, where $V$ is the particle volume. Assuming that the atomic magnetic moments always remain parallel (coherent rotation) the energy is the sum of the anisotropy and field energies, i.e.,

$$E = KV \sin^2\theta - MVH\cos(\theta - \psi) \quad (31)$$

The orientation of the magnetic moment is determined by minimizing the energy $E$, that is we set $\mathrm{d}E/\mathrm{d}\theta = 0$. This gives

$$\frac{\mathrm{d}E}{\mathrm{d}\theta} = 2KV \sin\theta \cos\theta + MVH\sin(\theta - \psi) = 0 \quad (32)$$

In general there are four solutions of Eqn. (32), two minima and two maxima (which separate the minima). We can illustrate the behavior using the special case of $\psi = 0$, that is, the easy axis is aligned with the field, Then Eqn. (32) becomes

$$2KV \sin\theta \cos\theta + MVH\sin\theta = 0 \quad (33)$$

Eqn. (33) has a solution at $\sin\theta = 0$, i.e., $\theta = 0$ or $\pi$. Further solutions occur at $2KV\cos\theta = -MVH$, so that

$$\cos\theta = -MH/2K \quad (34)$$

which are maxima.

These results can be used to illustrate the reversal process in the following way using Fig. 2. A large positive field is first applied to the sample, taking it to point (a) on the hysteresis loop. When the field is reduced to zero the energy maximum stops the system from becoming demagnetized. The magnetization still lies along the easy direction, i.e., in this case parallel to the applied field. This gives a remanent magnetization (point b). In negative fields the magnetization would prefer to reverse, in order to be parallel to the field direction. In order to do this it would have to rotate over the maximum energy, $E_{max}$. Thus there is an energy barrier to rotation, of value $E_b = E_{max} - E_{min}$. It is straightforward to show that

$$E_b = KV\left(1 - \frac{M^2H^2}{4K^2}\right) - MVH\left(\frac{MH}{2K}\right) - (-MVH) = KV\left(1 + \frac{M^2H^2}{4K^2}\right) \quad (35)$$

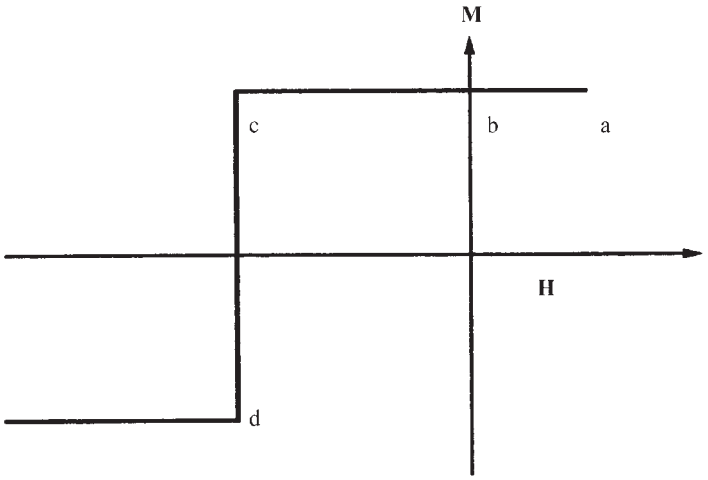

***Figure 2***
Hysteresis loop for a SW particle with the field applied parallel to the easy axis.

Therefore, the energy barrier becomes zero when $(MH/2K) = 1$, that is, when $H = -2K/M = -H_K$.

At this point, the *coercive force,* the magnetization rotates into the other minimum, i.e., into the field direction (points c to d). Thus $H_K$ is the maximum coercive force for a particle. For a particle oriented at some angle $\psi$ the behavior consists of a mixture of reversible and irreversible rotation.

The coercive force at some angle $\psi$ is less than $H_K$. For a system of particles with randomly orientated easy axes an average over all orientations gives a hysteresis loop that has a remanence of half the saturation magnetization and a coercivity of $0.479H_K$.

The SW model is still extensively used, especially in materials where the long-range interaction effects are more important than intrinsic grain properties. Generally, agreement with experiment is obtained for a low "effective value" of $H_K$ which takes some account of the nonuniform magnetization processes as is discussed later in relation to thin film simulations.

### *3.2 The Nucleation Problem*

Consider a ferromagnetic body in a magnetic field large enough to cause saturation. The field is slowly reduced to zero and then increased in a negative sense. At some point the original state becomes unstable and the magnetization makes a transition to a new energy minimum. The field at which the state becomes unstable is the "nucleation field." This can be determined analytically for a few simple geometries. In a sense, SW is the simplest nucleation theory. The limitations of nucleation theory can be seen by considering the final state after transition.

In a complex system there may be more than one accessible minimum, rather than the one state of SW theory. Consequently, nucleation theory cannot predict the magnetization curve of anything but the simplest materials and in this sense its predictions are more mathematically than physically interesting. Numerical micromagnetics with its novel techniques for determining the magnetic state at any point of the hysteresis loop is where predictions become accessible to experimental verification.

## *4. Numerical Micromagnetics*

### *4.1 Calculation of Stationary States: Energy Minimization Versus Dynamic Approach*

The first numerical micromagnetic approaches following the resurgence of interest in micromagnetic calculations in the mid-1980s were based essentially on energy minimization. Della Torre (1985, 1986) uses this approach in some calculations on the behavior of elongated particles. The approach works reasonably well but is prone to numerical instabilities.

A more sophisticated minimization technique was developed by Hughes (1983) in studies of longitudinal thin film media consisting of strongly coupled spherical grains (the strong coupling arising from exchange interactions between grains). In these materials strong cooperative reversal is important and a straightforward energy minimization technique was problematical during the magnetization reversal process.

A number of sophisticated energy minimization approaches are possible using standard numerical techniques. For example a number of workers have used conjugate gradient techniques. However, the basic problem arises from the nature of the micromagnetic problem itself. Essentially, it is relatively easy to track

a well-defined energy minimum as it evolves with the magnetic field. This is usually the case, for example, in the decrease from magnetic saturation towards the remanent state where no irreversible behavior occurs. The energy minimum in which the system resides is essentially a local energy minimum on a very complex energy surface. The magnetization reversal process can be seen as the disappearance of the local energy minimum due to the action of a sufficiently large field applied in a sense opposite to the original "positive" saturation direction.

The magnetization reversal process takes place when the minimum in the positive field direction vanishes and the system makes a transition into an energy minimum closer to the negative field direction. If the energy surface has a complex topology it may contain a number of energy minima accessible during the magnetization reversal process. Energy minimization is a very poor technique for predicting the correct minimum.

Magnetization reversal is intrinsically a dynamic phenomenon and in order to predict magnetization states correctly after reversal we should in principle take account of the dynamic behavior of the system as far as is possible. Victora (1987) first used a dynamic approach in studies of longitudinal thin films. The approach is based on the Landau–Lifshitz (L–L) equation of motion of an individual spin, which has the form

$$\frac{d\mathbf{M}}{dt} = \gamma_0 \mathbf{M} \times \mathbf{H} - \frac{\alpha\gamma_0}{M_s} \mathbf{M} \times \mathbf{M} \times \mathbf{H} \qquad (36)$$

Here, $\gamma_0$ is the gyromagnetic ratio and $\alpha$ is the damping constant. In Eqn. (36) the first term leads to gyromagnetic procession. In the absence of damping this will be eternal and would not lead to the equilibrium state in which the magnetization is parallel to the local field.

The second term represents damping. This ensures that the system eventually reaches the equilibrium position. It should be noted that other forms of the dynamic equation are possible, including the Gilbert form. However, in the limit of small damping, these forms are equivalent although the Gilbert equation is probably more physically correct.

Also, in the limit of large damping, in which case the second term of Eqn. (36) dominates, the Landau–Lifshitz equation is equivalent to a steepest decent energy minimization approach. The L–L equation is the most widely used dynamic approach currently.

Eqn. (36) is easy to solve numerically for a single spin. However, the micromagnetic problem is represented by a set of strongly coupled equations of motions which is a somewhat more difficult numerical problem. The types of system considered can for convenience be considered as of two types.

(i) Weakly coupled systems. Typical examples here might be a set of grains with uniform magnetization coupled by magnetostatic and perhaps weak exchange interactions. For this type of system a simple numerical technique such as the Runge–Kutta approach with adaptive step size will probably suffice.

(ii) Strongly coupled systems. These examples tend to have strong exchange coupling, for example, in the case of studies of nonuniform magnetization processes in a single grain or a set of strongly exchange coupled grains. In terms of the differential equations the system in this case is referred to as "stiff." Although Runge–Kutta will still give a solution, the step size tends to become very small and the computational times involved, increasingly long. It is more usual under these circumstances to use an alternative technique, for example, predictor–corrector algorithms.

The numerical technique essentially entails the determination of the local field **H** at each point in the system followed by a determination of the small magnetization changes using Eqn. (36). The whole system is updated simultaneously at each time step after which the local field is recomputed and this procedure is carried out until the system evolves into an equilibrium state. Equilibrium can be determined using a number of criteria:

(i) Magnetization changes at a given step below a certain minimum value, and

(ii) Comparison of the direction of the local magnetization and the local field. Essentially the convergence is determined dependent on the maximum value of $\mathbf{M} \times \mathbf{H}$ for the system.

The technique used depends to some extent on the system studied. In a sense this is the easiest part of numerical micromagnetics. A number of numerical techniques are available for the solution of Eqn. (36) and it is not too difficult to create algorithms based on the dynamic approach which are robust in terms of finding stationary states and also reliable in finding new stationary states after the nucleation of a magnetization reversal event.

Two problems remain however. The first is the determination of the local field **H** which is a rather difficult and specific problem on which considerable effort has been expended. However, a further problem is in the microstructure of the material itself and the approximations which need to be made in order to make the problem amenable to a numerical solution whilst retaining some physical realism. The following section considers some aspects of the problem of microstructure in micromagnetics.

### *4.2 Microstructural Simulations*

Numerical micromagnetics involves a discretization of space. The behavior of the spin associated with each small volume element is described by Eqn. (36). Because of the exchange and magnetostatic interactions this leads to a finite set of coupled equations of

motion of the form of Eqn. (36) which have to be solved numerically. The spatial discretization is an important part of the problem.

### *(a) Particulate systems*

Nanostructured particulate systems are essentially of two types. The first is so-called granular magnetic solid, essentially a heterogenous alloy consisting of magnetic particles in a nonmagnetic matrix. This is often produced by sputtering, evaporation, or laser ablation. These systems have a microstructure consisting of relatively randomly distributed grains and can be modeled by placing grains at random into the computational cell. The spatial disorder in this system has been shown (El Hilo *et al*. 1994) to be an important factor in determining the effects of exchange coupling in the materials.

For example, standard micromagnetic calculations with an ordered system lead to an enhancement of the remanent magnetization due to intergranular exchange coupling but also predict a decreased coercive force due to the effects of cooperative magnetization reversal. In a system with a random microstructure, however, the effects of the cooperative reversal are decreased and although the exchange coupling leads to an enhanced remanence the reduction in the scale of the cooperative reversal can also lead to a small enhancement of the coercive force. Consequently, it is important to stress that the microstructure of a material needs to be modeled as realistically as possible.

In the case of particular materials produced by the solidification of a fluid precursor, for example, by the polymerization of a ferrofluid or the production of particulate recording medium from a magnetic dispersion, it is known that magnetostatic interactions are important because they give rise to flux closure and consequent modifications to the microstructure.

Vos *et al*. (1993) have demonstrated the importance of microstructure by comparing the chaining effects which occur in standard particulate media with the behavior of barium ferrite. In the latter case the particles consist of small platelets which tend to form long stacks under the influence of magnetostatic interactions. The calculations of Vos *et al*. indicate very different behavior for the two types of microstructure. However, the actual microstructures used were created using an *ad hoc* procedure.

Chantrell *et al*. (1996) have demonstrated the importance of the correct simulation of microstructure in particulate systems, and have developed a sophisticated molecular dynamic approach Coverdale *et al*. 2001 to the prediction of microstructures.

### *(b) Granular thin metallic films*

Although these are similar to particulate materials in that they consist of well-defined grains, these materials are generally considered as a separate case, essentially because of their different applications and also because they consist, to a first approximation at least, as a single layer of grains.

In these systems, clearly magnetostatic interactions between the metallic grains will be very strong and there is also the possibility of some exchange coupling across grain boundaries. Generally these materials are alloys, for example, of chromium. The intention is that the chromium segregates to grain boundaries giving rise to good magnetic isolation.

The first models of these materials were produced from the mid–1980s onwards and in many ways remain largely unchanged. The models consist of spherical grains which are assumed to rotate coherently and can therefore be treated as a single spin, situated on a regular hexagonal lattice. The reason for this uniformity is that it simplifies the magnetostatic field calculation because fast Fourier transform techniques can be used (as described in the following section).

Many simulations still use this rather idealized model, even though it has been shown that it drastically overestimates the cooperative reversal. Miles and Middleton (1990) were the first to develop a simulation based on an irregular grain structure with a distribution of particle volumes. This and later work (Walmsley *et al*. 1996) demonstrate conclusively that the size of magnetic features in the materials is critically affected by the microstructure and, as one might expect, is significantly smaller in materials with some disorder.

The other problem with the assumed microstructure is the intrinsic assumption of coherent reversal, which means that the intrinsic coercivity (assumed to be due to coherent rotations) is probably overestimated.

The parameters $h_{int}$ and $C^*$ represent the magnetostatic and exchange coupling strengths with respect to the intrinsic coercivity and are empirical parameters which essentially hide the micromagnetic deficiencies of the model. At attempt to produce a realistic microstructure is described by Schrefl and Fidler (1992). The microstructure is produced via a voronoi construction. Essentially this entails, for a two-dimensional system at least, distributing points at random in space and bisecting the line between points to produce grain boundaries. This produces an irregular grain structure and has been used in granular three-dimensional systems (Schrefl and Fidler 1992) and longitudinal thin films (Tako *et al*. 1996).

These models represent the state of the art in terms of microstructural simulations. It is desirable to carry out a discretization of the systems at the subgrain level, since this allows the correct simulation of nonuniform magnetization processes. The uniform mesh is no longer appropriate. Finite element methods are necessary, and are outlined in *Micromagnetics: Finite Element Approach*.

## 5. Magnetostatic Field Calculations

Here we consider relatively common and easily applied approaches. More sophisticated techniques are necessary for calculations using finite elements, and these will be outlined in *Micromagnetics: Finite Element Approach*.

### 5.1 Dipole Sum—the Bethe–Peierls–Weiss Approximation

This is by far the easiest approach to adopt. We start with the interaction field written as

$$\mathbf{H}_i = \sum_{j \neq i} \mathbf{H}_{ij} \tag{37}$$

where

$$\mathbf{H}_{ij} = -\frac{\mathbf{m}_j}{r^3} + \frac{3(\mathbf{m}_j \cdot \mathbf{r})\mathbf{r}}{r^5}$$

is the interaction field at element $i$ due to element $j$. $\mathbf{m}_i$ and $\mathbf{m}_j$ are the magnetic moments of each element and $\mathbf{r}$ is the spatial separation.

Clearly the determination of fields via Eqn. (37) is an $N^2$ problem. In order to make the calculation feasible for large systems the usual approximation is to divide the problem into a direct summation over some region $V$ around a given site $i$ and to use a continuum approximation to the field outside this region. For a spherical cut off the result is of the form (in cgs units)

$$\mathbf{H}_i = \sum_{j \in V} \mathbf{H}_{ij} + \frac{4\mathbf{M}}{3} - N_d \mathbf{M} \tag{38}$$

The first term is a direct summation within a region $V$ surrounding $i$. Outside this region the material is treated as a uniformly magnetized continuous material of magnetization $\mathbf{M}$ (in cgs units). The problem of determining the field at the center of the spherical cut out than reduces to solutions of

$$\mathbf{H}_d = \int_{\partial V} \frac{(\mathbf{r} - \mathbf{r}') \cdot \mathbf{M}(\mathbf{r}')\hat{\mathbf{n}}}{|\mathbf{r} - \mathbf{r}'|^3} \mathrm{d}S \tag{39}$$

over surfaces $\partial V$ representing the inside surface of the cut out region and the outside of the magnetized body. Eqn. (39) follows directly from Eqn. (23) given the assumption of a uniform magnetization, $\nabla \cdot \mathbf{M} = 0$.

The second and third terms in Eqn. (38) are the "Lorentz" and "demagnetizing" fields arising from the internal and external surfaces respectively, with $N_d$ a shape-dependent demagnetizing factor. These factors arise directly from analytical solution of Eqn. (39).

### 5.2 Hierarchical Calculation

The hierarchical approach is a more sophisticated calculation which improves on the Bethe–Peierls–Weiss approximation. Essentially, a dipole sum is again carried out within a central area around the point at which the field is to be calculated. In the simplest case the remaining material is represented by "cells" of similar size, taken as having a total moment obtained by adding all the moments in the cell. This is then used to calculate the field due to the cell at the central point and a summation of these contributions is taken. This approach was used by Miles and Middleton (1991). It is possible to improve the accuracy by adding higher order (multipole) terms. Such fast multipole methods are often used in electrostatic calculations.

The beauty of the hierarchical calculation is that it can be applied to systems with disordered microstructures which is not easily the case for methods such as the fast Fourier transform, a description of which follows.

### 5.3 Fast Fourier Transform Techniques

This was developed by Mansuripur and Giles (Mansuripur and Giles 1988, Giles *et al.* 1990) specifically for simulation of magneto-optic recording media and has since become widely used. Its advantage is that the use of FFTs give rise to a scaling with $N \ln N$ rather than $N^2$. The disadvantage is the need for a lattice in order to carry out the discrete Fourier transform. The problem can be formulated in a general way using the following three-dimensional representation formulas:

$$\mathbf{M}(\mathbf{x}) = \sum_{pqr} \mathbf{m}_{pqr} e^{i(\mathbf{k}_{pqr} \cdot \mathbf{x})} \tag{40}$$

$$\phi(\mathbf{x}) = \sum_{pqr} \psi_{pqr} e^{i(\mathbf{k}_{pqr} \cdot \mathbf{x})} \tag{41}$$

Here, $\mathbf{k}_{pqr} = (k_p, k_q, k_r)$ with $k_p = 2\pi p/L_z$, $k_q = 2\pi q/L_y$, $k_r = 2\pi r/L_z$. By substitution into Eqn. (16) and comparing coefficients it is straightforward to show that

$$\phi_{pqr} = -\frac{4\pi i}{|\mathbf{k}_{pqr}|^2} \mathbf{m}_{pqr} \cdot \mathbf{k}_{pqr} \tag{42}$$

Determination of $-\nabla\phi$ then gives the field value.

# Micromagnetics: Finite Element Approach

Since the early 1970s finite element modeling has become increasingly important in such different areas as continuum mechanics, electromagnetic field computation, and computational fluid dynamics. The integration of computer-aided design, finite element processing, and postprocessing methods for visualization of the numerical results makes finite element software a highly flexible tool in industrial research and development. The possibility of solving partial differential equations on irregular-shaped problem domains and of adjusting the spatial resolution using adaptive mesh refinement techniques are among the advantages of the finite element method. The use of the finite element method in micromagnetic simulations allows the realistic physical microstructures to be taken into account, which is a prerequisite for the quantitative prediction of the magnetic properties of thin film recording media or permanent magnets.

Finite element models of the grain structure are obtained from a Voronoi construction and subsequent meshing of the polyhedral regions. Finite element micromagnetic codes have been developed for the calculation of equilibrium states and the simulation of magnetization reversal dynamics. In either case short-range exchange and long-range magnetostatic interactions between the grains considerably influence the magnetic properties. The numerical evaluation of the magnetostatic interaction field makes use of well-established techniques of magnetostatic field calculation based on the finite element or the boundary element method.

Numerical micromagnetics at a subgrain level involves two different length scales which may vary by orders of magnitude. The characteristic magnetic length scale on which the magnetization changes its direction, is given by the exchange length in soft magnetic materials and the domain wall width in hard magnetic materials. For a wide range of magnetic materials, this characteristic length scale is in the order of 5 nm which may be either comparable or significantly smaller than the grain size. Adaptive refinement and coarsening of the finite element mesh enables accurate solutions to be found of the magnetization distribution at a subgrain level.

## 1. Finite Element Models of Granular Magnets

The simulation of grain growth using a Voronoi construction (Preparata 1985) yields a realistic microstructure for a permanent magnet. Starting from randomly located seed points, the grains are assumed to grow with constant velocity in each direction. Then the grains are given by the Voronoi cells surrounding each point. The Voronoi cell of seed point $i$ contains all points in space which are closer to seed point $i$ than to any other seed point. In order to avoid strongly irregular-shaped grains, it is possible to divide the model magnet into cubic cells and to choose one seed point within each cell at random. An example is the grain structure of Fig. 1 which is used to simulate the magnetic properties of nanocomposite, permanent magnets.

Different crystallographic orientations and different intrinsic magnetic properties are assigned to each grain. In addition, the grains may be separated by a narrow intergranular phase (Fischer and Kronmüller 1998). Once the polyhedral grain structure is obtained, the grains are further subdivided into finite elements. The magnetization is defined at the nodal points of the finite element mesh. Within each element

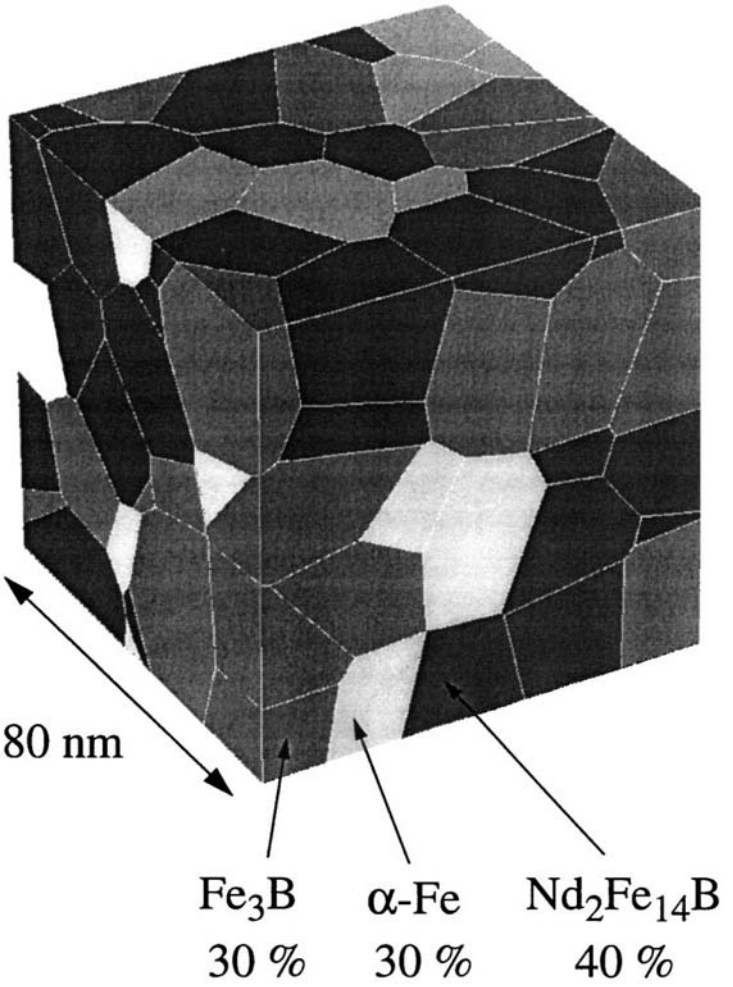

***Figure 1***
Finite element model of a nanocomposite permanent magnet obtained from a Voronoi construction. The plot gives the grain structure on the surface of a cubic magnet. The different colors refer to magnetically hard ($Nd_2Fe_{14}B$) and ($\alpha$-Fe, $Fe_3B$) soft grains.

the magnetization is interpolated by a polynomial function. Thus the magnetization $\mathbf{M}(\mathbf{r})$ may be evaluated everywhere within the model magnet, using the piecewise polynomial interpolation of the magnetization on the finite element mesh. Figure 2(a) illustrates the interpolation of the magnetization using a linear function on a triangular finite element. The magnetization on a point $\mathbf{r}$ within the element

$$\begin{aligned}\mathbf{M}(\mathbf{r}) &= (A_1\mathbf{M}(\mathbf{r}_1) + A_2\mathbf{M}(\mathbf{r}_2) + A_3\mathbf{M}(\mathbf{r}_3))/ \\ &\quad (A_1 + A_2 + A_3) \\ &= (A_1/A)\mathbf{M}_1 + (A_2/A)\mathbf{M}_2 + (A_3/A)\mathbf{M}_3 \quad (1)\end{aligned}$$

is the weighted average of the magnetization at the nodal points 1, 2, and 3.

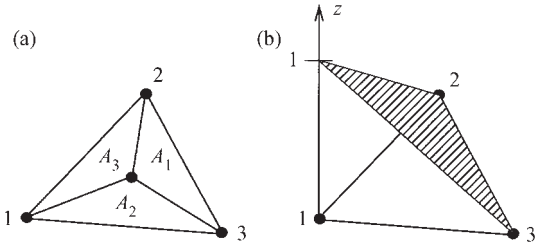

***Figure 2***
(a) Linear interpolation of the magnetization within a finite element. (b) The hatched area denotes the shape function of node 1, which equals one on node 1 and is zero on all the other nodes of the element.

$A$ denotes the total area of the element and $A_i$ are the areas of the subtriangles (see Fig. 2). A similar interpolation scheme applies for tetrahedral elements in three dimensions. The functions $\varphi_i = A_i/A$ are called shape functions. The shape function $\varphi_i(\mathbf{r})$ equals one on the node $i$ and is zero on all the other nodes of the element. The shape function $\varphi_i(\mathbf{r})$ satisfies the conditions

$$\varphi_i(\boldsymbol{x}_j) = \delta_{ij} \tag{2}$$

where $\mathbf{r}_j$ denotes the cartesian coordinates of the nodes $j = 1, \ldots, n$. Figure 2(b) depicts the shape function $\varphi_1$ . The finite element mesh is used to integrate the total magnetic Gibbs free energy over the magnet. The energy integral is then replaced by a sum over cells (triangles, tetrahedrons, hexahedrons, ...) and Eqn. (1) is applied to perform the integration of the energy over each cell.

Within the framework of micromagnetism (Brown 1963, Aharoni 1996), the magnitude of $\mathbf{M}$ is assumed to be a constant over the whole magnet, which depends only on the temperature

$$|\mathbf{M}| = M_s(T) \tag{3}$$

The linear interpolation, Eqn. (1), does not preserve the magnitude of the magnetization within a finite element. However, the deviation of $|\mathbf{M}|$ from $M_s$ within an element may be used as an error indicator for adaptive refinement schemes. Successive refinement of elements, where $|\mathbf{M}|$ deviates from $M_s$ will lead to a fine mesh in areas with large spatial variation of the magnetization direction. After several refinement steps the constraint, Eqn. (3), will be approximately fulfilled on the entire finite element mesh (see Sect. 5).

## 2. Total Magnetic Gibbs Free Energy and Effective Field

In numerical micromagnetics generally the following scheme is used in order to calculate a hysteresis loop. At first the model magnet is saturated by applying a high external field. The uniform magnetic state with magnetization pointing parallel to the field direction corresponds to a minimum of the total magnetic Gibbs free energy. The repeated minimization of the energy for decreasing and increasing applied field provides the hysteresis curve. A small change of the external fields alters the energy surface slightly and thus the system is not in equilibrium any more. Unless the change of the external field alters the curvature of the energy surface, the current position of the system will be close to a local minimum of the energy. If the local minimum vanishes as the curvature changes the system has to find its path towards the next local minimum. The Gilbert equation of motion (Gilbert 1955)

$$\frac{\partial \mathbf{M}}{\partial t} = -|\gamma|\mathbf{M} \times \mathbf{H}_{\text{eff}} + \frac{\alpha}{M_s}\mathbf{M} \times \frac{\partial \mathbf{M}}{\partial t} \tag{4}$$

is believed to describe the physical path the system follows towards equilibrium.

The effective field $\mathbf{H}_{\text{eff}}$ which provides the torque acting on the magnetization is the negative functional derivative of the total magnetic Gibbs free energy, $\mu_0 \mathbf{H}_{\text{eff}} = -\delta E/\delta \mathbf{M}$. The first term on the right hand side of Eqn. (4) describes the gyromagnetic precession, where $\gamma$ is the gyromagnetic ratio of the free electron spin. The second term describes the dissipation of energy. It causes the magnetization to be become aligned parallel with the effective field as the system proceeds towards equilibrium. $\alpha$ is a dimensional damping parameter. Alternatively, numerical minimization methods may be used to compute the equilibrium states which considerably reduce the computation effort as compared to the numerical integration of the Gilbert equation.

Both static and dynamic micromagnetic finite element calculations start from the discretization of the total magnetic Gibbs free energy

$$E = \int \mathrm{d}V \{e_{\text{ex}}(\mathbf{r}) + e_{\text{K}}(\mathbf{r}) + e_{\text{m}}(\mathbf{r}) + e_{\text{z}}(\mathbf{r})\} \tag{5}$$

which is the integral over the sum of the exchange energy density, the magneto-crystalline anisotropy energy density, the magnetostatic energy density, and the Zeeman energy density. When $\mathbf{M}(\mathbf{r})$ is approximated by piecewise polynomial functions on the finite element mesh, the energy functional reduces to an energy function with the nodal values of the magnetization, $\mathbf{M}_i = (M_{x,i}, M_{y,i}, M_{z,i})$, as unknowns. The total energy may be written as

$$\begin{aligned} E &= E(\mathbf{M}(\mathbf{r})) = E(\mathbf{M}_1, \mathbf{M}_2, \ldots, \mathbf{M}_n) \\ &= E(M_{x,1}, M_{y,1}, M_{z,1}, M_{x,2}, M_{y,2}, M_{z,2}, \ldots, \\ &\qquad M_{x,n}, M_{y,n}, M_{z,n}) \end{aligned} \tag{6}$$

where $n$ is the total number of nodal points. The minimization of Eqn. (6) with respect to the $3n$ variables $M_{x,i}$, $M_{y,i}$, $M_{z,i}$ subject to the constraint $|\mathbf{M}_i| = M_s$ provides an equilibrium distribution of the magnetization.

To satisfy the constraint, Eqn. (3), polar coordinates $\theta_i$, $\phi_i$ for the magnetization at the node $i$ may be introduced, such that $M_{x,i} = M_s \sin\theta_i \cos\phi_i$, $M_{y,i} = M_s \sin\theta_i \sin\phi_i$, and $M_{z,i} = M_s \cos\theta_i$. An alternative approach (Koehler 1997) is to normalize the magnetization in the discretized energy function, Eqn. (6), replacing $M_{x,i}$, $M_{y,i}$, $M_{z,i}$ by $M_{x,i}/|\mathbf{M}_i|$, $M_{y,i}/|\mathbf{M}_i|$, $M_{z,i}/|\mathbf{M}_i|$. In both cases, the minimization may be effectively performed using a conjugate gradient method (Gill *et al.* 1993).

Conjugate gradient-based minimization techniques require the gradient of the energy to select the search directions. Using polar coordinates, the gradient of

the energy can be expressed as

$$\frac{\partial E}{\partial \theta_i} = \frac{\partial E}{\partial M_{x,i}} \frac{\partial M_{x,i}}{\partial \theta_i} + \frac{\partial E}{\partial M_{y,i}} \frac{\partial M_{y,i}}{\partial \theta_i} + \frac{\partial E}{\partial M_{z,i}} \frac{\partial M_{z,i}}{\partial \theta_i} = -V_i \mu_0 \mathbf{H}_{\text{eff},i} \cdot \frac{\partial \mathbf{M}_i}{\partial \theta_i} \tag{7}$$

$$\frac{\partial E}{\partial \phi_i} = \frac{\partial E}{\partial M_{x,i}} \frac{\partial M_{x,i}}{\partial \phi_i} + \frac{\partial E}{\partial M_{y,i}} \frac{\partial M_{y,i}}{\partial \phi_i} + \frac{\partial E}{\partial M_{z,i}} \frac{\partial M_{z,i}}{\partial \phi_i} = -V_i \mu_0 \mathbf{H}_{\text{eff},i} \cdot \frac{\partial \mathbf{M}_i}{\partial \phi_i} \tag{8}$$

In Eqns. (7) and (8) the effective field $\mathbf{H}_{\text{eff}}$ has been introduced. The effective field at the nodal points of the finite element mesh can be calculated within the framework of the box method. The effective field at the nodal point $i$ of the finite element mesh can be approximated by (Gardiner 1985)

$$\mu_0 \mathbf{H}_{\text{eff},i} = -\left(\frac{\delta E}{\delta \mathbf{M}}\right)_i \approx -\frac{1}{V_i} \frac{\partial E}{\partial \mathbf{M}_i} \tag{9}$$

where $V_i$ is the volume of a "box" surrounding the nodal point $i$. The following conditions hold for the box volumes

$$\sum_i V_i = \int \mathrm{d}V \quad \text{and} \quad V_i \cap V_j = 0 \quad \text{for} \quad i \neq j. \tag{10}$$

## 3. *Magnetostatic Field Calculation*

Both static and dynamic micromagnetic calculations are required to evaluate the effective field at the nodal points of the finite element mesh. The effective field is the sum of the exchange field, the anisotropy field, the magnetostatic field, and the external field. The exchange field and the anisotropy field depend only locally on the magnetization or its spatial derivatives and thus may be directly calculated using Eqn. (9). The magnetostatic field depends on the magnetization distribution over the entire magnet. It arises from the nonzero divergence within the grains ("magnetic volume charges") and the intersection of the magnetization with the grain surface ("magnetic surface charges").

Numerical micromagnetics can make use of the well-established methods for the finite element calculation of magnetostatic fields (Silvester and Ferrari 1983). The magnetostatic field either is derived from a magnetic scalar or a magnetic vector potential. The finite element discretization of the corresponding partial differential equation leads to a system of linear equations. Owing to the local character of the equations the corresponding system matrix is symmetric and sparse. State of the art solution techniques for a sparse linear systems consist of a preconditioning step, followed by the iterative solution of the linear system using a conjugate gradient-based method.

For a given finite element mesh the preconditioning of the system matrix has to be done only once, reducing the effort for the subsequent calculations of the magnetostatic field to about $n^{1.3}$, where $n$ is the total number of grid points. Thus the use of the finite element method to treat the auxiliary problem of the magnetostatic field provides an alternative fast solution technique without any restriction on the geometry of the magnetic particles.

### 3.1 *The Magnetostatic Boundary Value Problem*

The magnetostatic contribution to the effective field is the negative gradient of the magnetic scalar potential. The magnetic scalar potential satisfies the Poisson equation

$$\nabla^2 U(\mathbf{r}) = \nabla \cdot \mathbf{M}(\mathbf{r}) \tag{11}$$

Outside the magnetic particle $\mathbf{M}$ equals zero and thus Eqn. (11) reduces to the Laplace equation. At the boundary of the magnet $\Gamma$ the boundary conditions

$$U^{\text{int}} = U^{\text{ext}}, \ (\nabla U^{\text{int}} - \nabla U^{\text{ext}}) \cdot \mathbf{n} = \mathbf{M} \cdot \mathbf{n} \tag{12}$$

hold. Here $\mathbf{n}$ denotes the outward pointing normal unit vector on $\Gamma$. The magnetic scalar potential is regular at infinity

$$U \propto 1/\mathbf{r} \quad \text{for} \quad \mathbf{r} \to \infty \tag{13}$$

The Galerkin method is applied to transfer the magnetostatic boundary value problem to a system of linear equations. The partial differential equation, Eqn. (11), is multiplied by test functions $\varphi_i$ and integrated over the problem domain

$$\int_{\Omega_{\text{int}}} \mathrm{d}V \varphi_i \nabla^2 U(\mathbf{r}) + \int_{\Omega_{\text{ext}}} \mathrm{d}V \varphi_i \nabla^2 U(\mathbf{r}) = \int_{\Omega_{\text{int}}} \mathrm{d}V \varphi_i \nabla \cdot \mathbf{M}(\mathbf{r}) + \int_{\Omega_{\text{ext}}} \mathrm{d}V \varphi_i \nabla \cdot \mathbf{M}(\mathbf{r}) \tag{14}$$

Here $\Omega_{\text{int}}$ and $\Omega_{\text{ext}}$ denote the space within and outside the magnet, respectively. Integration by parts moves the second derivative of the potential and the first derivative of the magnetization vector to the test function

$$\int_\Gamma \mathrm{d}S \varphi_i (\nabla U^{\text{int}} - \nabla U^{\text{ext}}) \cdot \mathbf{n} - \int_{\Omega_{\text{int}} \bigcup \Omega_{\text{ext}}} \mathrm{d}V \nabla \varphi_i \nabla U = \int_\Gamma \mathrm{d}S \varphi_i \mathbf{M} \cdot \mathbf{n} - \int_{\Omega_{\text{int}}} \mathrm{d}V \nabla \varphi_i \cdot \mathbf{M} \tag{15}$$

Substituting the boundary condition, Eqn. (12), into Eqn. (15) the surface integrals cancel.

Within the framework of the Galerkin method, the shape functions $\varphi_i$, given by Eqn. (2), are used as test functions. Like the magnetization, the magnetic scalar potential is interpolated by a piecewise polynomial

function over a finite element $e$

$$U(\mathbf{r}) = \sum_i \varphi_i^e(\mathbf{r}) U_i = \varphi_i^e(\mathbf{r}) U_i \tag{16}$$

where $U_i$ denote the values of the magnetic scalar potential at the nodes of the element. Then the volume integrals in Eqn. (15) break into sums of integrals over the finite elements

$$\sum_e \int \mathrm{d}V \, \nabla\varphi_i \nabla\varphi_j^e U_j = \sum_e \int \mathrm{d}V \, \nabla\varphi_i \cdot \varphi_j^e \mathbf{M}_j \tag{17}$$

The summation over the contributions of the individual finite elements in Eqn. (17) leads the sparse, linear system of equations that gives the potential $U_i$ at the nodes $i$ of the finite element mesh.

### *3.2 The Open Boundary Problem*

In order to impose the regularity condition Eqn. (13), the finite element mesh has to be extended over a large region outside the magnetic particles. As a rule of thumb the distance between the boundary of the external mesh and the particle should be at least five times the extension of the particle (Chen and Conrad 1997). Various other techniques have been proposed to reduce the size of the external mesh or to avoid a discretization of the exterior space. The use of asymptotic boundary conditions (Yang and Fredkin 1998) reduces the size of the external mesh compared to truncation. At the external boundary Robbin conditions are applied, which are derived from a series expansion of the solution of the Laplace equation for $U$ outside the magnet and give the decay rate of the potential at a certain distance from the sample (Khebir *et al.* 1990).

A similar technique that considerably reduces the size of the external mesh is the use of space transformation to evaluate the integral over the exterior space in Eqn. (15). Among the various transformations proposed to treat the open boundary problem, the parallelepipedic shell transformation (Brunotte *et al.* 1992), which maps the external space into shells enclosing the parallelepipedic interior domain, has proved to be most suitable in micromagnetic calculations. The method can be easily incorporated into standard finite element programs transforming the derivatives of the nodal shape functions. This method was applied in static three-dimensional micromagnetic simulations of the magnetic properties of nanocrystalline permanent magnets (Schrefl and Fidler 1998, Fischer and Kronmüller 1998)

An alternative approach for treating the so-called open boundary problem is a hybrid finite element/boundary element method (Fredkin and Koehler 1990, Koehler 1997). The basic concept of this method is to split the magnetic scalar potential into $U = U_1 + U_2$, where the potential $U_1$ is assumed to solve a closed boundary value problem. Then the equations for $U_2$ can be derived from Eqns. (11) and (12), which hold for the total potential $U = U_1 + U_2$. The potential $U_1$ accounts for the divergence of the magnetization and $U_2$ is required to meet the boundary conditions at the surface of the particle. The latter also carries the magnetostatic interactions between distinct magnetic particles.

The potential $U_1$ can be computed from the closed boundary value problem

$$\nabla^2 U_1(\mathbf{r}) = \nabla \cdot \mathbf{M}(\mathbf{r}) \quad \text{for} \quad \mathbf{r} \in \Omega_{\text{int}} \tag{18}$$

$$U_1 = 0 \quad \text{for} \quad \mathbf{r} \in \Omega_{\text{ext}} \tag{19}$$

$$\nabla U_i \cdot \mathbf{n} = \mathbf{M} \cdot \mathbf{n} \quad \text{for} \quad \boldsymbol{r} \in \Gamma \tag{20}$$

The potential $U_1$ is the solution of the Poisson equation within the magnetic particles and equals zero outside the magnets. At the surface of the magnets, natural boundary conditions hold. The potential $U_2$ satisfies the Laplace equation everywhere

$$\nabla^2 U(\mathbf{r}) = 0 \quad \text{for} \quad \mathbf{r} \in \Omega_{\text{int}} \cup \Omega_{\text{ext}} \tag{21}$$

and shows a jump at the boundary of the magnetic particles

$$U_2^{\text{int}}(\mathbf{r}) - U_2^{\text{ext}}(\mathbf{r}) = U_1^{\text{int}}(\mathbf{r}), (\nabla U_2^{\text{int}} - \nabla U_2^{\text{ext}}) \cdot \mathbf{n} = 0 \quad \text{for } \mathbf{r} \in \Gamma \tag{22}$$

A standard finite element method may be used to solve Eqns. (18)–(22). Eqns. (21) and (22) define a double layer potential which is created by a dipole sheet with magnitude $U_1 \cdot U_2$ can be evaluated using the boundary element method. After discretization, the potential $U_2$ at the boundary nodes follows from a matrix vector multiplication $U_2 = \mathbf{B}\, U_1$, where $\mathbf{B}$ is a $m \times m$ matrix which relates the $m$ boundary nodes with each other. Once $U_2$ at the boundary has been calculated, the values of $U_2$ within in the particles follow from Laplace's equation with Dirichlet boundary conditions, which again can be solved by a standard finite element technique.

The matrix $\mathbf{B}$ depends only on the geometry and the finite element mesh and thus has to be computed only once for a given finite element mesh. Since the hybrid finite element boundary element method does not introduce any approximations, the method is accurate and effective. The use of the boundary element method easily treats the magnetostatic interactions between distinct magnetic particles and requires no mesh outside the magnetic particles. Süß and coworkers (Süß *et al.* 1999) applied the hybrid finite element/boundary element method, in order to simulate the effect of magnetostatic interactions on the reversal dynamics of magnetic nanoelements.

### *3.3 Static Micromagnetics Using a Magnetic Vector Potential*

The use of a magnetic scalar potential in micromagnetic calculations, requires the solution of a system of linear equations associated with the magnetostatic boundary value problem, whenever the total magnetic Gibbs free energy or the effective field has to be evaluated. An alternative approach for treating the magnetostatic interactions is the use of a magnetic vector potential. Then micromagnetic problem can be reformulated as an algebraic minimization problem with the nodal values of the magnetization angles $\theta_i$, $\phi_i$, and the nodal values of the magnetic vector potential **A** as unknowns. The method applies an alternative function to express the magnetostatic energy.

Brown (1963) proposed an upper bound for the magnetostatic energy

$$\int \mathrm{d}V e_\mathrm{m} \leqslant W(\mathbf{A}) = \frac{1}{2\mu_0}\int \mathrm{d}V(\nabla \times \mathbf{A} - \mu_0 \mathbf{M})^2 \quad (23)$$

If minimized with respect to **A**, the functional $W(\mathbf{A})$ reduces to the magnetostatic energy of the magnetization distribution $\mathbf{M}(\mathbf{r})$. Thus it is possible to replace the magnetostatic energy in the total magnetic Gibbs free energy with $W(\mathbf{A})$ and treat **A** as an additional variable. The simultaneous minimization of the energy with respect to **M** and **A** provides the equilibrium configuration of the magnetization (Aharoni 1996). Again spherical coordinates can be introduced to satisfy the constraint (3).

The integral on the right hand side of Eqn. (23) is an integration over the entire space and proper techniques to treat the open boundary problem have to be applied. The first variation of Eqn. (23) gives the unconstrained curl–curl equation for the magnetic vector potential which is the equation commonly solved in magnetostatic field calculations. Thus the use of a magnetic vector potential in numerical micromagnetics treats the magnetostatic field in the very same way as conventional finite element packages for magnetostatic field calculation (Demerdash and Wang 1990).

This method was applied to predict the theoretical limits for the remanence and the coercive field of nanocomposite permanent magnets (Schrefl and Fidler 1998). These magnets consist of a mixture of magnetically hard and soft phases. The complex, multiphase microstructure considerably influences the magnetic properties and thus has to be taken into account in micromagnetic models. Figure 3 gives the numerically calculated demagnetization curves for the $Nd_2Fe_{14}B$ magnet depicted in Fig. 1 as a function of the average grain diameter. Intergrain exchange interactions considerably enhance the remanence compared with the remanence of noninteracting, randomly oriented grains. Figure 4 presents the magnetization distribution in a slice plane for zero applied field and an average grain size of 20 nm.

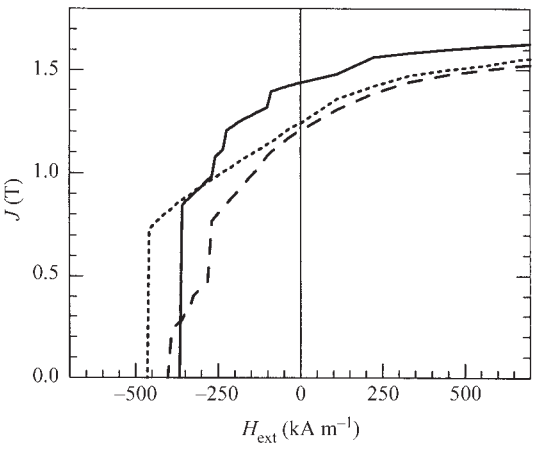

***Figure 3***
Numerically calculated demagnetization curves as a function of the mean grain size for the nanocomposite magnet of Fig. 1. —, 10 nm; ⋯⋯, 20 nm; - - - -, 30 nm.

The magnetization remains parallel to the saturation direction within the soft magnetic grains, whereas it rotates towards the direction of the local anisotropy direction within the hard magnetic grains.

## *4. Dynamic Micromagnetics Using the Finite Element Method*

Either a box scheme or the Galerkin method can be applied to discretize the Gilbert equation of motion, Eqn.(4), in space. The Gilbert equation (4) reduces to three ordinary differential equations for each node of the finite element mesh, using the box scheme, Eqn. (9), to approximate the effective field. The resulting system of *3n* ordinary differential equations describes the motion of the magnetic moments at the nodes of the finite element mesh. The system of ordinary differential equations is commonly solved using a predictor corrector method or a Runge Kutta method for mildly stiff differential equations. Small values of Gilbert damping constant $\alpha$ or complex microstructures will require a time step smaller than 10 fs, if an explicit scheme is used for the time integration. In this highly stiff regime backward difference schemes allow much larger time steps and considerably reduce the required CPU time.

An implicit time integration scheme can be derived, applying the Galerkin method directly to discretize the Gilbert equation (4). A backward difference method (Hindmarsh and Petzold 1995) is used for time integration of the resulting system of ordinary differential equations. Since the stiffness arises mainly from the exchange term, the magnetostatic field can be treated explicitly. During a time interval $\tau$, the Gilbert equation is integrated with a fixed

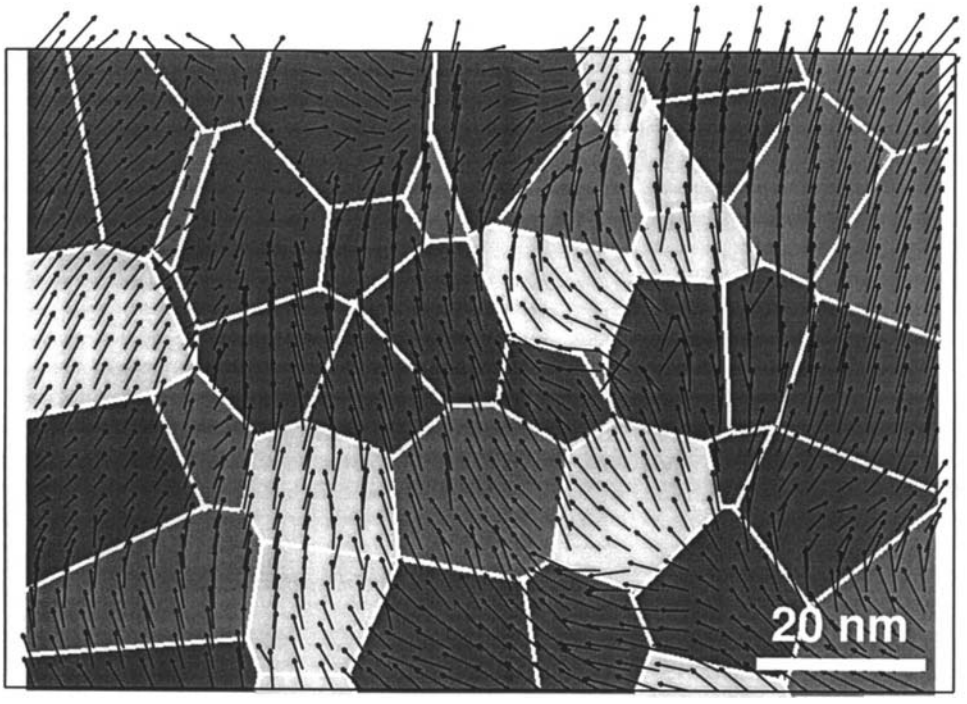

***Figure 4***
Magnetization distribution within a nanocomposite magnet for zero applied field. The arrows denote the direction of the magnetization in a slice plane parallel to the saturation direction. The mean grain size was 20 nm.

magnetostatic field using a higher order backward difference method. The magnetostatic field is updated after a time $\tau$ which is taken to be inversely proportional to the maximum torque $\max_i$, $|\mathbf{M}_i \times \mathbf{H}_{\text{eff},i}|$ over the finite element mesh. The hybrid finite element/boundary element method is used to calculate the magnetostatic field. Figure 5 presents the flow chart of the semi-implicit time integration scheme. In highly stiff regimes the semi-implicit scheme requires less central processing unit (CPU) time as compared with a Runge–Kutta method, despite the need to solve a system of nonlinear equations at each time step.

A semi-implicit time integration scheme was applied to calculate the magnetization reversal dynamics of patterned Co elements, taking into account the small scale, granular structure of the thin films elements (Schrefl *et al*. 1999). Dynamic micromagnetic calculations using the finite element method and backward difference were originally introduced by Yang (Yang and Fredkin 1996) and applied to the study of magnetization reversal dynamics of interacting ellipsoidal particles (Yang and Fredkin 1998).

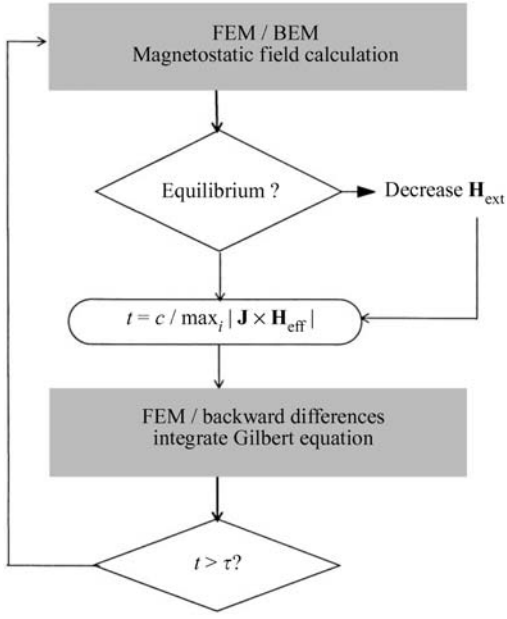

***Figure 5***
Flow chart of the semi-implicit time integration scheme used to solve the Gilbert equation of motion.

## 5. *Adaptive Meshing*

The finite element method effectively treats magnetization processes in samples with arbitrary geometries

or irregular microstructures. Adaptive refinement schemes allow the magnetization distribution to be solved on a subgrain level, improving the accuracy of the solution while keeping the computational effort to a minimum. Finite element mesh refinement was applied in micromagnetic simulations of longitudinal thin film media (Tako *et al*. 1997), domain structures in soft magnetic thin films (Hertel and Kronmüller 1998), and domain wall motion in permanent magnets (Scholz *et al*. 1999).

## 6. *Refinement Indicators*

The discretization of the micromagnetic equations gives rise to two types of discretization error. One is associated with the evaluation of the exchange field, the other arises from the finite element computation of the magnetostatic field. Improvements in the micromagnetic resolution can be made by a uniform increase in the level of discretization. However, this places more computational modes in areas where the magnetization remains uniform. Ideally, it would be most efficient to place new nodes where the error is highest.

The aim of adaptive mesh refinement schemes is to obtain a uniform distribution of the discretization error over the finite element mesh (Penman and Grieve 1987). In order to decide where to refine the mesh, refinement indicators should give a good estimate of the local error. A second criterion for the selection of error estimators for adaptive meshing are the computational costs. Error estimators should be cheap to evaluate and thus error indicators derived from the current finite element solution on an element-by-element basis are preferred. Within the framework of classical micromagnetism the magnitude of the magnetization vector is assumed to be constant.

This condition can only hold at the nodal points of the finite element mesh, using a linear interpolation of the magnetization on a finite element. Bagnérés-Viallix (Bagnérés-Viallix *et al*. 1991) proposed use of the deviations in the length of the magnetization vector from $M_s$ in the center of an element as refinement indicator. The magnetization distribution of a one-dimensional domain wall can be calculated analytically. Thus the true discretization error of the finite element solution can be evaluated. Numerical investigations of one-dimensional mesh refinement showed that the error estimator based on the norm of the magnetization shows the very same functional dependence on the number of finite elements as the true error of the solution.

Refinement indicators that point out the exchange discretization error are usually based on the spatial variation of the magnetization (Hertel and Kronmüller 1998). They identify domain walls, vortices, or magnetic inhomogenities near edges and corners. In order to consider the discretization error associated with the magnetostatic field calculation, Tako *et al*. (1997) suggested a refinement indicator based on the divergence and curl of both the magnetization and magnetic field. Simulating the magnetization structure of two-dimensional magnetic nanoelements, Ridley *et al*. (1999) showed that this refinement indicator correctly identifies the regions where the true error in the computed magnetic field is high.

### *6.1 Finite Element Micromagnetics Using Adaptive Mesh Control*

In longitudinal thin film media the granular microstructure significantly influences the remanent magnetization distribution. Tako (Tako *et al*. 1997) showed that adaptive refinement clearly improves both the efficiency and accuracy of the computations of magnetization patterns in thin film microstructures obtained form a Voronoi construction. A refinement indicator based on the spatial variation of both magnetization and magnetic field is used to point out elements in which refinement is necessary.

Elements which show a refinement indicator greater than 20% of the maximum value over all elements are subdivided by regular division. The numerical results indicate a significant improvement in the calculated magnetization structure after refinement. The magnetization tends to form vortices which do not fully develop in the coarse grid. With further refinement the structure is allowed a lower energy state to be attained allowing a more complete development of the solenoidal structure. During the refinement process the total energy decreases by about 50% which clearly indicates the success of the refinement indicator.

Hertel and Kronmüller (1998) proposed an r-refinement scheme to resolve vortices in micromagnetic simulations of domain structures in soft magnetic, thin film elements. The discretization error is reduced by moving nodes of the finite element mesh towards regions where higher accuracy is needed. In micromagnetic simulations of domain structures in soft magnetic thin films, this was accomplished by shrinking the elements in regions with strong inhomogeneities. Thus, a high mesh density, which results in a high micromagnetic resolution, was obtained near vortices and domain walls, while keeping the number of elements constant.

In hard magnetic materials the magnetization is uniform within magnetic domains whereas it is highly nonuniform in domain walls, near nucleation sites, vortices, or grain boundaries. A coarse mesh may be sufficient in regions where the magnetization is almost uniform. Local mesh refinement near grain boundaries, domain walls, vortices, and nucleation sites significantly reduces the number of degrees of freedom. As domain walls can move because of external fields,

the discretization has to be adjusted adaptively during the simulation. Scholz *et al.* (1999) presented an algorithm that adapts the finite element mesh to the solution of the Gilbert equation.

Refinement of the tetrahedral mesh at the current wall position and coarsening within the bulk of the domains leads to a high density mesh that moves together with the wall. After each time step, error indicators based on the deviations of $|\mathbf{M}|$ from $M_s$ are calculated for each element. If the maximum error indicator over all elements, $\eta_{max}$, exceeds a certain threshold the following refinement scheme is applied: Elements whose error indicators exceeds $0.1\,\eta_{max}$ are marked for refinement, whereas elements with an error indicator lower than $0.01\ \eta_{max}$ are marked for coarsening.

Then, the finite element mesh is refined by subdividing elements, which are marked for refinement. Coarsening is effected by removing finite elements which have been created by an earlier refinement step (Bey 1995). Figure 6 shows the regions of fine mesh at the current wall position during the simulation of domain wall motion in thin $Nd_2Fe_{14}B$ specimens. The wall moves towards the boundary of a misoriented grain, where it remains pinned owing to a reduction in the exchange and anistropy energy stored in the wall.

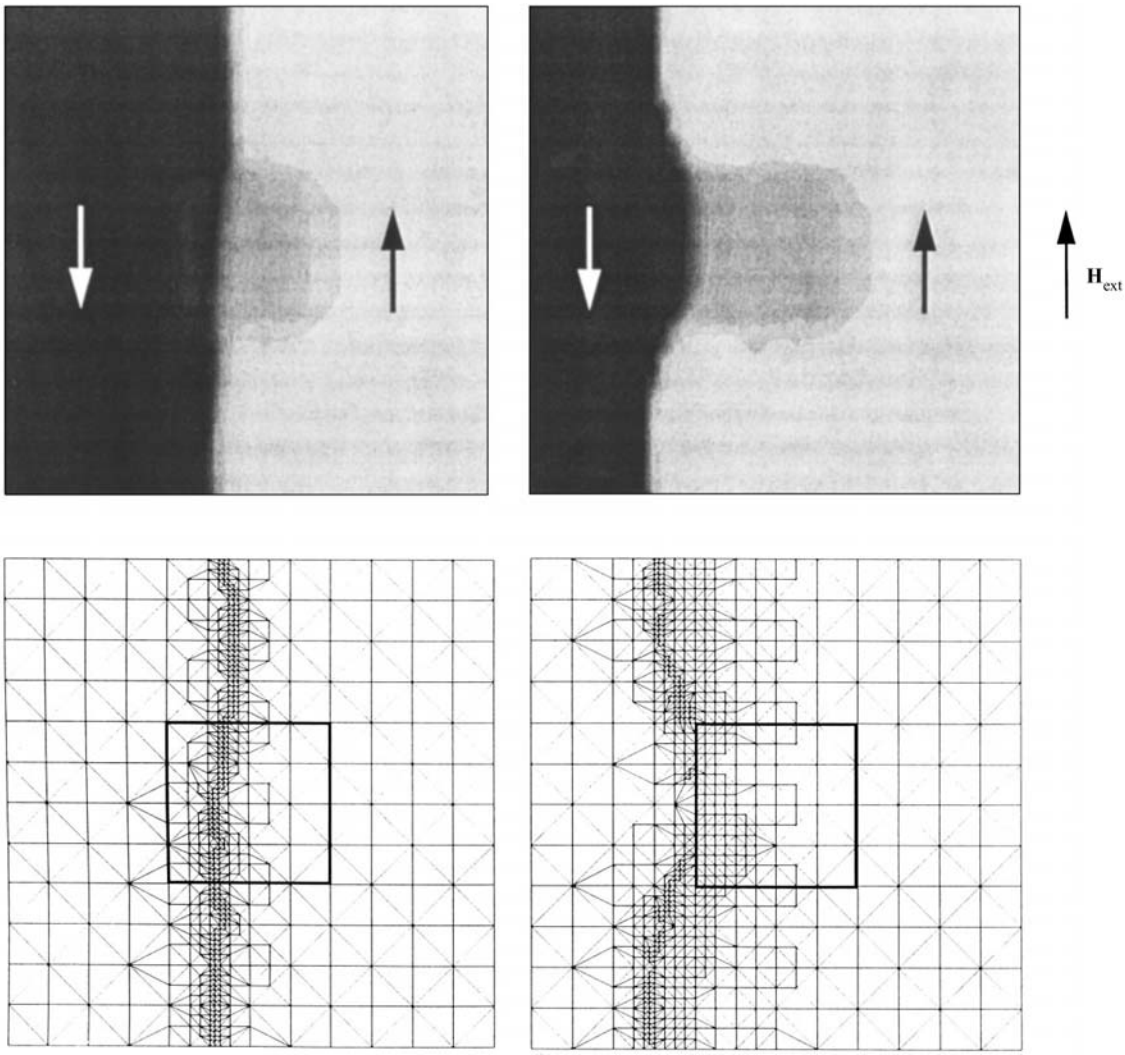

***Figure 6***
Adaptive mesh refinement: magnetization distribution and corresponding finite element mesh during the simulation of domain wall motion. The wall becomes pinned at the grain boundary of a misoriented grain.

## 7. Summary

Micromagnetism treats magnetic material as classical continuous media, described by appropriate differential equations governing their static and dynamic behavior. The numerical solution of the governing equations can be effectively performed using finite element and related methods which easily handle complex microstructures. Finite element techniques for an effective solution of the basic static and dynamic equations were compared. These include various methods for treating the so-called open boundary problem in magnetostatic field calculation and discretization schemes that allow sparse matrix methods for the time integration of the equation of motion.

Finite element simulations successfully predict the influence of microstructural features like grain size, particle shape, and edge irregularities on the magnetic properties. Adaptive refinement and coarsening of the mesh controls the discretization error and provides optimal grids for micromagnetic finite element simulation of magnetization processes in longitudinal thin film media, vortex formation in soft magnetic thin films, and of domain wall motion in hard magnetic platelets.

# Monolayer Films: Magnetism

This article is concerned with what changes in magnetic ordering phenomena when the thickness of a single crystal (epitaxial) film is reduced to an atomic scale, i.e., in ultrathin ferromagnetic films (UFF), in epitaxial films consisting of a few atomic layers only. We focus on intrinsic magnetic thin film phenomena, i.e., on those which result from the bare reduction of one of the sample dimensions, and the modified electronic state of surface atoms (surfaces in our sense include interfaces). These intrinsic phenomena are the subject of basic theoretical models. Our approach is

experimental. We report experimental data on intrinsic magnetic properties of model structures, to be discussed in the light of theoretical models. To be concise, we will refer frequently to the more extended review (Gradmann 1993). For further reading see articles in Heinrich and Bland (1994).

Experimental work on UFF crucially depends on the preparation of flat ultrathin epitaxial structures, which is now done preferentially by epitaxial growth in ultra-high vacuum (UHV, pressures of the order $10^{-10}$ torr. Epitaxial growth is discussed briefly and with emphasis on UFF in Gradmann (1993), in more detail in articles in King and Woodruff (1997). It has been known from diffraction methods for a long time, and visualized in detail by scanning tunneling microscopy (STM), that even the best-grown epitaxial films contain a high level of structural defects. A detailed discussion of the film real structure is beyond the scope of this article (but see articles covering growth phenomena). We choose data from the best available flat epitaxial films. One should have the imperfect structure of even the best epitaxial films in mind.

The intrinsic UFF properties to be discussed in this article are (i) enhanced thermal decrease of magnetic order, as a result of reduced size (size effect, Sect. 1), (ii) changed (ground state) magnetic moments in surfaces (interfaces) (surface effect, Sect.2) and (iii) outstanding magnetic anisotropies, in particular magnetic surface anisotropies (MSA), and the related, technologically important phenomenon of perpendicular magnetization (Sect.3). A discussion of the Dead Layers problem will be included in Sects.1 and 2.

## *1. Enhanced Thermal Decrease of Magnetic Order (Size Effect)*

The basic phenomena of enhanced thermal decrease of magnetic order are shown in Figs. 1 and 2: with decreasing number of atomic layers, $D$, we observe, as a result of the reduced magnetic coordination, an enhanced thermal decrease of spontaneous magnetization $M_s(T;D)$ (Fig. 1), including a change in shape of the thermal profile, and a monotonic decrease of the Curie temperature $T_c(D)$ (Fig. 2). The full line in Fig. 2 is a power law $(T_c(\infty) - T_c(D)) \propto D^{-\lambda}$ with $\lambda = 1.27$, near the theoretical prediction $\lambda = 1.4$ (Gradmann 1993, p. 52). Qualitatively, the pattern of Figs. 1 and 2 is representative for all UFF systems investigated so far.

A more detailed discussion of thermal decrease of magnetic order is done, as for bulk ferromagnets, separately for the low temperature (spin-wave) regime (roughly $T < T_c/2$) and the critical regime near $T_c$.

For the spin-wave regime, the main body of available theories was worked out in the 1960s; for a report see Gradmann (1974). In spin-wave theories,

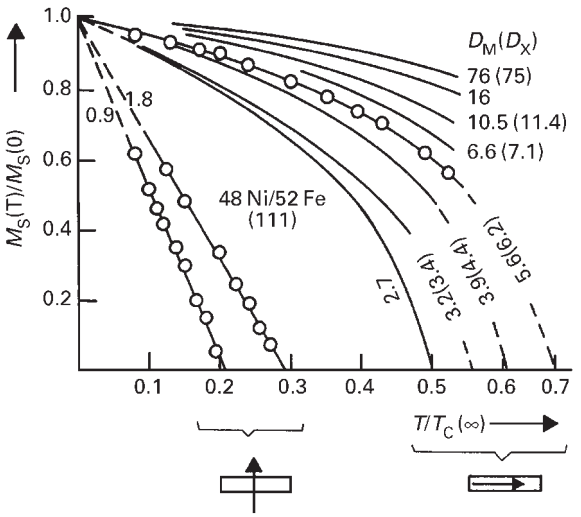

***Figure 1***
Temperature dependence of magnetization in UFF, of type Cu(111)/48Ni52Fe(111)/Cu(111); number of atomic layers $D$ as parameter ($D_M$ from magnetometry, $D_x$ from x-ray fluorescence). The orientation of magnetization is indicated. Films for $D > 2$ are magnetized in the plane, films for $D < 2$ show perpendicular magnetization (from Gradmann 1974).

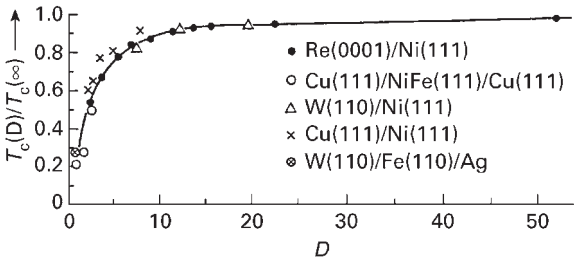

***Figure 2***
Curie temperatures for densely packed cubic UFF versus the number of atomic layers, $D$ (from Gradmann 1993).

homogeneous ground state magnetization is assumed. The reduced magnetic moment at finite temperatures then is inferred by the finite size (thickness) only. For experimental analysis of this size effect, it is convenient to cast the theoretical results in the form

$$\mu(T;D) \cdot D = \mu_{\text{bulk}}(T) \cdot [D - D_{\text{c,size}}(T)] \qquad (1)$$

where $\mu(T;D)$ is the magnetic moment per atom in a sample consisting of $D$ atomic layers, and $\mu_{\text{bulk}}(T)$ is the bulk moment (Gradmann 1974, Gradmann *et al.*

1997). The size effect is represented by $D_{c,size}(T)$, which turns out to be roughly proportional to $T$, with a weak (logarithmic) dependence on anisotropies (or external fields) only. Equation (1) can be read in the sense that the size-induced thermal decrease of magnetic moment per area, given by $-\mu_{bulk}(T) \cdot D_{c,size}(T)$, is independent of $D$. For the limit of a few monolayers thickness, this can be explained from the two-dimensional nature of the spectrum of thermally excitable spin wave states ($k_z \neq 0$ states are frozen). This spectrum is independent of $D$, and so is the number of excited magnons and therefore the thermal decrease of magnetic moment. The thermal decrease of magnetization therefore scales with $1/D$. For the limit of thick films, the $D$-independent decrease of magnetic moment per area can be interpreted as resulting from both surfaces, acting independently. In general, Eqn. (1) turns out as a numerical result of spin wave theories; it is confirmed by experiment (Gradmann 1993, Fig. 32).

The enhanced thermal decrease is a result of reduced magnetic coordination in the surface. Accordingly, one expects a local profile, this decrease being strongest in the surface atomic layer. This local structure of thermal decrease can be conveniently discussed in terms of spin wave parameters. For bulk ferromagnets, it is well known that the thermal decrease follows the $T^{3/2}$-law of Bloch, $\mu(T) \propto [1 - \alpha \cdot T^{3/2}]$. Rado noted as early as 1957, in an unpublished conference note, that the spin wave parameter $\alpha$ near the bulk surface should be twofold enhanced in comparison with the bulk, because spin waves show antinodes in the surfaces, and the intensity in the antinode is twice the mean intensity. For bulk surfaces, the Rado enhancement could be confirmed by spin polarized electron scattering. For UFF, conversion electron Mössbauer spectroscopy (CEMS) with monolayer probes of $^{57}$Fe showed up as a powerful tool to analyze locally the thermal decrease of magnetic order (Gradmann 1993, pp. 52–60). Surprisingly, the local magnetization in UFF of Fe(110) on W(110) also follows a $T^{3/2}$-law, the only modification being given by a local variation of the spin-wave parameter $\alpha$. For the monolayer Fe(110), $\alpha$ is 10-fold enhanced. Local profiles of $\alpha$ across UFF have been determined experimentally using CEMS; they show the Rado enhancement near the surface (Gradmann 1993, Figs. 38, 39).

The experimental investigation of the critical temperature regime has been limited so far to the monolayer regime of thickness, in part because for the case of thick films $T_c$ cannot be reached without destroying the film structures, in part because structural inhomogeneities mask the intrinsic critical behavior (finite size tails, caused by islanding of the films see articles on growth phenomena). In the monolayer regime only, basic models of two-dimensional magnetism could be verified for selected epitaxial film systems. In particular, the thermodynamically stable pseudomorphic ML Fe(110) on W(110) has been shown to represent the two-dimensional Ising model with remarkable accuracy. Similarly, the double layer Fe(100) on W(100) represents the two-dimensional $xy$ model. Monolayer magnetism has been reviewed by Elmers (1995), with emphasis on experiments with well-defined ferromagnetic monolayers.

## 2. *Changed Ground State Magnetic Moments in Surfaces (Surface Effect)*

The calculation of enhanced (or reduced) magnetic moments in the surfaces of metallic ferromagnets is one of the most interesting applications of first principles band structure theories (Freeman and Wu 1991). The theories apply to the ground state. The calculations usually are performed not for bulk surfaces but for UFF targets. In an analogous way, experimental data for surface magnetic moments are obtained from UFF moments, and their dependence on $D$, as measured at finite $T$. An extrapolation to $T = 0$ is required for comparison with theory.

The following scheme has been used for evaluation of UFF moments in terms of surface magnetization (Gradmann 1974, Gradmann *et al.* 1997). We consider magnetic moments per atom, $\mu(T; D) = p(T; D) \cdot \mu_{Bohr}$, expressed by Bohr magneton numbers $p(T; D)$. In extension of Eqn. (1), and changing from moments to magneton numbers, we write

$$p(T; D) \cdot D = p_{bulk}(T) \cdot D + [p_{size}(T) + (p^{(1)}_{surf} + p^{(2)}_{surf})] \tag{2}$$

In using this Ansatz, we assume that the integral excess magnetic surface moments $\mu^{(i)}_{surf} = p^{(i)}_{surf} \cdot \mu_{Bohr}$ can be considered as independent of temperature. In other words, the temperature-dependent size-effected excess magneton numbers $p_{size}(T)$ are superimposed by the temperature-dependent surface-effected ones $p^{(i)}_{surf}$. This approximation seems to be sufficient for the present state of analysis. Some temperature dependence of $p^{(i)}_{surf}$ remains as a correction to be investigated in forthcoming high precision treatments. Equation (2) can be rewritten as

$$p(T; D) \cdot D = p_{bulk}(T)[D - D_c(T)] \tag{3}$$

with

$$D_c(T) = -\frac{[p_{size}(T) + (p^{(1)}_{surf} + p^{(2)}_{surf})]}{p_{bulk}} \tag{4}$$

The experimental analysis consists in plotting the magnetic moment per area, which is proportional to $p(D; T) \cdot D$, versus $D$. The axial section $D_c(T)$ then is at first glance suggestive of a magnetic dead layer. In this interpretation, it played some historic role in the spectacular work of Liebermann *et al.*

(1970). However, the present analysis shows that this interpretation is misleading and that $D_c(T)$ is nothing but an indication of enhanced decrease of magnetic moments near surfaces, superimposed from surface and size effects. Measured at finite $T$, an experimental value of $D_c(T)$ is roughly indicative of $T_c(D_c) = T$. In order to obtain absolute values of $p_{surf}$ for some combination of surfaces (interfaces) from magnetometry, one needs to extrapolate to $T = 0$, where $p_{size}$ disappears. This extrapolation is possible because $p_{size}(T)$ is proportional to $T$ (Gradmann 1974, Wagner *et al.* 1997).

An alternative approach to determine $p_{surf}$ is given by evaluation of spin polarized electron diffraction (SPLEED) by dynamical diffraction theories. This difficult approach has been carried out for the two clean surfaces Ni(111) and Fe(110) (Gradmann and Alvarado 1985).

Experimental data for surface excess magneton numbers are shown in Table 1, for selected surfaces. Some theoretical results are included; they show that first principles theories are now able to calculate the surface excess moments correctly. The enhanced surface moment in Fe(110) is explained from band narrowing as a result of reduced number of nearest neighbors. Accordingly, a further reduction of nearest neighbors in steps results in a further increase of magnetic moment by some tenths of a Bohr magneton (Albrecht *et al.* 1992). The coverage by noble metal results in moderate changes of moment below $1\,\mu_B$. Remarkably strong values of $p_{surf}$ are induced by Pd as a substrate or coverage material. Apparently, this results from a magnetic polarization of Pd by the neighboring ferromagnetic film, in tight similarity with the formation of giant moments of polarized Pd around Ni, Fe, and Co impurities in bulk Pd. Interestingly, the polarizability of Pd is enhanced if Pd is not used as a coverage material, but as a substrate which in turn is prepared as an ultrathin epitaxial film on Re(0001) and therefore strained by the Re/PD misfit of 0.3% in the plane (Gradmann 1993, pp. 72–4).

## 3. Magnetic Anisotropies

For applications, by far the most important properties of UFF are their outstanding magnetic anisotropies. In general, magnetic anisotropies are the magnetic evidence of broken symmetries in the lattice of any magnetic sample. Intrinsic magnetic anisotropies of UFF result from the strong intrinsic anisotropies of their lattice: The anisotropic shape results in the volume type anisotropy of magnetostatic energy, known as magnetic shape anisotropy, which always supports in-plane magnetization. The broken symmetry in both surfaces is the origin of the surface-type magnetic surface anisotropy (MSA) that may support in-plane or perpendicular magnetization. In the latter case, MSA may overcome shape anisotropy, in the very thinnest films, and thus result in perpendicular magnetization (see *Magnetic Films: Anisotropy*).

To be quantitative, we restrict ourselves (i) to the dominating anisotropies that depend on the tilt angle of the magnetization with respect to the surface normal, $\theta$ only (out-of-plane anisotropies) and (ii) to the leading term which is proportional to $\cos^2\theta$. For a discussion of in-plane anisotropies and of higher order anisotropies see Fritzsche *et al.* (1994). The temperature dependence of MSA has been discussed by Farle *et al.* (1997).

In the second order out-of-plane approximation, the anisotropic part of the free energy $F$ of an UFF of volume $V$ and area $A$ is given by

$$F = \left[\left(\frac{J_s^2}{2\mu_0} + K_V\right) \cdot V + (K_s^{(1)} + K_s^{(2)}) \cdot A\right] \cos^2\theta \quad (5)$$

The anisotropy constant in brackets is determined for a given film by magnetometric methods (torsion magnetometry, torsion oscillation magnetometry, ferromagnetic resonance, magnetic loop tracing). The volume term is composed of the dipolar shape anisotropy $J_s^2/2\mu_0$ (always positive, easy plane) and an additional crystalline term $K_V$(of any sign). The

surface term is composed by the surface anisotropy constants $K_s^{(i)}$ of both surfaces ($i = 1; 2$) (we use the notation $\sigma = K_s \cos^2\theta$ as introduced by Néel (1954) in his pioneering work on MSA; unfortunately, the opposite sign is used in part of the literature after 1980). To separate the volume terms from surface terms, one uses a film series with variable thickness $t$, all other parameters being fixed (or assumed to be fixed). The separation then is done by plotting $F$ versus $t$ or versus $1/t$. In both cases, a linear plot confirms the Ansatz of Eqn. (5); volume and surface anisotropies can be taken from slopes and axial sections, respectively, in a straightforward manner.

The phenomenological anisotropy constants $K_s$ include all terms that are proportional to the film surface, or scale with $1/t$. The following contributions may be distinguished (Gradmann 1993). (i) Intrinsic MSA results from the bare existence of the surface (interface), by the modified electronic state of surface/interface atoms. It is this contribution that Néel had in mind when proposing the existence of MSA (Néel 1954). Intrinsic MSA is the subject of first principles band structure calculations. Usually, it is the leading MSA contribution. (ii) Dipolar MSA: surface corrections to dipolar energies result both from the atomic structure of an ideal surface and from the roughness of real surfaces. (iii) Crystalline roughness MSA: the electronic state of step and kink atoms is different from surface atoms, resulting in step and kink anisotropies which roughly are collected in a crystalline roughness contribution. Step anisotropies could be determined for steps on Fe(110) (Gradmann *et al.* 1997). Step anisotropies may enforce or reduce the intrinsic MSA. (iv) Apparent MSA from $1/t$ scaling shape anisotropy: By the size effect discussed in section 1, $J_s$ decreases with decreasing $t$. It turns out that this results in a contribution to shape anisotropy which scales with $1/t$. (v) Apparent MSA from $1/t$ scaling relaxing strain. For small misfit $f$, the epitaxial UFF is pseudomorphic with the substrate up to a critical thickness $t_c$ which increases with decreasing $f$. For $t > t_c$, the misfit is accommodated gradually by misfit dislocations, resulting in a relaxing strain which roughly scales with $t_c/t$, and in a strain induced anisotropy which scales in the same way. Apparently, this is the most important one of the extrinsic MSA contributions. It disappears in the pseudomorphic range $t > t_c$. Accordingly, intrinsic MSA can be isolated if the analysis is restricted to the pseudomorphic range.

Table 2 shows magnetic surface anisotropy constants $K_s$ for selected interfaces. For comparison with bulk anisotropies, the constants are alternatively given as anisotropy energies per atom, $e_s$. Shape anisotropies for Ni, Fe, and Co are included in this notation, for comparison. Note that for a couple of interfaces $e_s$ is negative, supporting perpendicular magnetization.Perpendicular magnetization is expected and observed for $e_s^{(1)} + e_s^{(2)} + D \cdot e_s^{\text{shape}} < 0$, if volume type

***Table 2***

Magnetic surface anisotropy constants, $K_s$, and surface anisotropy energies per atom, $e_s$, for selected surfaces (interfaces). Data from sandwich samples on single crystal substrates. Surface energy is defined as $\sigma = K_s \cos^2\theta$, where $\theta$ is the angle between magnetization and surface normal (Néel notation). Data for Ni(111)/Cu, Co(0001)/Cu and Co(0001)/Au from the pseudomorphic range of thickness (intrinsic MSA); this is indicated by bold faces. Shape anisotropies for Ni, Fe, and Co for comparison.

| Co(0001)/Ag | −0.42 | −82 | Kohlhepp *et al.* 1995 |
| **Co(0001)/Au** | **−0.37** | **−126** | Kohlhepp *et al.* 1993 |
| Co(0001)/Pd | −0.92 | −312 | Purcell *et al.* 1992 |
| Co(0001)/Pt | −1.15 | −392 | McGee *et al.* 1993 |
| Co, shape | | +90 | |

anisotropies can be neglected ($e_s^{(i)}$ and $e_s^{shape}$ are anisotropy energies per atom for interface (i) and for shape anisotropy, respectively). For Co(0001), negative volume type magnetocrystalline and strain anisotropies support perpendicular magnetization. Co(0001) therefore is the most important magnetic part of perpendicularly magnetized multilayers.

Whereas a separation of the different MSA contributions discussed above is not possible in general, the intrinsic MSA is usually considered as leading contribution. For the systems shown in Table 2 in bold faces, the pseudomorphic range has been used. Accordingly, they represent the intrinsic MSA to a good approximation. Higher order terms of MSA (Kohlhepp and Gradmann 1995) are not considered in the data. Because they enter the measurement differently for different methods, the omission of higher order anisotropies creates an uncertainty of the order of 10% in the data. The MSA constants in Table 2 therefore must not be taken as high precision natural constants, but rather as useful parameters to describe a complex variety of anisotropy phenomena in a reasonable model.

## 4. Conclusions

We have shown for representative examples that magnetic order in ultrathin ferromagnetic films (UFF) deviates from the bulk case by an enhanced thermal decrease of magnetic order, by modified moments in the surfaces and by strong surface-specific anisotropies, which may induce the technologically important phenomenon of perpendicular magnetization. Other interesting aspects of UFF magnetism, like the opportunity to epitaxially prepare magnetic matter in metastable states which do not exist in bulk (fcc Fe, bcc Co, for a review see Prinz (1991)), and to study their magnetic properties, could not be discussed. We focused on metallic ferromagnets on metallic substrates. There is presently strong interest in extending the field to nonmetallic, in particular semiconducting substrates.

New preparation methods like pulsed laser deposition (PLD), in combination with structural testing by scanning tunnel microscopy (STM) open new aspects of the field (Ohresser *et al*. 1999). UFF are important as building blocks for existing and forthcoming magnetic multilayers and nanostructures and the bewildering rich magnetic ordering in them.

## Mössbauer Spectrometry

Since the discovery of recoil-free $\gamma$-ray resonance emission and absorption in solids by R. L. Mössbauer (1958), this phenomenon, termed the Mössbauer effect, has been developed as a useful spectroscopic method to study various solids. Although its principles look somewhat complicated, today's Mössbauer spectroscopy is no longer a strange and difficult method. Usually, as sketched in Fig. 1, $\gamma$-rays from a radioactive source placed on a moving stage pass through a foil specimen and an absorption spectrum is recorded. The data are analyzed in terms of the hyperfine interactions between the $\gamma$-absorbing nuclei in the specimen and the surrounding electrons and atoms, and give useful information on the phases, the crystalline and bonding states, and the atomic, magnetic, electronic, and defect structures.

Before introducing the principles and techniques of Mössbauer spectroscopy, here is a simple explanation of the Mössbauer effect. As is shown on the left-hand side of Fig. 2, when an excited nuclear state drops to the ground level by emitting a $\gamma$-ray, a recoil motion of the nucleus will reduce the $\gamma$-ray's energy, $E_0$, by the amount of the recoil energy, $Mv^2/2$, where $M$ is

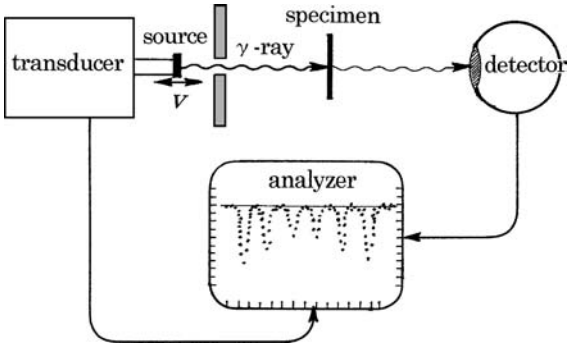

***Figure 1***
Alignment of apparatus for Mössbauer spectroscopy.

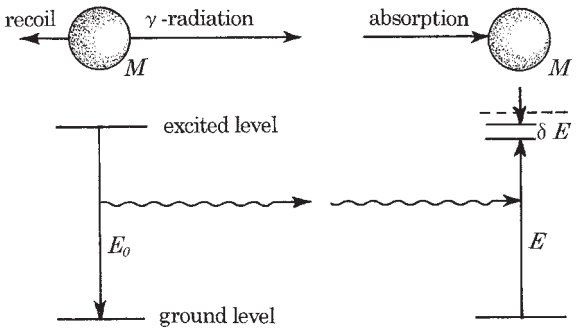

***Figure 2***
Relation between $\gamma$-ray emission and absorption by nuclei and the recoil reaction.

the nuclear mass and $v$ the recoil velocity. The $\gamma$-ray emitted in this way would not be absorbed by a nearby nucleus of the same species in the ground level because of the energy deficit. By the laws of momentum and energy conservation are given

$$MV = M(V + v) + \frac{E}{c} \quad \text{and} \tag{1}$$

$$\frac{MV^2}{2} + E_0 = \frac{M(V + v)^2}{2} + E \tag{2}$$

where $V$ is the initial velocity given to the nucleus prior to the emission, $E$ is the energy of the emitted $\gamma$-ray which is different from $E_0$, $c$ is the light velocity, and $E/c$ is the $\gamma$-ray's momentum. From the two equations, the decrease of the $\gamma$-ray energy is given as

$$\delta E = E_0 - E = \frac{E^2}{2Mc^2} - \frac{EV}{c} \tag{3}$$

The first term on the right-hand side is the recoil energy and the last term is the Doppler effect produced by $V$. The latter could compensate the former to maintain the $\gamma$-ray's energy as $E_0$, but the necessary Doppler velocity will be of the order of $100\,\mathrm{ms}^{-1}$ in ordinary cases; this is difficult to reproduce and control at the usual laboratory scale. In addition, for absorption, another Doppler effect-aided supplement of energy is needed.

In the actual situation, however, a nucleus in a solid is bound by the surrounding electrons, which are also bound to its neighboring atoms by chemical bonds. This will make the mass, $M$, in Eqn. (3) extremely large so that the recoil energy will be effectively zero. This is the essential feature of the recoil-free emission and absorption of $\gamma$-rays discovered by Mössbauer. More exactly, the problem must be treated by lattice dynamics in quantum theory, taking into account the coupling between the recoil

motion and lattice phonons to find the probability, $f$, of recoil-free reactions.

### *1. Principles and Elements of Mössbauer Spectroscopy*

The actual situation at nuclear levels is more complicated than the above and the $\gamma$-ray absorption will not always take place, even in the recoil-free condition, because the levels' small shifts and splits occur to produce detuning against the $\gamma$-ray energy. The modified level structure, called the hyperfine structure, arises from the interactions with environmental electronic configurations. This difficulty in tuning or resonance was solved by Mössbauer himself by changing and controlling the incident $\gamma$-ray's energy with a tiny Doppler motion to offset the shifts and splits. As already stated, using the Doppler motion to compensate the recoil energy is unnecessary, but the Doppler velocity used by Mössbauer is an indispensable tool for the spectroscopy.

The necessary relative Doppler motion between the $\gamma$-ray source and the specimen is given by a moving stage on a transducer shown in Fig. 1. A velocity of $\pm 10\,\mathrm{mms}^{-1}$ corresponds to about $\pm 10^{-7}$ eV in practical cases which is as small as $10^{-4}$ times the above mentioned recoil energy but large enough to cover the ordinary range of hyperfine energies. The given Doppler velocity is registered in the abscissa of a display screen in Fig. 1 as the energy scale, and the amount of $\gamma$-ray transmission at each velocity is recorded in the ordinate. In the real experimental setup a function generator, a high voltage supply, a multichannel pulse height analyzer, and amplifiers are necessary. Reflection-type spectroscopy is also possible by utilizing conversion electrons or conversion x rays. The data analysis is done by computer.

In addition to the most popular and useful $^{57}$Fe isotope with $^{57}$Co source ($^{57}$Co decays by electron capture to an excited level of $^{57}$Fe), $^{119}$Sn, $^{121}$Sb, $^{125}$Te, $^{129}$I, $^{151}$Eu, $^{161}$Dy, $^{197}$Au, $^{237}$Np, and some ten more isotopes are available, using suitable radioisotope sources. In addition, monochromatized synchrotron orbital radiation has become available as a $\gamma$-ray source.

In order to analyze the obtained spectra, at least three elements of the hyperfine structure—the isomer shift, the quadrupole splitting, and the nuclear Zeeman splitting—must be considered. A downward arrow at the upper left corner of Fig. 3 indicates the transition from the first excited level to the ground level of $^{57}$Fe formed from $^{57}$Co, resulting in the emission of a 14.4 keV $\gamma$-ray to be absorbed by another stable $^{57}$Fe nucleus in the specimen.

However, Coulomb interactions between the nuclear and electron charges always exist, the amounts of which are different between the excited and ground states and between the source and the specimen. The

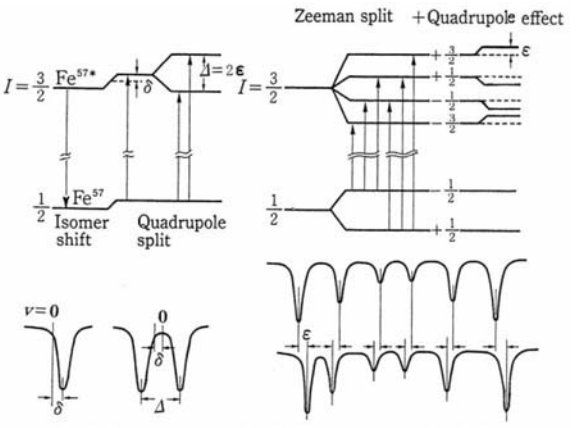

***Figure 3***
Schematic presentation of hyperfine structures, possible level transitions, Mössbauer parameters, and Mössbauer spectra expected from them.

difference between the emission and absorption energy is the isomer shift, $\delta$, which is given as

$$\delta = \frac{C\Delta R}{R}\left(|\Psi_{\mathrm{A}}(0)|^2 - |\Psi_{\mathrm{S}}(0)|^2\right) \tag{4}$$

where $C$ is a certain constant, $\Delta R$ is the nuclear radius difference between the excited and ground states, and $\Psi_{\mathrm{A}}(0)$ and $\Psi_{\mathrm{S}}(0)$ are the wave functions of s electrons of the absorber (specimen) and the source, respectively. The isomer shift $\delta$ can be measured as the deviation of the center of the absorption peak in the Doppler velocity scale, as the lower left schematic shows. It yields information, through the s electron density $|\Psi(0)|^2$, on the phases, atom coordinations, chemical bonds, ionic states, alloying states, etc.

A nucleus with a spin state greater than $\frac{1}{2}$ has an electric quadrupole moment. When such a nucleus is placed in an electric field gradient, the electric quadrupole interaction makes the nuclear level split. In the case of $^{57}$Fe, the excited level with the spin $I=\frac{3}{2}$ splits into two and the ground level with $I=\frac{1}{2}$ does not split, as the level schematics in the upper part and the lower middle spectrum in Fig. 3 show. The amount of splitting is given by

$$\Delta = 2\varepsilon = \pm\frac{eQV_{zz}}{2}\left(1+\frac{\eta^2}{3}\right)^{1/2} \tag{5}$$

where $e$ is the electron charge, $Q$ the nuclear quadrupole moment, $V_{zz}$ the principal axis component of the field gradient, and $\eta$ an asymmetry parameter of the field. By measuring the lattice asymmetry and distortion $\Delta$, the effects of coordinating atoms, a charged impurity nearby, clustering of atoms, etc., can be studied.

Another important hyperfine interaction is the nuclear Zeeman effect, by which a nuclear level with a spin $I$ is split into $(2I+1)$ levels when placed in a magnetic field. In the case of $^{57}$Fe, the excited level splits into four and the ground level into two. There are six possible transitions between them, giving rise to a six-line spectrum, as the right-hand parts of Fig. 3 show. The peak height ratios are normally 3:2:1:1:2:3. The eigenvalues of the splits are given by

$$E_m = -\frac{\mu H_i m_I}{I} \tag{6}$$

where $\mu$ is the nuclear moment, $H_i$ is the internal magnetic field, and $m_I$ is the magnetic quantum number. Equation (6) shows that $H_i$ is obtained from the total breadth of the sextet spectrum. It is 330 kOe in pure iron at room temperature. As the temperature increases, the total breadth decreases due to the flipping of atom moments, and disappears at the Curie point $T_c$. When coupled with the quadrupole effect, the sextet becomes asymmetrical as shown by the right-hand lowest spectrum. The Zeeman splitting gives information on various kinds of magnetic states.

The lineshape of each spectral component is of the Lorentzian type, and the linewidth is different for different nuclides. It is influenced by alloying and instrumental errors too. The recoil-free fraction $f$ and, therefore, the peak height decreases with increasing temperature. The temperature dependence of $f$ and $\delta$ give us the Debye temperature of the material. When thermally assisted atomic jumps take place, the linewidth exhibits another increase, $\Delta\Gamma$, from which the diffusion constant $D$ can be measured.

The total absorption area, $A$, is another important parameter directly connected with the amount of the Mössbauer atoms and the recoil free fraction, $f$. When polarized $\gamma$-rays are used to see the magnetic spin orientations in the specimen, one more parameter, $\theta_m$, the angle between the beam and the spin orientation, is needed.

## 2. *Typical Examples of Mössbauer Studies in Material Science*

Figure 4 shows a simple example of $^{57}$Fe Mössbauer spectroscopy to study the tempering process of steel. After being water-quenched from the f.c.c. austenite phase, 1.6 wt.% carbon steel at room temperature shows a spectrum consisting of a large paramagnetic single absorption peak from the retained austenite $\gamma$ phase ($\delta = -0.01\,\mathrm{mms}^{-1}$) and six line ferromagnetic peaks from the martensite $\alpha_m$ phase ($\delta = +0.01\,\mathrm{mms}^{-1}$, $\Delta = 0.01\,\mathrm{mms}^{-1}$, $H_i = 334$ kOe). The subpeaks and shoulders as well as line broadening arise from the influence of the interstitial carbon atoms. Tempering for 30 min at 210 °C makes the spectrum sharper, and tempering at 280 °C causes a noticeable decrease of the central peak due to the austenite decomposition. Some new subpeaks emerge too. After 410 °C annealing the spectrum shows no austenite but clear ferromagnetic cementite ($\theta$; $Fe_3C$) precipitates, corresponding to the separated and shadowed component ($\delta = +0.18\,\mathrm{mms}^{-1}$, $\Delta = 0.01\,\mathrm{mms}^{-1}$, $H_i = 208$ kOe) in the figure. In such a way the structure and behavior of materials can be studied.

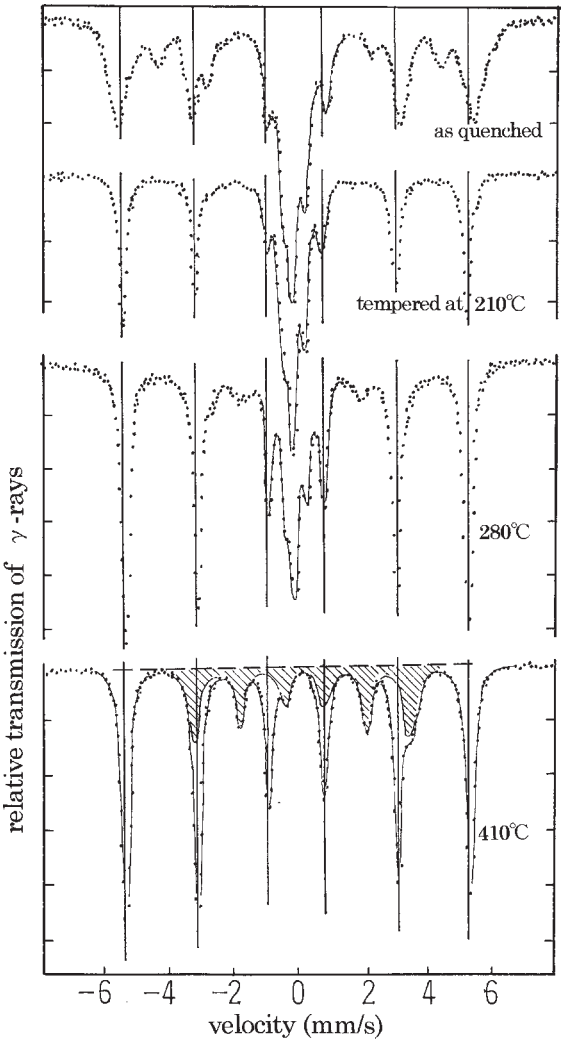

***Figure 4***
Mössbauer spectra obtained from the water-quenched and tempered plain carbon steel containing 1.6 wt.% carbon.

Another popular material is magnetite, $\alpha$-$Fe_3O_4$, which appears not only in materials science but also in earth, biological, and medical sciences. Magnetite has the inverse spinel structure, in which the tetrahedral (A) sites are occupied by $Fe^{3+}$ ions and the octahedral (B) sites by the mixture of $Fe^{3+}$ and $Fe^{2+}$

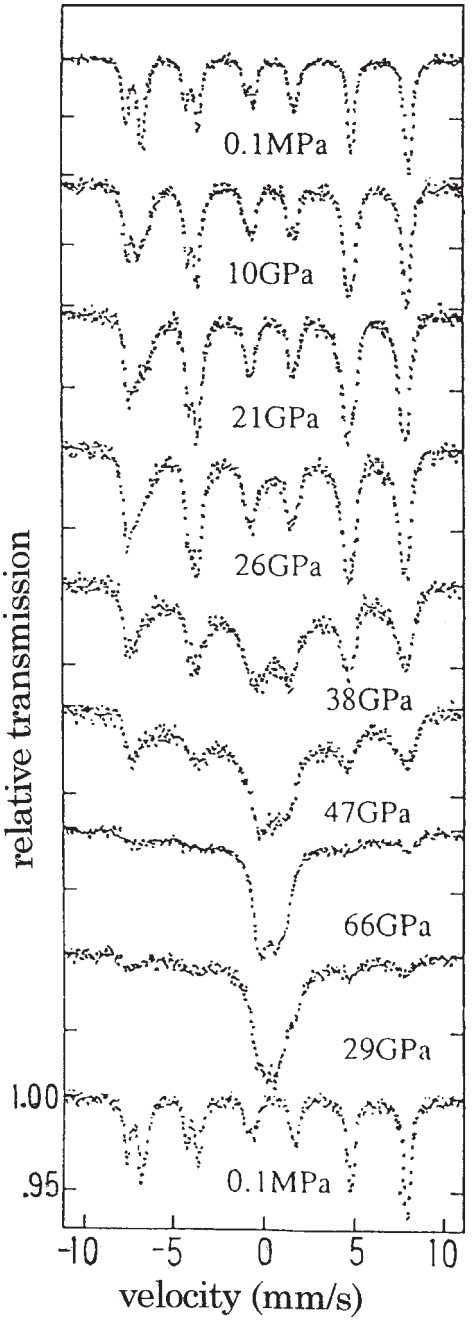

***Figure 5***
Mössbauer spectra of magnetite ($\alpha$-$Fe_3O_4$) under high pressures (after Pasternak *et al.* 1994).

ions, effectively giving the averaged ionic value, $Fe^{2.5+}$.

As an unusual example, a Mössbauer study of magnetite under high pressures, utilizing a special diamond anvil cell, is shown in Fig. 5 (Pasternak *et al.* 1994). Under low pressures, the $^{57}Fe$ spectrum exhibits a two-component ferromagnetic pattern, corresponding to the two different ionic states, as the uppermost spectrum shows. The outer smaller component arises from $Fe^{3+}$ ($\delta = +0.26\,mms^{-1}$, $\Delta = 0\,mms^{-1}$, $H_i = 490\,kOe$), and the inner larger one from $Fe^{2.5+}$ ($\delta = +0.67\,mms^{-1}$, $\Delta = 0\,mms^{-1}$, $H_i = 455\,kOe$). Under 26 GPa and higher pressures, a paramagnetic new phase with two-site iron appears ($\Delta = 0.3\,mms^{-1}$). An *in situ* dispersion-type x-ray analysis on the same specimen shows a monoclinic two-site structure. By lowering the pressure from 66 GPa, the reverse transition takes place with hysteresis, as the lower part of the figure shows.

Noticeable progress of Mössbauer spectroscopy has been achieved not only in the automation of measurement and analysis but also in methodology (Fujita 1999) including high-pressure and high-temperature measurement up to 1800 K (Fujita and Yoshida 1997), and simultaneous measurement of $\gamma$-rays, conversion electrons, and x-rays (Gonser 1998), and use of synchrotron orbital radiation (Gerdau *et al.* 1985). Many applications have been carried out with metals, ceramics, semiconductors, glasses, and other pure and compound materials, with further extension to biology, medicine, archeology, mineralogy, mining, etc.

## MRI Contrast Agents

Magnetic resonance imaging (MRI) is a powerful clinical modality in diagnostic medicine. The contrast agents are paramagnetic materials, used for improving the efficiency of MRI investigations. The MRI technique is based on the behavior of protons in

the body (mainly water protons) when exposed to magnetic fields (typically 0.5–1.5 T). The magnetic moments of protons align parallel to or antiparallel to the magnetic field direction. Since the number of spins aligned parallel is a little higher than the number aligned antiparallel, a macroscopic magnetization vector (MMV) is formed parallel to the external field ($B_0$). When a short radiofrequency pulse ($B_1$) is applied at right angles to $B_0$, some nuclei enter a higher energy state and the MMV flips into the transverse plane. In a receiver coil situated in the transverse plane, the precessing MMV induces a voltage which produces the MRI signal.

When the radiofrequency pulse is switched off, the excited protons lose energy and the MMV realigns with $B_0$. This process is called relaxation. The loss of energy may take place via interaction between the protons and the surrounding molecules, characterized by the time constant $T_1$, the longitudinal relaxation time. The decay of the MMV in the transverse plane occurs through energy exchange between the neighboring protons and because of inhomogeneities in $B_0$, characterized by the time constant $T_2$, the transverse relaxation time. The reciprocals of the relaxation times, $1/T_1$ and $1/T_2$, are referred to as the relaxation rates.

The intensity of MRI signals is proportional to the proton density and $T_1^{-1}$ and inversely related to $T_2^{-1}$. To obtain the MR image, the signals emitted by different volume elements of the body are spatially located in three dimensions with the use of magnetic field gradients. The differences in the signal intensities of the neighboring volume elements in a slice of the body result in the image contrast. The parameters influencing the signal intensity are often different in normal and diseased tissues, which leads to differences in the image contrast.

MRI was introduced as a noninvasive diagnostic tool, but certain clinical problems necessitated the use of exogenous materials, called contrast enhancement agents (CAs), which increase the differences in the signal intensities. The CAs are paramagnetic compounds which produce fluctuating magnetic fields in the proximity of protons in the body, resulting in shorter $T_1$ and $T_2$ values (faster relaxation). The CAs known so far can be divided into three groups (see also *Nuclear Magnetic Resonance Spectrometry*).

## 1. Paramagnetic Metal Complexes

For shortening the relaxation times of protons the most effective metal ions are $Gd^{3+}$, $Fe^{3+}$, and $Mn^{2+}$, each of which has a half-filled electron shell, a large magnetic moment and a relatively long electron spin relaxation time ($\sim 10^{-9}$ s). The aquo-metal ions are toxic; in order to decrease the toxicity, the ions are used in the form of complexes, which are well tolerated. In clinical practice, virtually only complexes

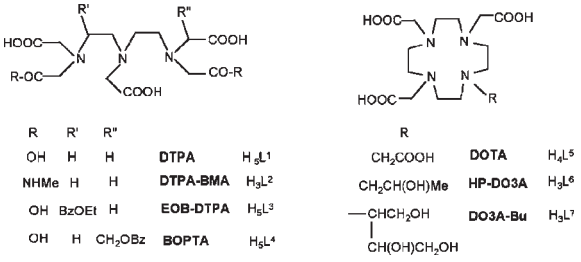

***Figure 1***
Formulas of ligands used for complexation of $Gd^{3+}$.

of $Gd^{3+}$ are used (the commercially available $Mn^{2+}$-dipyridoxyl-diphosphate is of merely marginal importance).

The complexes used as CAs must meet the following requirements: lack of toxicity, high water solubility, low osmolality, high relaxation enhancement effect, high thermodynamic and kinetic stability, quick excretability, and specific *in vivo* distribution. The ligands used for the complexation of $Gd^{3+}$ are the open-chain DTPA, the macrocyclic DOTA, and their derivatives (Fig. 1).

The stability constants of the $Gd^{3+}$ complexes formed with the ligands $L^1$–$L^7$ are very high (log $K_{GdL} \approx 22$–$26$). The only exception is $GdL^2$ (log $K_{GdL^2} = 16.85$), but $L^2$ is highly selective for $Gd^{3+}$ as compared with endogenous ions such as $Zn^{2+}$.

The ligands used are all octadentate in their $Gd^{3+}$ complexes. The ninth coordination site of the $Gd^{3+}$ is occupied by an $H_2O$ molecule. The protons of this molecule rapidly relax in the first coordination sphere and the fast exchange of this $H_2O$ with the bulk water results in the transfer of the paramagnetic effect of $Gd^{3+}$ to the surrounding water protons. To express the relaxation effect of paramagnetic compounds, the term relaxivity is used. The relaxivity ($1/T_{1,2}$, $mM^{-1}s^{-1}$) is the increase in the proton relaxation rate when the concentration of the CA increases by 1 mM. It is about 3.5–4.5 $mM^{-1}s^{-1}$ (at 20 MHz) for the clinically used CAs. The relaxivity of $Gd^{3+}$ complexes is comprised of inner sphere relaxation ($R_i$) and outer sphere relaxation ($R_o$). $R_i$ is proportional to the number of $H_2O$ molecules in the inner sphere, the magnetic moment of the central ion, and a correlation time, which depends on the tumbling rate of the complex, on the electron spin relaxation time of the $Gd^{3+}$ ion, and on the lifetime of water protons in the inner sphere, while the relaxation decreases in proportion to the sixth power of the $Gd^{3+}$-proton distance. $R_o$ depends on the diffusion rates of the complex and the water molecules. The contributions of the $R_i$ and $R_o$ to the measured relaxivity are approximately equal.

The $Gd^{3+}$ complexes are prepared by dissolving $Gd^{III}$ oxide, hydroxide, or carbonate together with

the protonated ligands. The negative charges of the complexes formed with $L^1$, $L^3$, $L^4$, and $L^5$ are neutralized by the protonated *N*-methyl-meglumine cation. The commercial products contain about 5% $Ca^{2+}$ complex, in order to diminish the release of free $Gd^{3+}$ in the body. The CAs are administered to the patients intravenously in 0.5MGdL solution, which can be painful, particularly in the case of the charged complexes, because of the high osmolality. To diminish this problem, nonionic compounds ($GdL^2$, $GdL^6$, and $GdL^7$) have been developed. The $Gd^{3+}$ complexes decrease the $T_1$ values of protons more significantly than the $T_2$ values, and they are used in $T_1$-weighted imaging to increase the signal intensity. The usual dose of GdL complexes is 0.1–0.3 mmol kg$^{-1}$ body weight. The low molecular weight CAs distribute rapidly in the extracellular space of the body. However, due to the fast diffusion of the water molecules through the cell membranes, the CAs shorten the $T_1$ and $T_2$ values of protons also in the intracellular space.

The $Gd^{3+}$ complexes formed with the ligands $L^1$, $L^2$, $L^5$, $L^6$, and $L^7$ are hydrophilic and are excreted through the kidneys into the urine ($t_{1/2} = 1.6$h). The lipophilic $GdL^2$ and $GdL^3$ are excreted partly through the liver and bile and can be used to image the liver. The tolerance to the CAs depends on the selectivity of the ligands for $Gd^{3+}$ over the endogenous ions ($Ca^{2+}$, $Zn^{2+}$, $Cu^{2+}$, etc.), which is expressed as the ratio of the conditional stability constants at physiological pH. A more important factor is the kinetic stability. Both the spontaneous and $H^+$-assisted dissociation of the complexes GdL and the direct exchange reactions with the endogenous ions and ligands must occur extremely slowly.

The $Gd^{3+}$ complexes formed with the macrocyclic ligands $L^5$, $L^6$, and $L^7$ are extremely inert under physiological conditions. The complexes of DTPA and its derivatives are not so sluggish but, because of the rapid excretion, the amount of the $Gd^{3+}$ released in the body is very low and the CAs are safe.

## 2. Superparamagnetic Particles

Superparamagnetic materials used as CAs are composed of single-domain crystals (mainly $Fe_3O_4$) which have much larger susceptibilities than those of paramagnetic compounds. The particles used are coated with a thin dextran or siloxane layer. They primarily shorten the $T_2$ values by creating large magnetic field inhomogeneities.

The relaxation effect and biodistribution depend greatly on the size of the particles. Particles larger than 50 nm have a short half-life in the blood and are localized mainly in the liver and spleen, from where the exretion is slow ($t_{1/2} \approx 3$–4 days). Ultrasmall superparamagnetic iron oxide particles (USPIO, $< 50$ nm) reside in the blood pool for a longer time ($t_{1/2} \approx 200$ min) and can be used as intravascular CAs for both $T_2$- and $T_1$-weighted images. USPIO agents have a more widespread tissue biodistribution, as they are taken up by the liver, spleen, marrow, and lymph nodes. Thus, the potential use and development of the USPIO agents is of great importance.

## 3. Stable Free Radicals

Nitroxide free radicals (NFRs) have one unpaired electron, localized in a nitrogen–oxygen bond. The six-membered ring piperidine nitroxides produce larger relaxivities than the five-membered ring pyrrolidine nitroxides. In animal experiments, however, pyrrolidine nitroxides are more resistant to reduction by chemical and enzymatic processes. The relaxation enhancement of the NFRs is much lower than that of paramagnetic complexes. Thus, the clinical use of NFRs seems less probable.

## 4. Future Developments

The main directions in the research and development of CAs are the increase of relaxivity and the creation of organ-specific materials. The attachment of $Gd^{3+}$ complexes to macromolecules (proteins, dendrimers, etc.) results in higher relaxivities due to the slower rotation of the molecules. Such CAs are transferred more slowly from the intravascular space and can be used in MR angiography. The $Gd^{3+}$ complexes of ''porphyrin-like'' ligands produce very high relaxivities. Some MRI agents can be used to quantify specific enzymatic activity. The development of CAs for $T_2$-weighted images opens up new vistas. Potentially, the complexes of $Dy^{3+}$ are the most interesting; these result in large proton chemical shifts and significantly shorten the $T_2$ values, and they are planned to be used as ''susceptibility agents.''

# Multilayer Optical Film Modeling

Optical multilayer thin film technologies have many applications ranging from complex high-performance mirrors, filters, and polarizers, to simple single-layer anti-reflection coatings. The design of optical coatings and calculation of their properties is a well-established science and several books (Macleod 1969, Heavens 1991) and substantial articles (Lissberger 1970) have been written on the topic.

More recently, the properties of multilayers have been exploited in the area of information storage with the introduction of CD–RW/DVD (rewritable Compact Disk/Digital Versatile Disk) optical technologies and rewritable magneto-optical systems such as the audio mini-disc. The optimization of these systems requires an understanding of the interaction of light with thin film multilayer media and an appreciation of the factors that determine the ultimate performance of any optical data readout system (see *Magneto-optical Effects, Enhancement of*). For such applications calculation of the optical and magneto-optical properties of the multilayers is crucial. The important properties are the intensity reflectance and transmittance in the optical case, and the Kerr and Faraday effects in the magneto-optical case (see *Faraday and Kerr Rotation: Phenomenological Theory*). To determine these it is necessary first to calculate reflection, transmission, Kerr, and Faraday amplitude coefficients ($r$, $t$, $k$, and $f$, respectively), which are different for each of the orthogonal $p$ and $s$ component polarization states.

In general, the calculation of optical and magneto-optical properties of a magnetic multilayer stack is complicated, particularly where the magnetization vector may be in an arbitrary direction. However, it is possible to simplify this problem considerably by treating such a system as a linear superposition of three principal magneto-optic configurations. These are the polar, longitudinal, and transverse configurations, which have been defined elsewhere (see *Faraday and Kerr Rotation: Phenomenological Theory*). A further simplification is possible for the polar configuration at normal incidence, which is a case particularly relevant to magneto-optical recording. In this instance, the optical and magneto-optical properties may be readily found using a simple reiterative technique normally applied to optical calculations.

In the space of this short article it is not possible or appropriate to give a detailed derivation of the mathematical formulations necessary for a complete description of all linear, first-order optical and magneto-optical effects. However, it is intended to give sufficient information, together with appropriate references, to enable the reader to understand the basic methods used for thin film and multilayer calculations.

The discussion commences with the simplest case of the reiterative reflectance formula and the normal incidence polar Kerr effect. Following this, a more general analysis is given that leads to a $4 \times 4$ characteristic matrix method that, whilst applicable to straightforward optical media, also applies to magnetic media and which is convenient for dealing with many-layered systems.

## 1. The Permittivity Tensor

The interaction between an electromagnetic wave and magnetic medium depends on the frequency-dependent magnetic and electric response of the material. In general, this response is quantified through material equations expressed in terms of the relative permeability, $\mu_r$, and the relative permittivity, $\varepsilon_r$. At the high frequencies of optical radiation, the magnetic interaction is negligible and $\mu_r$ is equal to its free space value of unity. Consequently, the medium response is described entirely by the permittivity. For an optically isotropic system, the relative permittivity is a scalar quantity. For a magnetic material, the unique direction of the magnetization vector imposes an anisotropy on the system and the permittivity becomes a skew-symmetric tensor. In general, if the direction of magnetization is defined by the unit vector, $\underline{\hat{\mathbf{m}}} = m_x\underline{\mathbf{i}} + m_y\underline{\mathbf{j}} + m_z\underline{\mathbf{k}}$, then the first-order permittivity tensor for any direction is

$$[\varepsilon_r] = n^2 \begin{bmatrix} 1 & -im_zQ & im_yQ \\ im_zQ & 1 & -im_xQ \\ -im_yQ & im_xQ & 1 \end{bmatrix} \qquad (1)$$

where $n$ is the isotropic complex refractive index and $Q$ is the complex *magneto-optical Voigt parameter*, which is responsible for magneto-optical effects. In most cases $|Q| \sim 1 \times 10^{-3}$, and for this reason higher order terms in $Q$, that may appear in Eqn. (1) have been omitted.

The effect of the above permittivity tensor is to introduce an optical anisotropy that results in the propagation of particular magneto-optical modes within the medium. In general, these modes are rather complicated to visualize. However, for the special case of a light wave traveling parallel to the magnetization vector there are two simple modes, both circularly polarized but with opposite senses, i.e., one is right handed and the other is left handed. These modes propagate within the medium experiencing refractive indices $n_+$ and $n_-$, respectively. The two refractive indices differ from each other by an amount of the order of $Q$ and the medium is said to exhibit *circular birefringence*. Consequently, the circularly polarized modes propagate through the medium at different velocities and are attenuated at different rates. The result is a change in the overall

polarization state of light on transmission or reflection from the medium and this constitutes a magneto-optical effect.

For the present case, where the permittivity tensor is described by Eqn. (1), the magneto-optical behavior is said to be *gyroelectric*. In cases where the magnetic permeability becomes important, circular birefringence may also arise out of a similar anisotropy in the permeability tensor $[\mu_r]$ and there may be a contribution to the magneto-optical behavior which is *gyromagnetic*. For further information on gyromagnetic modeling see Smith (1965) and Hunt (1966).

## 2. The Reiterative Reflectance Formula

When $s$ or $p$ polarized light of wavelength $\lambda_0$ is incident on the surface of a thin film, it is partly reflected and partly transmitted according to the well-known Fresnel equations. The transmitted light propagates into the film and may be attenuated depending on the imaginary part of the refractive index. If the film is nonabsorbing or sufficiently thin, the light undergoes multiple reflections as it travels back and forth within the film (Fig. 1). Consequently, the calculation of the net amplitude reflectance $r_1$ and transmittance $t_1$ involves a multiple beam summation that, for either $s$ or $p$ states, results in (Heavens 1991, pp. 55–9):

$$r_1 = \frac{r_{01} + r_2 e^{i2\rho_1}}{1 + r_{01} r_2 e^{i2\rho_1}}$$
$$t_1 = \frac{t_{01} t_2 e^{i2\rho_1}}{1 + r_{01} r_2 e^{i2\rho_1}} \qquad (2)$$

where $\rho_l = 2\pi n_1 d_1/\lambda_0$ is the phase thickness of the film, $r_{01}$,$r_{12}$ ($=r_2$) and $t_{01}$,$t_{12}$ are the amplitude coefficients at the two interfaces. Equations (2a) and (2b) may be applied reiteratively, extending the calculation to the amplitude reflectance and transmittance for multiple layers. In this case the reflectance at the upper boundary of the $l$th layer is:

$$r_l = \frac{r_{l-1,l} + r_{l+1} e^{i2\rho_l}}{1 + r_{l-1,l} r_{l+1} e^{i2\rho_l}} \qquad (3)$$

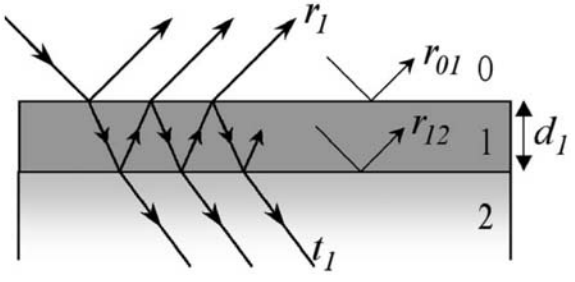

***Figure 1***
Multiple reflections in a single layer.

with a similar expression for transmittance. The calculation begins at the substrate and is applied repeatedly, layer by layer, toward the incident medium. At each stage in the calculation, $r_{l+1}$ is the system reflectance calculated in the previous step and $r_{l-1,l}$ is the Fresnel amplitude reflectance at a boundary between two semi-infinite media.

The method may be applied to the calculation of the magneto-optical polar Kerr effects at normal incidence. As mentioned in Sect. 1, the light can be expected to propagate as two circularly polarized modes encountering refractive indices $n_+$ and $n_-$. The latter are related to the Voigt parameter $Q$, and the isotropic refractive index $n$, by $n_\pm = n(1 \pm Q/2)$. Each of these modes gives rise to separate Fresnel reflection coefficients such that:

$$r_{\pm l-1,l} = \frac{n_{l-1} - n_{\pm l}}{n_{l-1} + n_{\pm l}} \qquad (4)$$

It follows that for a stack containing several magnetic layers, the reiterative scheme must be applied twice to determine the two amplitude reflection coefficients $r(n_+)$ and $r(n_-)$. The magneto-optical Kerr effect is then determined from the Kerr amplitude coefficient (see Sect. 3.4), which is related to the differential reflectance, $\delta r = r(n_+) - r(n_-)$, such that:

$$k = i\frac{\delta r}{2} \qquad (5)$$

This approach was applied by Gamble *et al.* (1985) to the optimization of polar Kerr effects in multilayers containing a single magnetic film. It has particular relevance to the design of magneto-optical recording media, which is dealt with in article *Magneto-optical Effects, Enhancement of*.

## 3. The Characteristic Matrix Method

So far the discussion has been limited to the specific and simple case of light propagating parallel or antiparallel to the magnetization, as for the polar configuration at normal incidence. In this case, the light propagates as two circularly polarized modes with different velocities and attenuating at different rates according to the refractive indices $n_+$ and $n_-$, giving rise to magneto-optical effects. A more general solution to the propagation of radiation in a magnetic medium requires the general mode structure to be determined for magnetization in an arbitrary direction and for any angle of incidence. This is usually done for a single layer in the three principal configurations and then the analysis is extended to multilayered systems. The analysis is outlined below.

All electromagnetic fields that exist within any medium must satisfy Maxwell's equations and the 3D

wave equation:

$$\nabla(\nabla \cdot \underline{\mathbf{E}}) - \nabla^2 \underline{\mathbf{E}} = -\mu_0 \frac{\partial^2 \underline{\mathbf{D}}}{\partial t^2} \tag{6}$$

where

$$\underline{\mathbf{D}} = \varepsilon_0[\varepsilon_r]\underline{\mathbf{E}} \tag{7}$$

It is assumed that the solutions to the equation are plane waves of angular frequency, $\omega$, described by:

$$\underline{\mathbf{E}} = \underline{\mathbf{E}}_0 \exp i(\underline{\mathbf{p}} \cdot \underline{\mathbf{r}} - \omega t) \tag{8}$$

where $\underline{\mathbf{E}}_0$ is the electric field amplitude, $\underline{\mathbf{p}}$ is the propagation vector, and $\underline{\mathbf{r}}$ is a position vector. For convenience, the Cartesian coordinate system is arranged so that the plane of incidence is always in the $x$–$z$ plane (Fig. 2). The vectors $\mathbf{r}$ and $\underline{\mathbf{p}}$ then reduce to:

$$\underline{\mathbf{r}} = x\underline{\mathbf{i}} + z\underline{\mathbf{k}} \tag{9}$$

and

$$\underline{\mathbf{p}} = p_x\underline{\mathbf{i}} + p_z\underline{\mathbf{k}} = \frac{2\pi}{\lambda_0} n(\alpha\underline{\mathbf{i}} + \gamma\underline{\mathbf{k}}) \tag{10}$$

where $\alpha$ and $\gamma$ are direction cosines ($\alpha^2 + \gamma^2 = 1$) as shown in Fig. 2 and $\lambda_0$ is the free space wavelength. Where there is no magneto-optical behavior, $p_z$ has two values, associated with positive and negative going waves with respect to the $z$-direction of the coordinate system. If magneto-optical activity exists, then for the polar and longitudinal configurations each of these waves propagates as two distinct modes that are convenient to label $p_z^{\pm}$. For each of these modes there are corresponding refractive indices $n_{\pm}$ and direction cosines $\gamma_{\pm}$,$\alpha_{\pm}$. In the polar case, for example, these are given by:

$$n_{\pm} = \mathrm{n}(1 \pm \gamma Q/2) \tag{11}$$

$$\gamma_{\pm} = \gamma(1 \pm \alpha^2 Q/2\gamma)$$

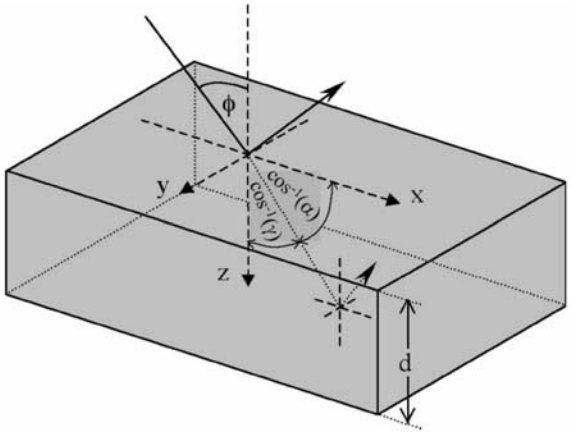

***Figure 2***
Conventions applied in the characteristic matrix model.

where $\alpha$, $\gamma$, and $n$ are the isotropic values that would apply if the magnetization were reduced to zero. Similar expressions to Eqns. (11a) and (11b) also exist for the longitudinal case.

For the transverse configuration, the magnetization is in the $y$ direction (Fig. 2), perpendicular to the direction in which the light is traveling. The result is that the light propagates as a single mode peculiar to the $p$ polarization state and consequently the magneto-optical effects are different from the other configurations.

The electric and magnetic fields, $\underline{E}$ and $\underline{H}$, corresponding to these modes of propagation in the medium are determined using Eqn. (6) and Maxwell's equations, which are common to all electromagnetic phenomena. Generally, each field has three components corresponding to the three principal directions $x$, $y$, and $z$. A full appreciation of the form of these fields requires knowledge of all three components. However, for the purposes of thin film and multilayer calculations, it is only necessary to determine those components lying in the plane of the film (i.e., the $x$–$y$ plane). The laws of electromagnetism require these electric and magnetic field components, that are tangential to the layer boundaries, to be continuous across the interfaces. This very important boundary condition means that the tangential field components provide a correlation between electromagnetic fields in adjacent materials and will be discussed further in Sect. 3.3. Again, taking the polar case as an example, the tangential fields are:

$$\begin{aligned}
E_x &= Ae^{i\delta_+} + Be^{i\delta_-} + Ce^{-i\delta_+} + De^{-i\delta_-} \\
H_y &= \frac{i}{Z\gamma}(AV_+e^{i\delta_+} + BV_-e^{i\delta_-} - CV_+e^{-i\delta_+} - DV_-e^{-i\delta_-}) \\
E_y &= \frac{i}{\gamma}(Ae^{i\delta_+} + Be^{i\delta_-} + Ce^{-i\delta_+} + De^{-i\delta_-}) \\
H_z &= -\frac{i}{Z}(AV_+e^{i\delta_+} - BV_-e^{i\delta_-} - CV_+e^{-i\delta_+} + DV_-e^{-i\delta_-})
\end{aligned} \tag{12}$$

where

$$V_{\pm} = \left(1 \pm \frac{Q}{2\gamma}\right)$$

and

$$\delta_{\pm} = \frac{2\pi}{\lambda_0} n\gamma V_{\pm} z$$

and $A$, $B$, $C$, and $D$ are arbitrary constants. The exponents in $t$ and $x$ have been omitted from the above expressions since the conditions must be satisfied for all time and every point on the interface. This leads to the well-known Snell's law and a common term that may be removed from each expression in Eqns. (12a)–(12d). The sign of the exponents of the partial

waves indicate the direction of propagation with the positive and negative signs indicating positive and negative going waves, respectively. The subscript signs correspond to the two magneto-optical modes that, of course, are magnetization dependent.

It is worth pointing out that in the polar case at normal incidence ($\alpha = 0$, $\gamma = 1$, $E_z = 0$) the electric field ($E_x$, $E_y$), reduces to two counter-rotating circularly polarized modes ($Ae^{i\delta_+}$, $-iAe^{i\delta_+}$) and ($Be^{i\delta_-}$, $-iBe^{i\delta_-}$). Furthermore, it is clear from Eqn. (11b) that $\gamma_\pm = 1$ and the two corresponding refractive indices are $n_\pm = n\,(1 \pm Q/2)$. This, of course, is the basis for the differential reflectance approach to the calculation of the polar Kerr effect.

At oblique incidence, for both polar and longitudinal configuration, the modes propagate in two directions $\gamma_\pm$ and are no longer circular but elliptical. In addition, each has field components in the direction of propagation and so can no longer be regarded as transverse electromagnetic (TEM) waves. In the transverse case the mode propagates in a single direction $\gamma$ and is linearly polarized in the $p$ plane. Again, there are field components both perpendicular and parallel to the direction of propagation in the magnetic medium and the mode of propagation is not a simple TEM mode.

The tangential field components are determined as a function of distance along the $z$ direction, as demonstrated by Eqns. (12a)–(12d) specifically for the polar configuration. Consequently, the equations relate the tangential field components at one boundary of a thin film, placed at $z = 0$ for example, to those at the other boundary at the film thickness $z = d$. It is possible to express this relationship conveniently in matrix form such that:

$$(F_z = 0) = [C](F_{z=d}) \tag{13}$$

where $(F)$ is a column matrix whose elements are $E_x$, $H_y$, $E_y$, and $H_x$ and $[C]$ is a $4 \times 4$ matrix that is characteristic of the film.

Each of the three principal magneto-optical configurations requires a different characteristic matrix. Moreover, each matrix may be decomposed into separate isotropic and anisotropic parts such that:

$$[C]_{P,L,T} = [C]_I + g_{P,L,T}[G]_{P,L,T} \tag{14}$$

where the subscripts refer to the principle configurations. The isotropic matrix $[C]_I$, corresponding to optical behavior of the film, would completely characterize the film if the relative permittivity $\varepsilon_r$ was a scalar quantity, i.e., if there was no magneto-optical activity. Hence, it remains the same for all three magneto-optical configurations. The anisotropic matrix accounts for the gyroelectric properties of the medium and leads to calculations of observed magneto-optical effects. To completely characterize the film optically and magneto-optically four characteristic matrices must be determined in all; an isotropic matrix and three anisotropic matrices corresponding to each of the three magneto-optical configurations. In the proceeding sections the details for each of these matrices will be given.

### *3.1 The Isotropic Matrix*

The isotropic matrix has the form:

$$[C]_I = \begin{bmatrix} C_{11} & C_{12} & 0 & 0 \\ C_{21} & C_{11} & 0 & 0 \\ 0 & 0 & C_{11} & C_{34} \\ 0 & 0 & C_{43} & C_{11} \end{bmatrix} \tag{15}$$

So there are five different elements, which are:

$$\begin{aligned} C_{11} &= \cos(\rho) \\ C_{12} &= -iZ\gamma \sin(\rho) \\ C_{21} &= -i \sin(\rho)/Z\gamma \\ C_{34} &= Z \sin(\rho)/\gamma C_{43} = \gamma \sin(\rho)/Z \end{aligned} \tag{16}$$

where $\rho$ is the phase thickness:

$$\rho = p_z d \tag{17}$$

and the optical impedance $Z$, has units of ohms and relates $E$ and $H$ such that $E = ZH$. The optical impedance may be related to the refractive index of the material through

$$Z = Z_0/n \tag{18}$$

where $Z_0$ is the optical impedance of free space and has the value 376.7 ohms. The direction cosines, $\alpha$ and $\gamma$, are related to the angle of incidence, $\varphi$, through Snell's law.

An important feature of the isotropic matrix is that it comprises two $2 \times 2$ submatrices $[I]_p$ and $[I]_s$ so that:

$$[C]_I = \begin{bmatrix} [I]_p & [0] \\ [0] & [I]_s \end{bmatrix} \tag{19}$$

These are associated specifically with either $p$ polarized light or $s$ polarized light. Consequently the $p$ and $s$ modes do not interact and can be treated separately.

Note that Eqn. (2a) for single layer reflectance may be derived using the isotropic matrix, the summation and matrix methods being completely consistent (Lissberger 1970). This is to be expected as both techniques are based on Maxwell equations and employ the same assumptions and boundary conditions (Heavens 1991, pp. 49–53).

***Table 1***
The elements of the gyroelectric characteristic matrices where $c = \cos(\rho)$ and $s = \sin(\rho)$. The parameters $\rho$ and $Z$ are given by Eqns. (17) and (18), respectively. The direction cosines $\gamma$ and $\alpha$ are determined using Snell's law.

| | $g$ | $G_{11}$ | $G_{13}$ | $G_{14}$ | $G_{23}$ | $G_{24}$ |
|---|---|---|---|---|---|---|
| Polar | $Q/2$ | 0 | $i\rho s$ | $(Z/\gamma)(\rho c - s)$ | $-(\rho c + s)/(Z\gamma)$ | $-i\,(\rho s/\gamma^2)$ |
| Longitudinal | $(Q/2)(\gamma/\alpha)$ | 0 | $-(\rho c + s)$ | $-i(Z/\gamma)\ \rho s$ | $i\,(\rho s/Z\gamma)$ | $(\rho c - s)/\gamma^2$ |
| Transverse | $Q(\gamma/\alpha)$ | $s$ | 0 | 0 | 0 | 0 |

### *3.2 The Gyroelectric Matrices*

The characteristic matrices for the polar and longitudinal configurations have the same form:

$$[C]_{P,L} = [C]_I + g_{P,L}\begin{bmatrix} 0 & 0 & G_{13} & G_{14} \\ 0 & 0 & G_{23} & G_{24} \\ G_{24} & G_{14} & 0 & 0 \\ G_{23} & G_{13} & 0 & 0 \end{bmatrix} \tag{20}$$

Thus, there are only four different gyroelectric elements for each of the configurations and these are summarized in Table 1, where the parameters $\rho$ and $Z$ are calculated according to Eqns. (17) and (18).

The magneto-optical behavior for the transverse configuration is different to the other two cases. For a *s* polarized excitation, where the electric field oscillates along the direction of magnetization, there is no gyroelectric effect. Thus the transverse effect is induced by *p* polarized light only. Like the isotropic case, there is no interaction between *p* and *s* modes; so, the gyroelectric effect is a linear *p* polarized effect stimulated by a *p* polarized excitation. It is, therefore, not surprising that the transverse characteristic matrix has a much closer resemblance to the characteristic matrix for isotropic media:

$$[C]_T = [C]_I + g_T\begin{bmatrix} G_{11} & 0 & 0 & 0 \\ 0 & -G_{11} & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \tag{21}$$

The gyroelectric part of the transverse matrix is much simpler than for the longitudinal and polar configurations, there being only two diagonal elements with the same magnitude but opposite sign (Table 1).

### *3.3 The Characteristic Matrix Method and Multilayers*

Up to now the discussion has dealt with the characteristic matrix and how it relates the tangential field components at the two extremities of a film (Eqn. (13)). It is appropriate to remember that the tangential field components only are being considered because at an interface they are continuous. Consequently, it is possible to relate the tangential electric and magnetic fields between adjacent layers and ultimately between the layers in a multilayer.

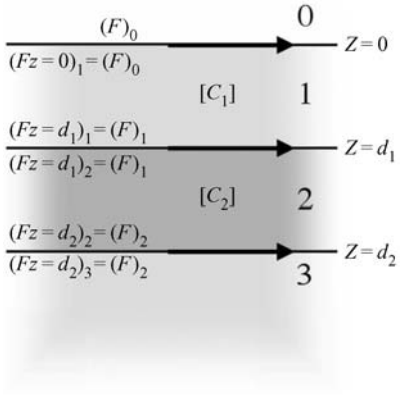

***Figure 3***
The concept behind the characteristic matrix model.

This may be illustrated by considering Fig. 3, which shows how the boundary conditions effect the field matrix $(F)$. Considering layer one first, at the $z = 0$ boundary between medium zero and layer one, $(F_{z=0}) = (F)_0$. By renaming the field matrix at the second interface $(F)_1$, Eqn. (13) may be rewritten:

$$(F)_0 = [C]_1(F)_1 \tag{22}$$

The tangential fields in medium zero and layer one have been related using the characteristics matrix for the layer $[C]_1$. Considering layer two, it is clear that a similar analysis may be applied to relate the tangential fields in layers one and two so that $(F)_1 = [C]_2(F)_2$. This leads to the conclusion that the fields in medium zero and layer two may also be related by multiplying the characteristic matrices of the two layers:

$$(F)_0 = [C]_1[C]_2(F)_2 \tag{23}$$

Therein lies the basis for multilayer matrix calculations in that for a stack of $L$ layers deposited on a substrate S in an ambient 0, the tangential fields at

the interfaces with the ambient and substrate are related by multiplying together all the characteristics matrices of the layers comprising the stack:

$$(F)_0 = \prod_{i=1}^{L} [C]_i (F)_S \tag{24}$$

Note that Eqn. (24) is of the same form as Eqn. (22) and consequently describes the multilayer as a single layer of characteristic matrix $[C]_M = \prod [C]_i$. To the first order, $[C]_M$ has the same form as the characteristic matrix for the single layers comprising the multilayer. For magneto-optic calculations, multiplying together the single layer matrices results in higher order terms in $Q$ appearing in the isotropic part of $[C]_M$ which are usually negligible. However, it is better to remove these terms completely and this may be done using a relatively simple scheme devised by Atkinson and Lissberger (1993).

### *3.4 The Calculation of Optical and Magneto-optical Effects*

It remains to calculate the optical and magneto-optical amplitude coefficients. The amplitude coefficients are related to the *s* and *p* polarized electric fields of the incident, reflected, and transmitted light (Fig. 4) such that:

$$\begin{aligned} r_{p,s} &= \frac{E^-_{O\ p,s}}{E^+_{O\ p,s}} \\ t_{p,s} &= \frac{E^+_{S\ p,s}}{E^+_{O\ p,s}} \\ k_{p,s} &= \frac{E^-_{O\ p,s}}{E^+_{O\ s,p}} \\ f_{p,s} &= \frac{E^+_{S\ p,s}}{E^+_{O\ s,p}} \end{aligned} \tag{25}$$

the *O* and *S* subscripts indicating the fields in the incident and substrate media, respectively, the + and − superscripts indicating direction of propagation. Consequently, it is necessary to express the tangential fields as *p* and *s* electric field components. It should be remembered that the net tangential field is a summation of the negative and positive going waves at the interface. With reference to Fig. 4, and using $E = ZH$, the boundary field matrix may be expressed in terms of the *s* and *p* components of the electric fields:

$$(F) = \begin{pmatrix} E_x \\ H_y \\ E_y \\ H_x \end{pmatrix} = \begin{pmatrix} (E_p^+ + E_p^-)\gamma \\ (E_p^+ - E_p^-)/Z \\ E_s^+ + E_s^- \\ -(E_s^+ - E_s^-)\gamma/Z \end{pmatrix} \tag{26}$$

The characteristic matrix equation, may then be related to the *p* and *s* electric field components in the incident medium and the substrate:

$$\begin{pmatrix} (E^+_{Op} + E^-_{Op})\gamma_0 \\ (E^+_{Op} - E^-_{Op})/Z_0 \\ E^+_{Os} + E^-_{Os} \\ -(E^+_{Os} - E^-_{Os})\gamma_0/Z_0 \end{pmatrix} = [C] \begin{pmatrix} E^+_{Sp}\gamma_S \\ E^+_{Sp}/Z_S \\ E^+_{Ss} \\ -E^+_{Ss}\gamma_S/Z_S \end{pmatrix} \tag{27}$$

The optical and magneto-optical coefficients, as defined by Eqns. (25a)–(25d), are determined by solving the relatively simple set of simultaneous equations represented by Eqn. (27).

The polar and longitudinal effects take the form of a change in the state of polarization known as the complex Kerr rotation in reflection and complex Faraday rotation in transmission. In both cases, the induced magneto-optical components, orthogonal to the incident linear polarization state, result in elliptically polarized light. The complex rotations are related to the amplitude coefficients ratios $k_{p,s}/r_{s,p}$ and $f_{p,s}/t_{s,p}$ as previously mentioned. The transverse effect is an exception in that it is a *p* polarized effect induced by a *p* polarized excitation. In this case, the effect is detected as a change in reflectance or transmittance. For details on how to determine the magneto-optical effects from the amplitude coefficients see article *Faraday and Kerr Rotation: Phenomenological Theory*.

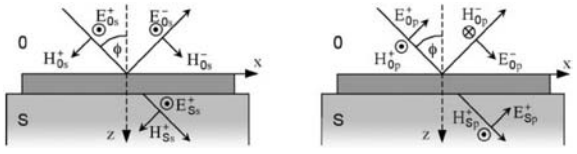

***Figure 4***
The *s* and *p* polarized electric and magnetic field components on reflection and transmission.

## *4. Concluding Remarks*

Accurate modeling of the interaction of light with multilayered recording media is important for the purposes of characterization and performance optimization. The two methods described are well-established and founded on Maxwell's equations and are consistent with each other. Both methods calculate the optical and magneto-optical amplitude coefficients, which are related to observable effects. The material parameters required for the calculations are the thickness, refractive index, and magneto-optical parameter for each layer constituting the multilayer.

The first method is a phenomenological approach where light undergoes a series of multiple reflections

within the media. It provides a relatively uncomplicated way to perform optical calculations but for the magneto-optical case is limited to the polar Kerr effect at normal incidence. The second, a matrix method, is a more general approach and is conveniently used for multilayer systems.

## Multilayers: Interlayer Coupling

The exchange coupling of magnetic films across metallic interlayers was first observed in 1986 for dysprosium and gadolinium films separated by yttrium interlayers, and for iron films separated by chromium interlayers (Salamon *et al.* 1986, Majkrzak *et al.* 1986, Grünberg *et al.* 1986. For ferromagnetic films like those of gadolinium and iron, the coupling leads to parallel or antiparallel alignment of the magnetizations on opposite sides of the interlayer, depending on the interlayer thickness $D$, as seen in Figs. 1(a) and 1(b) respectively. For obvious reasons, the coupling leading to (a) is called "ferromagnetic"(F), and to (b) "antiferromagnetic" (AF). For films with helical magnetic structure like dysprosium, the coupling leads to an angle, $\psi$, between the magnetic moments on both sides of the yttrium interlayer, which depends on the yttrium thickness, as seen in Fig. 1(c). The actual alignment is also affected by other interactions, like

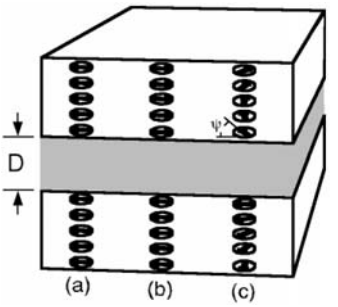

***Figure 1***
Coupling between magnetic films across metallic interlayer (dark shaded). Encircled arrows indicate moments in monolayer sheets parallel to the interfaces. The arrows indicate ferromagnetic coupling across the interlayer in (a) and antiferromagnetic coupling in (b). The magnetic coupling of films with a helical magnetic structure shown in (c) leads to a phase angle $\psi$.

anisotropy or an external field, $H_{ext}$. Large enough fields, $H_{ext,}$ overcome the coupling and align the magnetizations parallel.

In 1990, it was established (Parkin *et al.* 1990) that the oscillation of the magnetic coupling between F and AF alignment, as a function of interlayer thickness, is a general phenomenon of transition metal ferromagnets separated by nonmagnetic interlayers. Previously oscillations had only been seen for gadolinium separated by yttrium. The discovery in 1988 of the giant magnetoresistance (GMR) effect in the Fe/Cr system (see *Giant Magnetoresistance*) led to enhanced interest in the magnetic coupling of transition metal ferromagnets, because of the many applications of GMR.

### *1. Theoretical Models*

Interlayer exchange coupling is believed to be an indirect exchange interaction mediated by the conduction electrons of the spacer layer. It is closely related to the Ruderman–Kittel–Kasuya–Yoshida (RKKY) interaction between localized moments mediated by the conduction electrons of a host metal. The essential ingredients of the RKKY interaction, a localized spin-polarized perturbation and a sharp Fermi surface, lead to the well-known coupling oscillations. Like the exchange coupling in the rare earth metals themselves, the magnetic coupling of gadolinium, dysprosium, holmium, and erbium through yttrium and lutetium spacer layers has been described by the RKKY interaction.

For transition metal ferromagnets separated by paramagnetic interlayers, the description of the coupling needs to be modified. A phenomenological description of the coupling proposed to explain the

experimental observations (Bürgler *et al*. 2001) gives the interlayer coupling energy, $E_i$, per unit area as:

$$E_i = -J_1\cos(\theta) - J_2\cos^2(\theta) \quad (1)$$

Here $\theta$ is the angle between the magnetizations $\vec{M}_1$ and $\vec{M}_2$ of the films on both sides of the spacer layer. The parameters $J_1$ and $J_2$ describe the type and the strength of the coupling. If the term with $J_1$ dominates, then from the minima of Eqn. (1) the coupling is F (AF) for positive (negative) $J_1$. If the term with $J_2$ dominates and is negative, we obtain 90° coupling. The first term of Eqn. (1) is often called the bilinear coupling, and the second the biquadratic coupling.

The microscopic mechanism leading to the bilinear exchange coupling $J_1$ has essentially the same physical origin as the RKKY interaction. However, one must consider the itinerant nature of electrons in transition metal ferromagnets, which gives rise to the spin-split band structure and spin-dependent reflectivities at the paramagnet/ferromagnet interfaces. The spin-dependent reflectivity is illustrated in Fig. 2(a), where it is assumed that electrons with their spins parallel (antiparallel) to the magnetizations $\vec{M}_1$ and $\vec{M}_2$ are weakly (strongly) reflected at these interfaces.

This spin-dependent reflection at the interfaces gives rise to spin-dependent quantum well states that cause an oscillatory polarization in the interlayer. As a result, there are spin-dependent interference effects like the formation of standing electron waves for certain interlayer thicknesses as indicated in Fig. 2(a). Due to the similarity of the arrangement in Fig. 2(a) with an optical Fabry Perot interferometer, this is sometimes also called the Fabry Perot model of oscillatory coupling. Oscillations in the coupling, observed as the thickness of a magnetic layer or other overlayer is varied, are explained by additional spin-dependent interference effects.

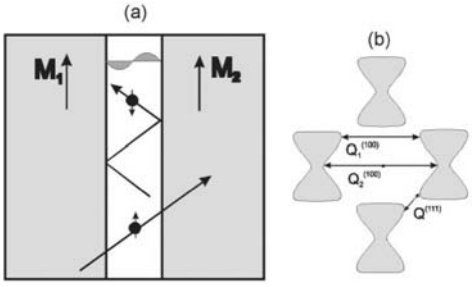

***Figure 2***
(a) Illustration of spin-dependent reflectivity at the nonmagnetic/magnetic interfaces for the explanation of oscillatory coupling; (b) a cross section of the gold Fermi surface with critical spanning vectors in the [100] and [111] directions.

The predominant contribution to the coupling is from electrons with wave vectors, $Q_i$, that are critical spanning vectors of the Fermi surface of the interlayer material, i.e., vectors in the direction perpendicular to the interface that connect two sheets of the Fermi surface parallel to each other. For the Fermi surface of gold shown in Fig. 2(b), there are two such vectors in the [100] and one vector in the [111] direction. The periods of the oscillatory coupling are given by $\Lambda = 2\pi/Q_i$ and thus are determined solely by the electronic properties of the interlayer material.

This quantum well model leads to the following dependence of $J_1^i$ of Eqn. (1), connected with the $i^{\text{th}}$ Fermi surface spanning vector $Q_i$, on the interlayer thickness $D$:

$$J_1^i = J_0^i\sin(Q_iD + \phi_i)/D^2 \quad (2)$$

The amplitude $J_0^i$ includes Fermi surface geometry factors and interface reflection probabilities. Good parallelism of the parts of the Fermi surface at the endpoints of a critical spanning vector will contribute to large amplitudes of the corresponding oscillatory coupling. This so-called ''nesting'' effect results in a decrease of the coupling with interlayer thickness as $D^{-1}$ rather than the more typical $D^{-2}$.

If, due to favorable band matching, electrons with one spin have good transmission at the interfaces, and with the other spin have good reflection, then the result will be large amplitudes in oscillatory coupling strength. This is thought to be the case for the coupling of cobalt across rhodium and ruthenium interlayers (see Table 1). In principle, the quantum well model can be extended to nonmetallic spacers using a complex Fermi surface, but materials difficulties have limited experimental work in this area.

The theoretical description of magnetic coupling assumes perfect interfaces. Experimentally, there is always some disorder at the interfaces. The interaction of Eqn. (2) is defined at each discrete interlayer thickness $D = nd$, where $d$ is the spacing of neighboring atomic layers in the interlayer. The direction of magnetization in a magnetic layer can only change over a finite lateral distance $l$, comparable to a domain wall width. If there are interlayer thickness fluctuations on a lateral length scale smaller than this magnetic response length $l$, the observed coupling strength is an average over regions of different thickness:

$$\bar{J}_1(t) = \sum_i \sum_n P(t,\ n)J_i(n) \quad (3)$$

where $P(t, n)$ is the fraction of the interlayer area that is $n$ layers thick when the average thickness is $t$. Short-period oscillations of the coupling are averaged out more readily than long-period oscillations, and therefore are only observed in samples with relatively smooth interfaces. Thickness fluctuations, and also

***Table 1***
Observed coupling strengths and periods.

| Sample | Maximum strength $\lvert J_1 + J_2 \rvert$ (mJ m$^{-2}$) at (thickness (nm)) | Periods in ML (nm) |
|---|---|---|
| Co/Cu/Co (100) | 0.4 (1.2) | 2.6 (0.47), 8 (1.45) |
| Co/Cu/Co (110) | 0.7 (0.85) | 9.8 (1.25) |
| Co/Cu/Co (111) | 1.1 (0.85) | 5.5 (1.15) |
| Fe/Au/Fe (100) | 0.85 (0.82) | 2.5 (0.51), 8.6 (1.75) |
| Fe/Cr/Fe (100) | $>1.5$ (1.3) | 2.1 (0.3), 12 (1.73) |
| Fe/Mn/Fe (100) | 0.14 (1.32) | 2 (0.33) |
| Co/Ru (0001) | 6 (0.6) | 5.1 (1.1) |
| Co/Rh/Co (111) | 34 (0.48) | 2.7 (0.6) |
| Co/Os (111-text'd) | 0.55 (0.9) | 7 (1.5) |
| Co/Ir (111) | 2.05 (0.5) | 4.5 (1.0) |

interfacial disorder on a finer scale due to alloying, lead to a measured magnetic coupling that is weaker than that expected theoretically.

Although $J_2$ of the biquadratic coupling term in Eqn. (1) can be of intrinsic origin, most experimental results to date are well explained by a model in which the biquadratic coupling is an extrinsic effect due to the thickness fluctuations of the interlayer. For example, if the bilinear coupling varies spatially due to the thickness fluctuations, the sum of the intralayer coupling energy (exchange stiffness) and interlayer coupling energies is minimized when the magnetizations of the layers fluctuate about their average directions. The energy is lowered the most when the average magnetizations of the two layers are perpendicular. This biquadratic coupling leads to observation of 90° coupling when the average bilinear coupling is small.

The RKKY description of magnetic coupling in rare-earth multilayers and the quantum well model of coupling in transition metal multilayers assume that the electrons in the spacer layers are noninteracting. At the other extreme, the electrons of the interlayer may be strongly interacting, as for example local moments coupled to each other in antiferromagnetic manganese. A phenomenological model for this situation, known as the torsion or proximity model, has been proposed (Slonczewski 1995) that treats the magnetic nature of the spacer layer and predicts slightly different observable behavior.

The appropriate description of the coupling may fall between the assumed noninteracting electrons of the interlayer in the RKKY and the quantum well models and the strongly coupled local moments of the torsion model. A model including an induced spin density wave was proposed to explain experiments on the coupling of dysprosium through yttrium and lutetium. There is also strong evidence from the temperature dependence of the coupling in an iron whisker-based Fe/Cr/Fe trilayer that the chromium electrons are in an interacting, itinerant, spin density wave state (Pierce *et al.* 1999).

## 2. *Experimental Methods and Examples*

Polarized neutron diffraction provided the initial evidence for the oscillatory exchange coupling of superlattices of gadolinium layers separated by yttrium interlayers. These measurements were supplemented by magnetization measurements that show the remanent magnetization and the saturation magnetization oscillating as a function of yttrium thickness.

The coupling of rare earths with complex spin structures like dysprosium, holmium, and erbium through interlayers of yttrium and lutetium can be studied with unpolarized neutron diffraction, because there are distinct magnetic scattering peaks deriving from the incommensurate magnetic order. The phase and chirality of the helical spin structure of dysprosium is preserved through yttrium spacer layers over 10 nm thick in superlattices grown along the c-axis direction. The stronger coupling found for c-axis superlattices, compared to a- or b-axis structures, was attributed to the directional properties of the interlayer Fermi surface.

Superlattices, as well as simpler trilayer structures, have been used to investigate the coupling of transition-metal ferromagnets. As an alternative to preparing many superlattices or trilayer samples, each with a specific interlayer thickness, it is possible with a trilayer to grow the spacer layer in the form of a wedge with continuously varying thickness. An example of such a structure is shown in Fig. 3(a).

The periods of the oscillatory interlayer coupling can be determined from the variation of the magnetic domains with changing thickness of the interlayer wedge. The domains can be detected optically with the magneto-optic Kerr effect, or by means of spin-polarized electrons using scanning electron microscopy with polarization analysis (SEMPA).

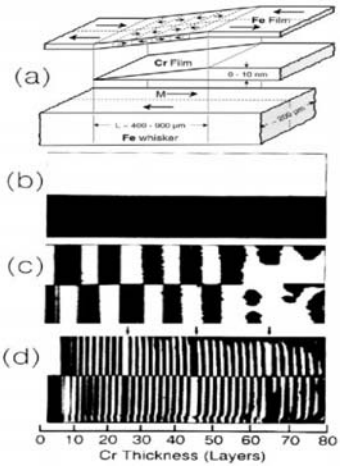

***Figure 3***
Magnetic domains in Fe/Cr/Fe samples seen by means of SEMPA, which display oscillatory coupling. Sketch of the sample seen in part (a); domains are observed in the bare whisker substrate (b); and in the upper iron film grown at 30 °C (c), and at 350 °C (d) (after Unguris *et al.* 1991).

Figures 3(b)-3(d) displays SEMPA magnetization images in which the black (white) regions correspond to magnetization to the left (right). Note that in part (b), the bare iron whisker displays two domains with a 180° wall in between. Parts (c) and (d) show domains in the upper iron film, separated from the whisker by a chromium spacer grown at an iron whisker substrate temperature of 30 °C and 350 °C, respectively. At 350 °C, the chromium grows in a layer-by-layer mode, forming a very smooth interface, while the lower temperature leads to a rougher chromium growth.

The striking difference in the magnetic domain patterns of parts (c) and (d) of Fig. 3 indicates how thickness fluctuations affect which periods of the magnetic coupling can be observed. For the near ideal growth in (d), both a short- and long-period coupling can be observed, with the short period clearly dominating. In (c), the short-period coupling is averaged out by thickness fluctuations as described by Eqn. (3), and only the long period is observed. The long and short periods were determined to be 12 ML and 2.1 ML respectively. The short-period oscillations derive from a wave vector connecting strongly nested regions of the chromium Fermi surface. The slight difference between this Fermi surface critical spanning wave vector and the lattice wave vector leads to phase slips in the short-period oscillations at the chromium thicknesses indicated by arrows.

For a measurement of coupling strengths, it is necessary to apply a magnetic field. The simplest and most frequently employed method is a measurement of the remagnetization curve, where the strength of the coupling is determined from the field required to switch from AF to F coupling. A measurement essentially of this type can be made in parallel with a sample structure as in Fig. 3(a) by using magneto-optical microscopy; the coupling strength is determined from the external field required to switch the antiferromagnetically coupled domains, causing them to disappear. Alternatively, one can measure the magnetic coupling by determining the frequency shifts of coupled spin wave modes, which represent the restoring forces caused by the coupling.

Remagnetization curves from trilayers consisting of two 6 nm f.c.c. cobalt films separated by two different thicknesses of copper are displayed in Fig. 4. The coupling is ferromagnetic in Fig. 4(a) and the films always reverse their magnetizations in unison. In Fig. 4(b), the strength of the antiferromagnetic coupling is determined by the field, $H_{flip}$, where the coupling changes from AF to F. In order to measure the strength of the coupling in ferromagnetically coupled regions by remagnetization curves, it is necessary to resort to a technique known as "spin engineering." To measure the coupling between two ferromagnetic films, $F_1$ and $F_2$, across an interlayer I, an additional thick ferromagnetic film, $F_0$, is added, such that it is strongly antiferromagnetically coupled to $F_1$ by using a proper interlayer, $I_0$, as shown in Fig 5. $F_1$ and $F_2$ can be held with their magnetizations opposite to the external field, H, until H overcomes the ferromagnetic coupling and reverses the magnetization of $F_2$,

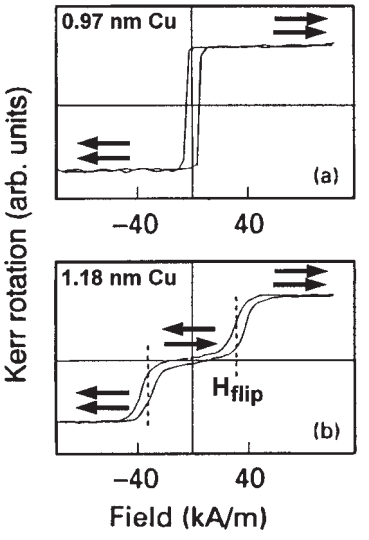

***Figure 4***
Remagnetization curves of a Co/Cu/Co trilayer structure: (a) with ferromagnetic coupling; (b) with antiferromagnetic coupling.

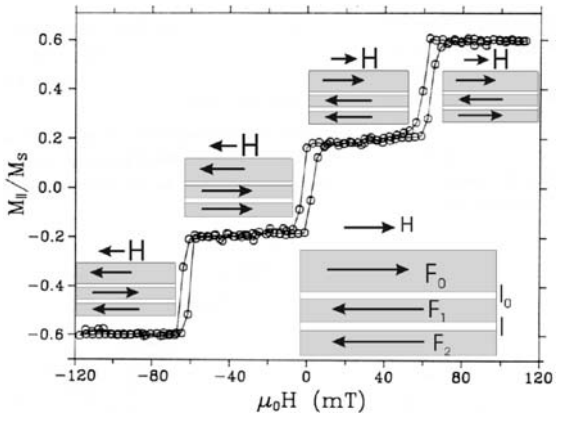

***Figure 5***
Structure (lower right side) and typical remagnetization curve of a Fe/Au/Fe sample with spin engineering.

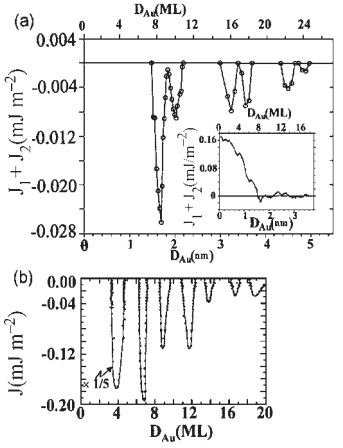

***Figure 6***
Coupling strength as a function of thickness in Fe/Au(wedge)/Fe on (a) Ag-buffered GaAs substrate; (b) on Fe whisker. The inset in (a) includes ranges where the coupling is ferromagnetic.

thereby determining the ferromagnetic coupling across I.

In Fig. 6(a) we see the result of an evaluation of remagnetization curves for a $Fe/Au_{wedge}/Fe$ structure grown on a silver-buffered GaAs(100) substrate. The spin engineering technique has been used to determine the positive values of the coupling. The coupling is strongly ferromagnetic in Fig. 6(a) for small $d_{Au}$, probably due to pinholes and magnetic bridges. For increasing $d_{Au}$ ferromagnetic coupling quickly decreases, until there are oscillations around zero. Two periods of oscillation are superimposed with an amplitude that is attenuated as a function of the interlayer thickness.

Measurements of the coupling strength in a $Fe/Au_{wedge}/Fe$ trilayer grown on an iron whisker, by observing the disappearance of antiferromagnetically coupled domains in a Kerr microscope, are shown in Fig. 6(b). Two periods of oscillatory coupling, 2.48 ML and 8.6 ML, were determined from the data. Both the samples used in Figs. 6(a) and 6(b) were grown very carefully; the stronger coupling for the iron whisker sample is indicative of the better growth occurring naturally on that substrate. The data of Fig. 6(b) were further analyzed, taking into account thickness fluctuations to obtain "unaveraged" values to compare with theory; the coupling strength for the short- and long-period oscillations was found to be 60% and 15% of that calculated respectively.

In Table 1 we have compiled some measured values for interlayer coupling strengths and periods. As shown in Fig. 3, the thickness fluctuations can obscure the short period oscillations by averaging but do not change the periods, which are determined by the interlayer Fermi surface. On the other hand, the thickness fluctuations dramatically affect the coupling strength, as seen from Fig. 6, and thus the values listed in Table 1 are representative coupling strengths for specific samples. Table 1 gives the maximum observed coupling strength, $|J_1+J_2|$, and the spacer layer thickness in ML (in nanometers) at which it was measured. The coupling strength also decreases with increasing temperature.

## 3. *Applications*

Applications of interlayer exchange coupling have been suggested. For example, antiferromagnetic coupling can be used in "artificial" antiferromagnets (van den Berg *et al.* 1996), i.e., layered structures of ferromagnetic films, coupled strongly antiferromagnetically, such that the total moment disappears. The advantage of such a structure as compared to a

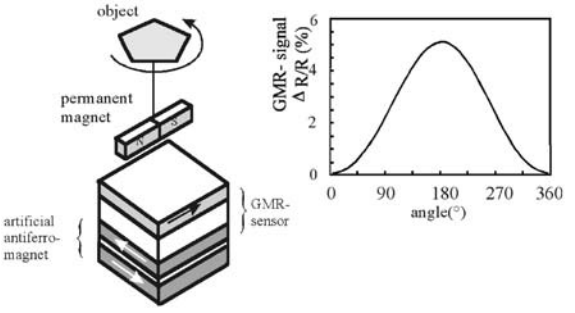

***Figure 7***
Sensor for the measurement of the rotational angle of an object by means of the GMR effect, which makes use of an artificial antiferromagnet on the basis of antiferromagnetic coupling.

natural antiferromagnet is that in this way it is easier to prepare an uncompensated surface with a net magnetic moment. This is of interest in the context of "exchange anisotropy" used for pinning the magnetization unidirectionally. At the surface of a natural antiferromagnet the moment can be largely compensated, due to surface roughness or other irregularities. Artificial antiferromagnets can replace natural ones, for example, in field sensors, where they are used to shift remagnetization curves using the exchange anisotropy effect. The application is displayed in the case of a rotational GMR type sensor in Fig. 7.

## Muon Spin Rotation (μSR): Applications in Magnetism

Following the pioneer work by Gurevich *et al.* in 1972, demonstrating the possibility to use polarized positive muons in the field of metal physics, numerous experiments using the *Muon Spin Rotation/Relaxation* (μSR) technique have been successfully undertaken with special emphasis on the study of magnetic phenomena in matter. Although some experimental and theoretical problems remain to be solved, it is fair to say that the μSR technique became widely recognized as a mature technique able to furnish a complementary point of view when investigating magnetism in matter.

The interest on this novel technique is based on the complementarity between the particular information extracted from the μSR studies and the one obtained from either more classical microscopic techniques (e.g., neutron diffraction, nuclear magnetic resonance (NMR), and Mössbauer spectroscopy) or bulk studies such as specific heat or magnetic susceptibility measurements. The details of the technique itself are extensively discussed in numerous review articles (e.g., Schenck 1985) and correspondingly, several articles provide extensive reviews of the magnetic materials investigated by μSR spectroscopy (e.g., Schenck and Gygax 1995, Dalmas de Réotier and Yaouanc 1997). A concise description of the method can be also found in Cox and Stoneham 1993.

### *1. The μSR Signal—The Basics*

A polarized $\mu^+$ beam is obtained by collecting the muons produced via the two-body decay of positive pions. Due to the zero value of the pion spin, the muon beam is 100% polarized (helicity $-1$) in the pion frame. After the implantation into the sample, the muons are decelerated within 100 ps and come to rest at an interstitial site without any significant loss of polarization. Subsequently, if the $\mu^+$ are subject to magnetic interactions, their polarization becomes time dependent ($\mathbf{P}_\mu(t)$). Due to the weak decay of the muon (average lifetime $\tau_\mu \sim 2.2\,\mu s$), the time

evolution of $\mathbf{P}_\mu(t)$ can be deduced by measuring the distribution as a function of time of the positron emitted after the muon decay (the positron is emitted preferentially along the direction of the decaying muon spin). In the time differential $\mu$SR technique, repeated measurements ($\sim 1 \times 10^7$) are made of the time interval between the $\mu^+$ implantation into the sample and the detection in a particular direction of the emitted positron.

The time histogram of the collected intervals has the form

$$N_{e+}(t) = B + N_0 \mathrm{e}^{-\frac{t}{\tau_\mu}}\left[1 + A\frac{P_\mu(t)}{P_\mu(0)}\right] \quad (1)$$

where the last part of the second term represents the asymmetric positron emission (with typically $A \sim 0.3$). $B$ is a time-independent background, $N_0$ is a normalization constant, and the exponential accounts for the decay of the $\mu^+$. $P_\mu(t)$ is defined as the projection of $\mathbf{P}_\mu(t)$ along the direction of the initial polarization, i.e., $P_\mu(t) = \mathbf{P}_\mu(t) \cdot \mathbf{P}_\mu(0)/P_\mu(0) = G(t)P_\mu(0)$, where $G(t)$ reflects the normalized $\mu^+$ spin auto-correlation function

$$G(t) = \frac{\langle \boldsymbol{S}(t) \cdot \boldsymbol{S}(0) \rangle}{S(0)^2} \quad (2)$$

which depends on the average value, distribution, and time evolution of the internal fields and, therefore, contains all the physics of the magnetic interactions of the $\mu^+$ inside the sample.

Equation (1) can therefore be written as:

$$N_{e+}(t) = B + N_0 \mathrm{e}^{-\frac{t}{\tau_\mu}}[1 + AG(t)] \quad (3)$$

where $AG(t)$ is often called the $\mu$SR signal and the envelop of $G(t)$ is known as the $\mu^+$ depolarization function. In the case of static local magnetic fields ($\mathbf{B}_\mu$) at the $\mu^+$ site, $G(t)$ is given by:

$$G(t) = \int f(\mathbf{B}_\mu)[\cos^2\theta + \sin^2\theta \cos(\gamma_\mu B_\mu t)]\mathrm{d}\mathbf{B}_\mu \quad (4)$$

where $f(\mathbf{B}_\mu)$ is the magnetic field distribution function, $\theta$ is the angle between the local field and $\mathbf{P}_\mu(0)$, $B_\mu = |\mathbf{B}_\mu|$ and $\gamma_\mu/(2\pi) = 13.553879\ (\pm 0.7\,\mathrm{ppm})\,\mathrm{kHzG}^{-1}$ is the gyromagnetic ratio of the muon. Therefore, the careful analysis of the $\mu$SR signal will provide information on the local field distribution at the interstitial site where the muon came at rest.

### *1.1 Transverse-field (TF) Technique—Muon Spin Rotation*

For this technique, an external field $\mathbf{H}_{\mathrm{ext}}$ is applied perpendicular to the initial muon polarization $\mathbf{P}_\mu(0)$. $\mathbf{P}_\mu(t)$ processes around the total field $\mathbf{B}_\mu$ at the muon site, the value of which can be extracted from the oscillatory component of $G(t)$, recalling that the $\mu^+$ frequency $\nu_\mu = \omega/(2\pi) = \gamma_\mu B_\mu/(2\pi)$. In addition to the determination of the muon Knight shift, this technique allows one to gain more insight on the inhomogeneous field distribution at the muon site caused by static fields and on the presence of $1/T_2$ processes responsible for homogeneous line broadening.

### *1.2 Zero-field (ZF) and Longitudinal-field (LF) Techniques—Muon Spin Relaxation*

With the ZF technique one monitors the time evolution of the muon ensemble under the action of internal magnetic fields. This technique is widely utilized to measure the spontaneous $\mu^+$ Larmor frequencies in magnetically ordered phases, providing information about the values of the static moment and the type of magnetic structures. The observation of spontaneous $\mu^+$ frequencies is, however, limited to systems where the presence of static electronic moments produces well-defined local fields at the $\mu^+$ stopping site. Hence, the $\mu^+$ spin autocorrelation function $G(t)$ depends sensitively on details of the magnetic structure and of course on the $\mu^+$ stopping site.

In a ZF experiment, a depolarization can occur due to the presence either of a static distribution of internal fields arising from static nuclear or electronic dipole fields, or of a time dependence of the internal fields at the muon site. This time dependence may arise from a fluctuation of the magnetic moments or from muon diffusion. In contrast, in a LF configuration (i.e., $\mathbf{H}_{\mathrm{ext}} \| \mathbf{P}_\mu(0)$), by choosing $\mathbf{H}_{\mathrm{ext}}$ to be stronger than the internal fields, the muon's states "up" and "down" are eigenstates of the Zeeman Hamiltonian and any inhomogeneous (static) distribution of the internal fields will not affect the time evolution of the $\mu^+$ polarization, which will remain constant. This behavior reflects the decoupling of the $\mu^+$ spin from the static internal fields. Hence, to pinpoint the origin of the depolarization, decoupling experiments in a longitudinal fields are routinely performed.

## *2. Why Muons?*

There are several advantages in using the $\mu$SR technique to study magnetic systems.

(i) Due to the large muon magnetic moment ($\mu_\mu = 8.89\,\mu_{\mathrm{N}}$), the technique is sensitive to extremely small internal fields (down to $\sim 1 \times 10^{-5}\,\mathrm{T}$) and, therefore, can probe local magnetic fields which can be nuclear or electronic in nature.

(ii) The local probe character of the muon makes $\mu$SR very sensitive to spatially inhomogeneous magnetic properties. Hence the occurrence of different phases in the sample will be reflected by different

components in the μSR signal, i.e.,

$$AG(t) = \sum_i A_i G_i(t) \qquad (5)$$

(iii) A careful analysis of the amplitude $A_i$ of these components furnishes a direct measure of the fraction of the sample involved in a particular phase (with the condition $\Sigma_i A_i = A$). Similarly, μSR is a powerful tool when magnetic order is of short range and/or random nature where neutron experiments will fail.

(iv) In addition, the μSR technique can be utilized to check the coexistence of different types of ground states at the microscopic level.

(v) In magnetic phases, the possibility given by μSR to independently extract the value of the ordered static moment and the sample volume involved in the magnetic phase allows one to overcome a shortcoming of other techniques (such as the neutron scattering technique) for which these two parameters are strongly coupled, therefore, hampering their absolute determination.

(vi) Since no applied field is necessary to polarize the spin of the implanted muons, μSR measurements can be made in the absence of a perturbative external field.

(vii) The muon is a spin-$\frac{1}{2}$ particle and consequently is free of quadrupolar interactions. This greatly simplifies the analysis of μSR, with a reduced set of adjustable parameters.

In the following, some exemplary studies illustrating some of the above described advantages of the μSR technique will be briefly discussed.

### 2.1 Small Values of the Ordered Magnetic Moments

The capability of μSR to detect weak static magnetism has been illustrated by the discovery of magnetic ground states in so-called *heavy-fermion* systems that were long considered examples of Fermi-liquid paramagnets. In these systems, composed by local magnetic moments, the competition between the demagnetizing on-site Kondo interaction and the intersite Ruderman–Kittel–Kasuya–Yosida interaction leads to a richness of different ground states (see also *Heavy-fermion Systems*; *Kondo Systems and Heavy Fermions: Transport Phenomena*). An example is the occurrence of itinerant magnetism of the heavy quasiparticles, which is characterized by extremely small static magnetic moments (of the order of $1 \times 10^{-3}\,\mu_B$).

Figure 1 exhibits the depolarization rate of μSR spectra obtained in zero-applied field for the heavy-fermion compound $CeRu_2Si_2$ (Amato *et al.* 1994). Below 2 K, the depolarization rate exhibits a significant increase corresponding to an enhancement of the field spread at the $\mu^+$ site of the order of $2 \times 10^{-5}$ T, which originates from the electronic moments. Considering that the different magnetic structures observed in isostructural compounds with

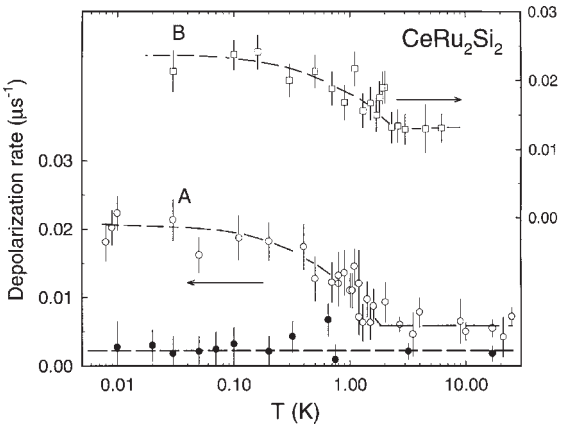

***Figure 1***
Temperature dependence of the ZF (open symbols) and LF ($B_{ext} = 0.6$ T, closed symbols) depolarization rates in $CeRu_2Si_2$ measured in two monocrystalline samples (A and B). The initial $\mu^+$-polarization was along the tetragonal *c*-axis.

light rare earth metals lead to nonzero net dipole field at the $\mu^+$ site, it was concluded that the field distribution with zero average value detected by μSR in $CeRu_2Si_2$ was due to static Ce moments of the order of $\mu_s \sim 1 \times 10^{-3}\,\mu_B$/Ce ordering in a complicated (possibly incommensurate) structure.

### 2.2 Coexisting Phases

In different classes of systems, the question of the coexistence of magnetism and superconductivity has attracted considerable attention. This is, for example, the case for the heavy-fermion compounds where both ground states are found to microscopically coexist for U-based systems and to occur in different domains in Ce-based systems. Such a conclusion was mainly extracted from μSR studies by carefully analyzing the potential presence of different components in the spectra which could reflect the coexistence in a sample of domains with different magnetic properties (muons stopping in different domains will contribute to different components of the signal.)

An interesting example of such studies is provided by the measurements on the heavy-fermion compound $CeCu_2Si_2$ (Feyerherm *et al.* 1997) which, at the opposite of what was concluded from thermodynamic studies only, gave strong evidence *against* a microscopic coexistence of superconductivity and magnetism. The conclusions drawn from the zero-field μSR data are based on the observation of two components in the $\mu^+$ depolarization function (see Fig. 2). One of the components shows a fast relaxation and is associated with magnetic domains developing below $\sim$1.3 K. The other exhibits a slow relaxation

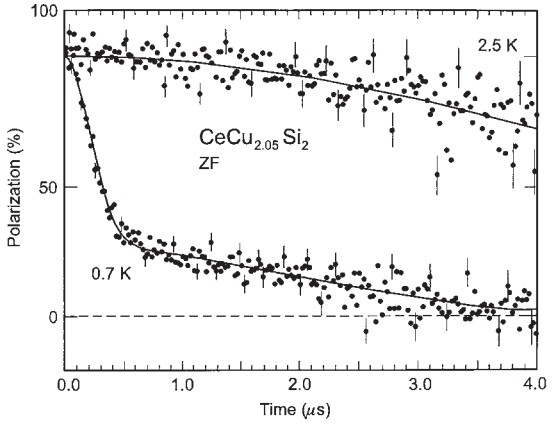

***Figure 2***
Time evolution of the $\mu^+$ polarization measured in zero-field in a $CeCu_{2.05}Si_2$ sample at low temperature. Note the clear two-component structure of the signal measured below 1 K.

and reflects paramagnetic domains which become superconducting below ~0.6 K. Systematic μSR studies have shown that the increase of the magnetic fraction (i.e., the amplitude $A_i$ of the corresponding component of the μSR signal) is strongly sample dependent and that the amount of magnetic phase is closely related to the sample-dependent size of the specific heat jump at the superconducting transition.

### *2.3 Short-range Magnetism*

In the family of the high $T_c$ (and magnetically related) compounds, some significant information was obtained from the μSR technique. In addition to the first indication of magnetic order in several compounds, the μSR technique has played a key role in the elucidation of phase diagrams due to its capability to detect short-range and random magnetism. An example is the studies on $La_2CuO_{4-\delta}$, for which the appearance of magnetism depends on the exact oxygen content (the input of $O^{2-}$ removes electrons and creates holes in the system). Whereas some oxygen deficiency stabilizes the magnetic state, an excess of oxygen suppresses the antiferromagnetic order and eventually leads to superconductivity. Figure 3 shows the spontaneous muon spin precession frequency ($\nu_\mu$) observed in zero field for different samples of $La_2CuO_{4-\delta}$ (Uemura *et al.* 1988). Since $\nu_\mu$ is proportional to the value of the static copper moment ($\mu_s$), the data indicate that $\mu_s$ changes only within ~15% for the different samples despite the large difference in the ordering temperatures (from 15 K to 300 K). This is in contrast to results from neutron scattering on three different monocrystalline samples (see Fig. 4) from which a sublattice

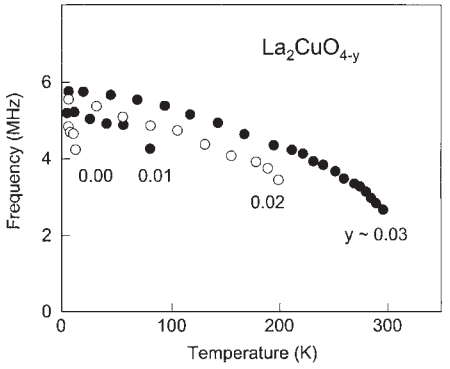

***Figure 3***
Temperature dependence of the spontaneous muon-spin precession frequency in $La_2CuO_{2-y}$ for various $y$ (from Uemura *et al.* 1988).

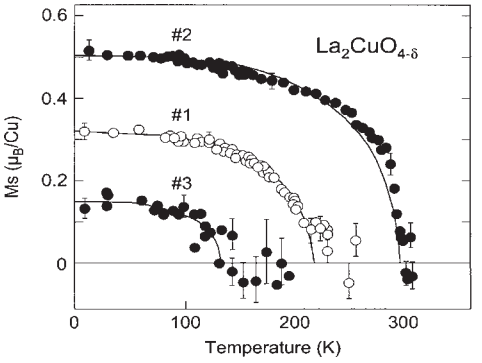

***Figure 4***
Sublattice magnetization derived from the magnetic Bragg-peak intensity of neutron scattering experiments on $La_2CuO_{2-\delta}$ samples with various $\delta$ (see Uemura *et al.* 1988 for details).

magnetization was derived from the intensity of the magnetic Bragg peaks, assuming that the whole volume exhibits long-range magnetism.

The difference between μSR and neutron results can be understood by considering the muon as a point-like probe in *real* space. Therefore, the field at the muon site will be mostly due to its neighboring copper moments, even if the spatial correlation characterizing the magnetic order may be short range. In contrast, the elastic magnetic scattering intensity measured in a neutron scattering experiment will probe the magnetic ordering in *reciprocal* space and will, therefore, only appear when the spatial 3D ordering is long range. It can, therefore, be concluded that the difference between μSR and neutron results is mainly due to a loss of long-range magnetism with increasing oxygen content (i.e., with increasing hole

concentration) introducing frustrations in the magnetic $CuO_2$ planes. Consequently, the value of the static copper moment extracted from the neutron data for samples with low $T_N$ is systematically underestimated due to the reduced fraction of the specimen exhibiting long-range magnetic order.

## 3. Intrinsic Difficulties of the Technique

The analysis of the μSR results can be hampered by several potential difficulties.

- To extract quantitative information, the knowledge of the muon stopping site is usually mandatory. To determine it unambiguously, precise Knight-shift measurements are necessary along the principal crystallographic directions. Therefore, and in addition to the intrinsic difficulties of such measurements, the muon site determination requires single crystals, which might be difficult to obtain for given compounds or alloys.
- Another potential problem is the presence of $\mu^+$ diffusion. Fortunately, observations show that diffusion is usually restricted to high temperatures. Since most aspects of magnetic phenomena occur at low temperature, $\mu^+$ diffusion will usually be of limited concern.
- An intrinsic problem of μSR is the addition of an extra positive charge in the lattice. This leads to a modified local charge distribution, due to the screening of the muon's positive charge, and to a slight lattice relaxation, reflected by a small shift in the position of the nearest neighbor ions. This latter effect can be exactly quantified by a careful comparison between the data and simple theoretical calculations.
- Another, more disturbing, effect of the implantation of a positive charge in the lattice is that the modification of the local charge density can possibly affect the crystal electric field (CEF) of the neighboring atoms (see *Localized 4f and 5f Moments: Magnetism*). In systems based on rare-earth or actinides elements (for which the splitting of the ground state due to CEF is rather small) this effect could lead to a slight change of the atomic magnetic susceptibility for the neighboring ions. It has been shown that this effect can be important for singlet ground-state systems where the splitting between the excited states and the singlet ground state is very low (i.e., $<1$ meV). It is, therefore, of primary importance to compare systematically, in each particular case, the atomic susceptibility sensed by the interstitial muon to the bulk susceptibility, to detect the potential presence of such muon-induced effects.

## 4. Future Developments

### 4.1 Low Energy Muons

Thin films, nanomaterials, and multilayered compounds have emerged as significant elements in science and technology. In response to the need of novel techniques to investigate the magnetic properties of these objects, the development of muon beams with energy in the range of one eV to several keV was needed. In this direction, promising results have been obtained by slowing down energetic muons in appropriate moderators consisting of a thin layer of a van der Waals gas frozen on a substrate (Morenzoni 1997). The availability of epithermal polarized muons, therefore, opens the possibility to extend the μSR technique to the study of thin films and surfaces.

### 4.2 Muon on Request

Another promising evolution of the technique has been the development of a muon on request setup, combining, for the case of time-differential μSR experiments, the advantages of continuous and pulsed muon beams (Abela *et al.* 1999). Although continuous muon beams possess a good time resolution, limited mainly by the design of the detectors, the presence of random background in the positron histograms limits the useful time interval to about 10 μs, excluding investigations of slow relaxation processes. On contrast, pulsed muon beams deliver many muons per pulse at low repetition rate ($\ll 1/\tau_\mu$) essentially without background on the histograms. However, the time resolution for such beams is strongly limited by the finite length of the muon pulses.

A method to solve the background problem at continuous beam is to extract *one* muon at a time out of a continuous beam by means of a fast-switching electrostatic deflector, on request from a μSR instrument. Since the positron histograms obtained are essentially background free, this system opens, due to the high time resolution, the unique possibility of studying slow relaxation phenomena in high magnetic fields.

## Nanocrystalline Materials: Magnetism

It is well known that the microstructure, noticeably the grain size, essentially determines the hysteresis loop of a ferromagnetic material. Figure 1 summarizes the typical variation of the coercivity, $H_c$, over the whole range of structural correlation lengths starting from atomic distances in amorphous alloys over grain sizes, $D$, in the nanometer region up to macroscopic grain sizes. The permeability shows an analogous behavior being essentially inversely proportional to $H_c$. The $1/D$-dependence of coercivity for large grain sizes (Pfeifer and Radeloff 1980) reflects the conventional rule that good soft magnetic properties require very large grains ($D > 100\,\mu m$). Thus, the reduction of particle size to the region of the domain wall width increases $H_c$ towards a maximum controlled by the anisotropies present. Accordingly, fine-particle systems have been mostly discussed as hard magnetic materials (Luborsky 1961). The lowest coercivities, however, are again found for the smallest structural correlation lengths, as in amorphous alloys ("grain size" of the order of atomic distances) and in nanocrystalline alloys for grain sizes $D < 20$nm. The extraordinary $D^6$-dependence of coercivity at small grain sizes, moreover, demonstrates how close soft and hard magnetic behavior actually can be. Indeed, the soft magnetic behavior on which we will focus in this article is only one manifestation of the novel and extraordinary magnetic properties that can be realized by establishing structural features on the nanometer scale. Thus, nanocrystalline microstructures are also of great interest because of their ability to enhance the properties of rare earth hard magnets (Buschow 1997).

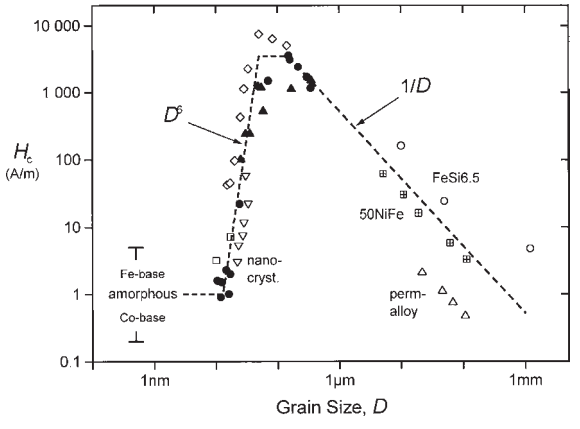

*Figure 1*
Coercivity, $H_c$, vs. grain size, $D$, for various soft magnetic metallic alloys: Fe–Nb–Si–B (▲), Fe–Cu–Nb–Si–B (●), Fe–Cu–V–Si–B (▽), Fe–Zr–B (□), Fe–Co–Zr (◇), NiFe alloys (⊞, △), and Fe–6.5wt.% Si (○).

The decrease of coercivity shown in Fig. 1 for small grain sizes has to be distinguished from superparamagnetic phenomena, i.e., the well-known decrease of coercivity in small, isolated or weakly coupled particles owing to thermal excitation (Kneller 1969, Luborsky 1961). In the present case we deal with small ferromagnetic crystallites well coupled by exchange interaction which results in low coercivity and, unlike superparamagnetic particles, in a simultaneously high permeability.

The most prominent examples of soft magnetic nanocrystalline materials are devitrified glassy Fe–Cu–Nb–Si–B alloys (Yoshizawa *et al.* 1988); further examples are devitrified Fe–(Cu)–Zr–B alloys (Suzuki *et al.* 1991) or Fe–Hf–C thin films (Hasegawa and Saito 1991). The alloy composition originally proposed and subsequently not much changed is $Fe_{73.5}Cu_1Nb_3Si_{13.5}B_9$ and can be considered as a typical FeSiB metallic glass composition with additions of copper and niobium. The material is produced by rapid solidification of an originally amorphous ribbon, typically 20 μm thick, which is subsequently annealed above its crystallization temperature. The resulting microstructure is characterized by randomly oriented, ultrafine grains of b.c.c. Fe–20at.% Si with typical grain sizes of 10–15nm, hereafter referred to as nanocrystalline. The grains are embedded in a residual amorphous matrix which occupies about 20–30% of the volume and separates the crystallites at a distance of about 1–2 nm. The formation of this particular structure is ascribed to the combined effects of copper and niobium (or other group 4 to 6 elements) and their low solubility in b.c.c. iron. Copper promotes the nucleation of the b.c.c. grains, while niobium hinders their growth and at the same time inhibits the formation of boride compounds. The structure and the associated magnetic properties are astonishingly insensitive to the precise annealing conditions over a wide range of annealing temperatures between about 500 °C and 600 °C. Only annealing at higher temperatures leads first to the precipitation of borides and subsequently to grain coarsening, both of which deteriorate the soft magnetic properties (Herzer 1997).

This article reviews the key mechanisms relevant to the soft magnetic properties in the nanocrystalline region. The materials highlighted will be the Fe–Cu–Nb–Si–B alloys which are widely used. They are of particular interest because of their superior soft magnetic properties compared to those of permalloys and cobalt-based amorphous alloys. The general features, however, also apply to other nanocrystalline magnetic materials.

## *1. Magnetocrystalline Anisotropy and Exchange Energy*

The major requirement for superior soft magnetic behavior generally is a low or vanishing magnetocrystalline anisotropy. For example, in b.c.c. Fe–20at.% Si, the constituent phase in nanocrystalline $Fe_{73.5}Cu_1Nb_3Si_{13.5}B_9$, the anisotropy constant is $K_1 \approx 8 kJm^{-3}$, i.e., far too large to explain the low coercivity ($H_c < 1 Am^{-1}$) and high permeability ($\mu_i \approx 10^5$) by itself.

The key to understanding is that the effective anisotropy contribution of the small, randomly oriented b.c.c. grains is essentially reduced by exchange interaction. The critical scale where the exchange energy starts to balance the anisotropy energy is given by:

$$L_0 = \sqrt{A/K_1} \tag{1}$$

where $A$ is the exchange stiffness constant, which is about $L_0 \approx 35$nm for the material parameters of b.c.c. Fe–20at.% Si. $L_0$ represents the minimum length scale over which the direction of the magnetic moments can vary appreciably and, for example, determines the order of the domain wall width. Thus, if the grain size, $D$, is reduced below $L_0$, the magnetization does not follow the randomly oriented easy axis of the individual grains, but increasingly is forced to align parallel by exchange interaction. As a consequence, the effective anisotropy is an average over several grains and, thus, considerably reduced in magnitude.

### *1.1 The Random Anisotropy Model*

The degree to which the magnetocrystalline anisotropy is finally averaged out has been successfully addressed in terms of the so-called random anisotropy model (Herzer 1990), which was originally developed in order to explain the soft magnetic properties of amorphous ferromagnets by Alben *et al.* (1978). The basic idea starts from an assembly of exchange coupled grains of size $D$ and volume fraction $v_{cr}$, with magnetocrystalline anisotropies oriented at random and embedded in an ideally soft ferromagnetic matrix. The effective anisotropy constant, $\langle K \rangle$, relevant to the magnetization process results from averaging over the $N = v_{cr}(L_{ex}/D)^3$ grains within the ferromagnetic correlation volume, $V = L_{ex}^3$, determined by the exchange length, $L_{ex}$, i.e., the scale on which exchange interaction forces the magnetic moments to align parallel. For a finite number, $N$, of grains within the exchange volume, there will be always some easiest direction determined by statistical fluctuations. Thus, the averaged anisotropy energy density, $\langle K \rangle$, is determined by the mean fluctuation amplitude of the anisotropy energy of the $N$ grains:

$$\langle K \rangle \approx \frac{v_{cr} K_1}{\sqrt{N}} = \sqrt{v_{cr}} K_1 (D/L_{ex})^{3/2} \tag{2}$$

As the local magnetocrystalline anisotropies are averaged out this way, the scale on which exchange interaction dominates expands at the same time. Thus, the exchange length, $L_{ex}$, has to be renormalized by substituting $\langle K \rangle$ for $K_1$ in Eqn. (1); i.e., $L_{ex}$ is self-consistently related to the averaged anisotropy by:

$$L_{ex} = \sqrt{A/\langle K \rangle} \tag{3}$$

The combination of Eqns. (2) and (3) then yields for grain sizes smaller than the exchange length:

$$\langle K \rangle \approx v_{cr}^2 K_1 (D/L_0)^6 = v_{cr}^2 D^6 K_1^4 / A^3 \tag{4}$$

The most significant feature predicted by the random anisotropy model is the strong variation of the effective anisotropy, $\langle K \rangle$, with the sixth power of the grain size. Thus, for $D \approx L_0/3$, i.e., grain sizes of the order of 10–15 nm, the magnetocrystalline anisotropy is reduced by three orders of magnitude towards a few joules per cubic meter, i.e., small enough to enable superior soft magnetic behavior. Correspondingly, the renormalized exchange length, $L_{ex}$, expands into the micrometer region and, thus, is almost two orders of magnitude larger than the natural exchange length $L_0$. High-resolution Kerr effect studies of nanocrystalline $Fe_{73.5}Cu_1Nb_3Si_{13.5}B_9$ indeed reveal very wide domain widths of approximately 2 μm (Schäfer *et al.* 1991).

If there are no other anisotropies, coercivity and initial permeability are closely related to $\langle K \rangle$ by:

$$H_c = p_c \frac{\langle K \rangle}{J_s};\ \mu_i = p_\mu \frac{J_s^2}{\mu_0 \langle K \rangle} \tag{5}$$

where $J_s$ is the average saturation magnetization of the material, and $p_c$ and $p_\mu$ are dimensionless prefactors close to unity. These relations, obvious for coherent magnetization rotation, in the region $D \ll L_{ex}$, also apply for domain wall displacements—actually, on the scale of the 10nm small grains the magnetization vector appears to rotate coherently if a 2 μm ($\approx L_{ex}$) wide domain wall passes by.

The predictions of the random anisotropy model provide a good guiding principle through the magnetic properties for grain sizes below about $L_0 \approx$ 40–50nm. Thus, the $D^6$-dependence is well reflected in the coercivity (Fig. 1) and the initial permeability (Herzer 1997).

### *1.2 Remanence Enhancement*

The hysteresis loops for $D < L_0$ typically show an enhanced remanence ($J_r/J_s > 0.90$), which is another very characteristic feature for the dominance of exchange interaction in this small grain size region. Actually, this remanence enhancement by exchange interaction is most attractive for novel, isotropic, nanoscale hard magnets (Buschow 1997). Yet at the smallest grain sizes, when the random anisotropy is

sufficiently washed out, more long-range uniaxial anisotropies take over and the remanence ratio decreases again to values around 0.5. Relevant to this are magnetoelastic and field-induced anisotropies, which limit the benefit of further grain size reduction (dashed horizontal line in Fig. 1 for $D < 10$nm). For further details of remanence enhancement in hard magnetic materials see *Magnets: Remanence-enhanced*.

### *1.3 Grain Coupling*

The crucial role of the exchange interaction for the magnetic softening at $D < L_0$ also becomes most evident from the temperature dependence of the magnetic properties, shown in Fig. 2. Thus, when the temperature approaches the Curie temperature, $T_c$, of the intergranular amorphous phase ($T_c^{am} \sim 200$–$300\,^\circ$C), which is much lower than the $T_c$ of the b.c.c. grains ($T_c \sim 600\,^\circ$C), the exchange coupling between the crystallites is largely reduced. As a consequence, the initial permeability then decreases by almost two orders of magnitude and the coercivity increases correspondingly. Simultaneously the domain structure changes from wide domains to a pattern of small, irregular domains (Schäfer *et al.* 1991).

With increasing measuring temperature the coercivity reaches a maximum and, finally, decreases towards zero. Interestingly, the latter occurs at a temperature (560 °C) below $T_c$ (607 °C) of the b.c.c. grains. This indicates the transition to superparamagnetic behavior, which has been confirmed by a more detailed analysis of Lachowicz and Slawska-Waniewska (1994).

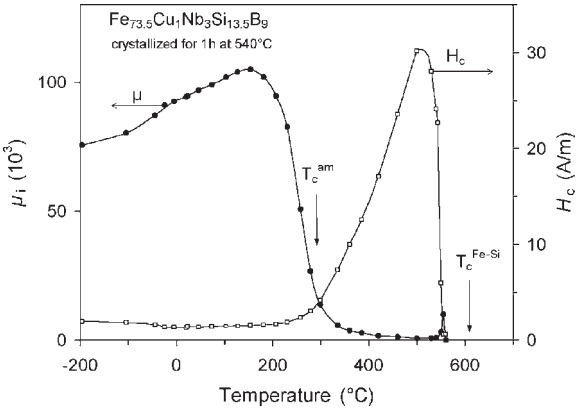

***Figure 2***
Initial permeability, $\mu_i$, and coercivity, $H_c$, of nanocrystalline $Fe_{73.5}Cu_1Nb_3Si_{13.5}B_9$ (annealed 1h at 540 °C + 4h at 350 °C in a transverse magnetic field) vs. measuring temperature (measuring frequency $f = 50$Hz). The arrows indicate the Curie temperatures of the residual amorphous matrix ($T_c^{am} = 291\,^\circ$C) and the b.c.c. grains ($T_c^{FeSi} = 607\,^\circ$C).

Thus, we find within a single sample a variety of phenomena ranging from soft, to hard, to finally superparamagnetic behavior being controlled by the strength of the interaction between the particles.

## *2. Magnetostriction*

Given a vanishing magnetocrystalline anisotropy, the next important requirement for excellent soft magnetic properties is the absence of magnetostriction in order to minimize magnetoelastic anisotropies. Indeed, it is a feature of nanocrystalline iron-based alloys that the phases formed can lead to low or vanishing saturation magnetostriction, $\lambda_s$ (Fig. 3). This is responsible for the increase of initial permeability up to one order of magnitude upon formation of the nanocrystalline state.

The behavior of $\lambda_s$ can be understood from the balance of the magnetostriction among the α-FeSi grains and the residual amorphous matrix:

$$\lambda_s = v_{cr}\lambda_s^{FeSi} + (1 - v_{cr})\lambda_s^{am} \qquad (6)$$

Thus, near-zero magnetostriction in nanocrystalline iron-based alloys requires a large crystalline volume fraction, $v_{cr}$, with negative magnetostriction in order to compensate for the high positive value of the amorphous iron-based matrix. This is achieved either by a high silicon content in the b.c.c. grains ($\lambda_s^{FeSi} \approx -6 \times 10^{-6}$ for $\alpha$-$Fe_{80}Si_{20}$) as in the Fe–Cu–Nb–Si–B system, or if the grains consist of pure α-iron ($\lambda_s^{FeSi} \approx -4 \times 10^{-6}$) as in Fe–(Cu)–Zr–B.

An important point to stress is that this balance of local magnetostriction constants to zero really results in stress-insensitivity of the magnetic properties as,

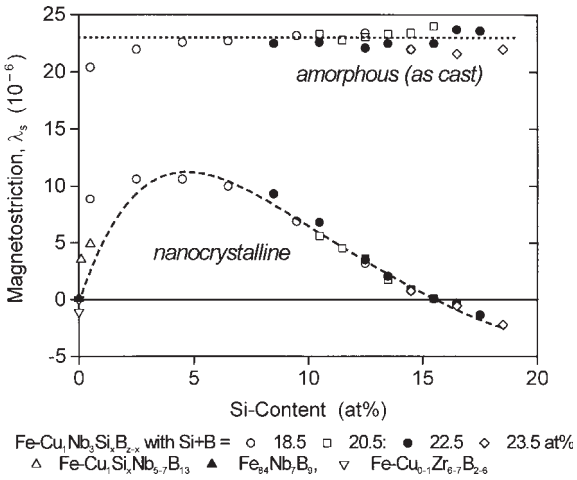

***Figure 3***
Saturation magnetostriction, $\lambda_s$, of Fe–Cu–Nb–Si–B alloys for the amorphous and nanocrystalline state as a function of silicon content.

for example, in Co(Fe)-based amorphous alloys. This is again a consequence of the averaging effect of exchange interaction for structural correlation lengths much smaller than the domain wall width. The situation thus contrasts with that for large-grained crystalline systems, where an average zero saturation magnetostriction does generally not imply stress-insensitivity of the hysteresis loop.

## 3. Applications

Another requirement for soft magnetic materials is that the shape of the hysteresis loop should be able to be varied according to the demands of various applications. Like in other soft magnetic materials, this can be realized in nanocrystalline alloys by magnetic field annealing, which induces an easy axis parallel to the applied field by atomic pair ordering. The resulting almost perfectly shaped loops indicate that the induced anisotropy clearly dominates over the other anisotropy contributions. Still, the anisotropy constant, $K_u$, can be tailored small enough in order to achieve the highest permeabilities (Fig. 4).

The anisotropy is primarily induced in the b.c.c. grains and depends upon the crystalline fraction, the silicon content, and the annealing conditions. In particular, the existence of a $DO_3$ superlattice structure at high silicon contents is the key factor such that $K_u$ is relatively small despite of the high $T_c$. The kinetics of anisotropy formation is significantly slower than in the amorphous state. As a consequence, the nanocrystalline alloys exhibit an excellent thermal stability of their magnetic properties surpassing by far those of amorphous alloys and even permalloys, which allow elevated application temperatures up to about 150 °C (see *Amorphous and Nanocrystalline Materials*).

The electrical resistivity of nanocrystalline materials is around 50 μΩcm for Fe–(Cu)–Zr–B alloys, but as high as 115 μΩcm in the case of Fe–Cu–Nb–Si–B alloys owing to the high silicon content in the b.c.c. grains. Combined with the low ribbon thickness inherent to the production process, this yields a favorable frequency dependence of permeability and low losses even at elevated frequencies, as in amorphous cobalt-based alloys.

The relatively inexpensive base composition (iron) and an established production technique coupled with the extraordinary combination of material properties discussed above means these materials can be used for a wide range of applications, such as magnetic cores for ground-fault interrupters, common mode chokes, and high-frequency transformers.

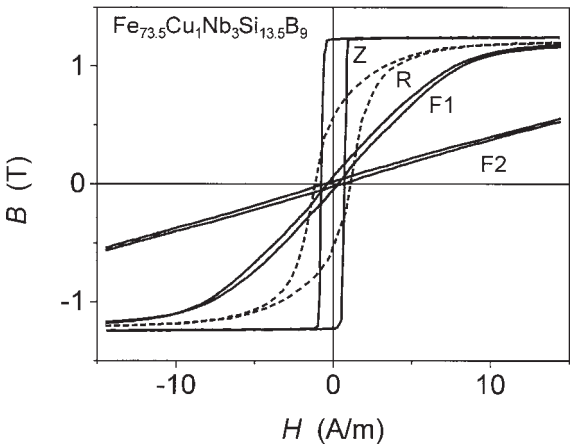

***Figure 4***
DC hysteresis loops of nanocrystalline $Fe_{73.5}Cu_1Nb_3Si_{13.5}B_9$ annealed for 1h at 540 °C without (R) and with a magnetic field applied parallel (Z) and transverse (F2; $K_u = 20 Jm^{-3}$, $\mu = 30 \times 10^3$) to the magnetic path. Sample F1 ($K_u = 6 Jm^{-3}$, $\mu = 100 \times 10^3$) was first crystallized at 540 °C and subsequently transverse field annealed at 350 °C.

# Nanosized Particle Systems, Magnetometry on

New techniques for performing and interpreting magnetization measurements can be used on nanosized particle systems. In this article measurements using magnetometers such as a Faraday balance, SQUID, or vibrating sample magnetometer are considered. Their aim is to obtain information about the magnetic properties of the entire sample but also if possible about the system constituents—the particles. This article will focus on two measurement strategies.

First, the magnetization $M$ ($B = \text{const.}$, $T$) is measured vs. temperature $T$ at a constant external magnetic field $B$. Before the measurement the sample is placed in a (high) magnetic field to "prepare" a well-defined low-temperature magnetic state (LTMS). As an example of LTMS which can be "prepared" in a definite and reproducible way we introduce the new idea of PHFC (positive high-field cooling) which for particles exhibiting magnetic anisoptropy energy opens attractive possibilities for measuring the magnetic moment of the particles and their anisotropy energy. After reaching this LTMS a (weak) magnetic field is applied and the magnetization during the warming up process (field warming = FW) is recorded.

The susceptibility vs. temperature derived from adjacent FW magnetization curves $M(B, T)$ and $M(B + \Delta B, T)$ exhibits a maximum at a temperature determined only by the particles' magnetic moment and the mean field applied, i.e., $B + \Delta B/2$.

The theory of superparamagnetism is applicable after PHFC in the limit of high enough magnetic fields and leads to a simple formula allowing the determination of the magnetic moment of the particles without any calibration of the magnetometer. After the PHFC process the magnetic anisotropy energy influences the starting magnetization for each applied (low) magnetic field differently before the FW measurement.

Second, the magnetization $M(T = \text{const.}, B)$ is measured vs. field at a constant temperature. Before this, the sample must be completely demagnetized. The initial magnetization curve is measured till reaching saturation. Subsequently, the hysteresis loop is measured. A useful criterion for the particle–particle interaction can easily be obtained relating the initial magnetization with the branches of the hysteresis loop.

## 1. Nanosized Single-domain Particles

Every modern textbook on magnetism (e.g., Craik 1995) deals with single-domain particles. The maximum size for such single-domain particles is determined by the so-called magnetic exchange length as summarized by Hernando (1999). From data obtained on popular ferromagnets it follows that this typical length scale is of the order of nanometers. Such nanosized particles considered in this article are of great technical importance because of their wide use in magnetic data storage technology.

### 1.1 Ideal Particle Systems

The properties of ideal particles considered in this article are as follows. All particles are single domain. The magnetization of one particle should (in a first approximation) be temperature independent. This means that the exchange coupling between the atoms inside the particle is very high. The magnetization of a particle will change its direction with respect to the particle body in a homogeneous way (coherent reversal). It will fluctuate like a single magnetic moment with a value of the order of $(10^4–10^5)\mu_B$. The particles do not exhibit any anisotropy energy (no easy axes of magnetization) and there is also no magnetic particle–particle interaction. Additionally it is assumed that the particles are all of the same size, i.e., no size distribution and therefore no distribution of particle magnetic moments. Such particle systems are superparamagnetic. For such particle systems there has for a long time existed a theory for their magnetic properties in thermodynamic equilibrium. Their magnetization will be described by the Langevin function considered later. The calculations presented in this article are performed with such ideal particle properties.

It has been shown that one of the features of real particle systems is that in the limiting case of high enough external magnetic fields this Langevin theory can be used to describe and evaluate their properties from measured magnetization and/or susceptibility curves (Hesse *et al.* 2000).

### 1.2 Stoner–Wohlfarth Particle Systems

A strong improvement in the physical understanding of the magnetic properties of particle systems can be achieved by introducing ideal particles with anisotropy energy, the Stoner–Wohlfarth model (Stoner and Wohlfarth 1948, Hesse *et al.* 2000).

The system may consist of particles with a homogeneous magnetization and a prolate ellipsoid shape. Without an external magnetic field the magnetization will point into the long direction (polar axis) of an ellipsoid of revolution. Both directions along this polar axis are equivalent. This fact is called uniaxial or bidirectional anisotropy (see *Magnetic Anisotropy*). From the shape of the particle there follows a difference in the magnetic stray dipole field energy when the magnetization is pointing parallel to the polar axis or perpendicular to it (see *Magnetic Layers: Anisotropy*). This anisotropy energy is described by the product $KV$ where the constant $K$ is the anisotropy energy density and $V$ is the volume of the particle (Stoner and Wohlfarth 1948, Craik 1995, Hesse *et al*. 2002).

The angle-dependent part of the energy $E$ concerning the particle's magnetization is given by a competition of the anisotropy energy (see *Magnetic Anisotropy*) and the Zeeman energy with maximum values $KV$ and $BM_0V$, respectively. With a magnetic moment of the particle equal to $\mu = M_0V$ ($M_0$ is the saturation value of the magnetization) in the external magnetic field $B$ and a fixed easy direction this energy becomes:

$$E(\alpha,\gamma) = -KV\cos^2(\gamma-\alpha) - M_0VB\cos(\alpha)B_{\text{switch}} = \frac{2K}{M_0}; \qquad \gamma = 0 \tag{1}$$

where $\alpha$ is the angle between the magnetization vector $M$ of the particle and the applied magnetic field $B$, and $\gamma$ represents the angle between the easy direction and $B$ (see also Fig. 2, below). If $0 < B < B_{\text{switch}}$ the energy $E(\alpha,\gamma)$ in Eqn. (1) exhibits two minima where the deeper one corresponds to the parallel orientation of the magnetization vector to the external field. If $B > B_{\text{switch}}$ only one minimum exists and in thermal equilibrium all magnetization vectors point in the field direction. This situation will be used in the PHFC process described later.

### *1.3 Real Particle Systems*

When performing magnetization measurements, experimentalists generally have to deal with real particle systems. Even if these particles satisfy the condition of being single domain, many complicating features in comparison to the ideal particles will appear from the following facts. There will be a distribution of particle sizes. As a consequence the system will exhibit a distribution of magnetic moments and a distribution of particle anisotropy energies. In the case of anisotropy there will be a distribution of easy axis orientations. Additionally, particle–particle interactions can be expected. The magnetization of a particle will not change its orientation by a uniform rotation process but will more or less perform a curling process (Aharony 1966).

All these complications will disturb the picture of an ideal superparamagnet. In real particle systems the magnetization of one particle will depend on temperature (internal particle excitations) which must be considered when the temperatures for magnetization measurements approach the Curie temperature of the particle material.

## *2. Basic Superparamagnetism*

The basic theory of (super)paramagnetism deals with the magnetization $M(B,T)$ of a very large number of identical particles (number density per unit volume $N$) with a magnetic moment $\mu$ measured in the direction of an external magnetic field $B$ in the state of thermodynamic equilibrium at a temperature $T$. For particles with large magnetic moments, the quantization of angular momentum can be neglected and therefore the Langevin function $L(x)$ can be used for describing the system. $M_0$ is the saturation value of the magnetization for $T \to 0$ or $B \to \infty$ and

$$x = \frac{\mu B}{k_{\text{B}}T} \equiv \frac{T_{\text{B-field}}}{T}$$

All relevant formulas are summarized as follows:

$$M(T,B) = M_0L(x);$$
$$M_0 = \mu NL(x) = \coth(x) - \frac{1}{x};$$
$$x = \frac{\mu B}{k_{\text{B}}T} \equiv \frac{T_{\text{B-field}}}{T} \tag{2}$$

In the following examples experiments on real particle systems (described in detail in Hesse *et al*. 2000, 2002) will be presented. The results are compared with calculations based on the Langevin paramagnetism. The parameters assumed for calculations are chosen to be close to the properties of the real particle system. For simplicity the following abbreviations are introduced: in cases where the anisotropy energy $KV$ is in competition with the magnetic energy $\mu B = M_0VB$ we use their temperature equivalents defined as $KV = k_{\text{B}}T_{\text{aniso}}$ and $\mu B = k_{\text{B}}T_{\text{B-field}}$.

## *3. Susceptibility Versus Temperature*

Besides the magnetization, the susceptibility is a very important and informative quantity. If the system in question is in thermodynamic equilibrium at the temperature $T$ in the magnetic field $B$ the susceptibility $\chi$ is a measure of the change of magnetization when we increase the magnetic field by an amount $\Delta B$. In the exact mathematical limit $\Delta B$ must tend to zero. In laboratory practice a finite small $\Delta B$ can be accepted. Then, the susceptibility $\chi_{\text{lab}}$ is obtained. The dimensionless susceptibility is in the case of the

Langevin function describing the paramagnetism accompanied by a susceptibility function $H(x)$. The theory is summarized in the following equations:

$$\chi(T, B = B_{\text{applied}}) = \mu_0 \lim_{\Delta B \to 0} \left[ \frac{M(T, B + \Delta B) - M(B)}{\Delta B} \right]$$

$$\chi(T, B = B_{\text{applied}}) = \mu_0 \left[ \frac{\partial M}{\partial B} \right]_{B = B_{\text{applied}}} = \mu_0 \frac{\mu N}{B}$$

$$\begin{aligned} H(x)H(x) &= x \left\{ \left[ 1 - (\coth x)^2 \right] + \left( \frac{1}{x} \right)^2 \right\} \chi_{\text{lab}} \left( T, B + \frac{\Delta B}{2} \right) \\ &= \mu_0 \left[ \frac{M(T, B + \Delta B) - M(B)}{\Delta B} \right] \\ &\quad \times \chi_{\text{initial}}(T) = \chi(T, B_{\text{applied}} = 0) \\ &= \mu_0 \left[ \frac{\Delta M}{\Delta B} \right]_{B=0} \end{aligned} \tag{3}$$

Considering the course of the susceptibility vs. temperature $T$ (at constant magnetic field $B$) it is obvious that this function exhibits a maximum. This maximum corresponds to a temperature $T_{\max}$. This fact is not well known because for "classic" paramagnets with atomic moments of the order of one Bohr magneton and an external magnetic field of 1 T we expect $T_{\max} = 0.35\,\text{K}$. Kunkel *et al.* (1988) demonstrated the existence of a maximum in experiments on paramagnets exhibiting magnetic moments of the order of 1 $\mu_B$ by performing measurements in high magnetic fields.

The situation changes dramatically if we consider modern nanosized materials with magnetic particles exhibiting moments of the order of $(10^4$–$10^5)\mu_B$. From the properties of the susceptibility function $H(x)$ it follows that

$$1.9 k_B T_{\max} = \mu B \frac{T_{\max}}{[K]} = n \frac{\mu_{\text{Bohr}}}{1.9 k_B} \frac{B}{[T]} = 0.354 n \frac{B}{[T]} \tag{4}$$

where the square brackets [ ] serve to indicate that the units used to measure temperature and field are kelvin and tesla, respectively. The (dimensionless) number of Bohr magnetons is indicated by $n$. For example, if $n = 10^5$ and $B = 1\,\text{mT}$ we find $T_{\max} = 35.4\,\text{K}$. Of course, $T_{\max}$ is proportional to the magnetic field applied. A useful feature of the formula is that it allows the determination of the particles' magnetic moment from $T_{\max}$ without any calibration of the magnetometer.

This simple and valuable law holds for ideal paramagnets, for particles without any anisotropy energy, without interaction, and without any size distribution. Can such a theory be of value for real particle systems, for real experiments? It has been shown (Hesse *et al.* 2000) that in the limit of high applied external magnetic fields the theory of ideal superparamagnets becomes applicable. To achieve this it is necessary to prepare the low-temperature magnetic state (LTMS) of the particle system in a quasiparamagnetic state by the process of positive high-field cooling (PHFC).

## 4. The Positive High-field Cooling Process and the Quasi-paramagnetic Low-temperature State

As mentioned above, the particles considered must be fixed in space. We cool down the sample to low temperatures in an applied field $B > B_{\text{switch}}$ starting from high temperatures. The result is that all magnetic moments are pointing parallel to the external magnetic field (in the positive direction). For the magnetization measurement we lower the field value to $B_{\text{low}} < B_{\text{switch}}$ and start the FW (field warming) process. As a consequence of the PHFC the projections of all magnetic moments show a component in the (positive) field direction.

This way the blocking behavior is eliminated. Heating up this LTMS persists up to rather high temperatures, which exceed the usual blocking temperature due to the stabilization of the magnetic moment direction by the magnetic field. Such LTMS is named the quasiparamagnetic state.

After the PHFC process performing FW magnetization measurements in different $B_{\text{low}}$ magnetic fields the maxima in the susceptibility (Fig. 1) and the particles' anisotropy energy (Fig. 3) become visible. In Fig. 1(a) two calculated magnetization curves $M(B)$ and $M(B + \Delta B)$ vs. temperature are presented. The resulting susceptibility is derived as $\chi_{\text{lab}}$ from the difference $(M(B + \Delta B) - M(B))$ and clearly shows the expected maximum. In the calculation a magnetic moment of $\mu = 10^4 \mu_B$ was assumed, together with $B = 15\,\text{mT}$ and $B + \Delta B = 18\,\text{mT}$ corresponding to values of $T_{\text{B-field}}$ of 100 K and 120 K, respectively. In Fig. 1(b) results of measurements performed on nickel nanoparticles fixed in an aluminum oxide matrix are presented. The susceptibility was derived from adjacent curves of magnetization. One can clearly observe the maximum of the susceptibility and its shift towards higher temperatures with increasing magnetic field. The details are described by Hesse *et al.* 2000).

## 5. Magnetization and Anisotropy

Next it will be shown that the PHFC process offers a rather simple way to measure the particles' magnetic anisotropy energy. For simplicity in the first step it is assumed that the sample is textured. This means that all particles are oriented parallel to each other with respect to their easy axis of magnetization. All the easy axes have the same angle with respect to the magnetic field (Fig. 2). The Stoner–Wohlfarth model is chosen

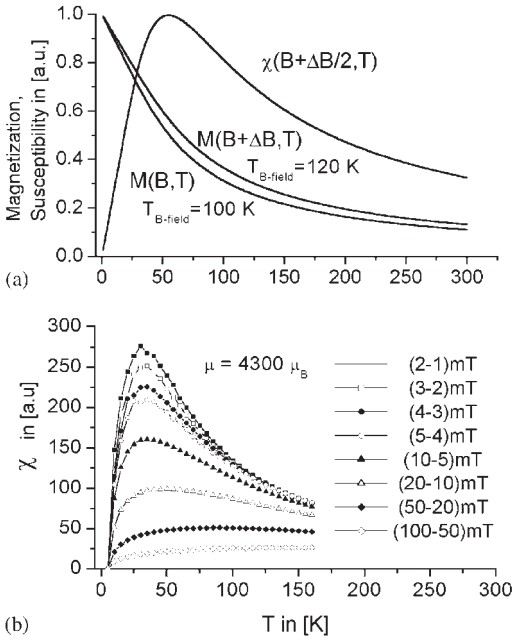

***Figure 1***
(a) Calculated magnetization $M(B)$ and $M(B+\Delta B)$ vs. temperature and the resulting susceptibility exhibiting a maximum. In the calculation a magnetic moment of $\mu = 10^4 \mu_B$ and $B = 15\,\mathrm{mT}$, $B + \Delta B = 18\,\mathrm{mT}$ were assumed corresponding to $T_{B-field}$ of 100 K and 120 K, respectively. (b) The susceptibility $\chi_{Lab}$ derived from FW magnetization measurements after PHFC (presented in Fig. 3) performed on nickel nanoparticles. The field differences used for $\chi_{lab}$ calculations are indicated. The maximum of the susceptibility and its shift with increasing magnetic field towards higher temperatures can be observed. The sample details are described by Hesse *et al*. (2000).

for a more detailed description. If the angle between the applied external magnetic field and the easy axis is $\gamma$, the projection of the magnetization vector at very low temperature along the applied magnetic field (in the quasiparamagnetic state) becomes $M_0 \cos\,\alpha$ (see Fig. 2). In order to calculate the temperature dependence of the magnetization observed in the following FW process intuitive formulae (Eqns. (5)) are proposed. Here a function $L^*(x)$ is used:

$$\begin{aligned} M(B,T) &= N\mu\cos(\alpha) L^*\left(\frac{\mu B_{\mathrm{res}}}{k_B T}\right) B_{\mathrm{res}} \\ &= \sqrt{(B + B_{\mathrm{aniso}}\cos\gamma)^2 + (B_{\mathrm{aniso}}\sin\gamma)^2}\cos\alpha \\ &= \frac{B + B_{\mathrm{aniso}}\cos\gamma}{\sqrt{(B + B_{\mathrm{aniso}}\cos\gamma)^2 + (B_{\mathrm{aniso}}\sin\gamma)^2}}\mu B_{\mathrm{aniso}} \\ &= k_B T_{\mathrm{aniso}} = KV \end{aligned} \tag{5}$$

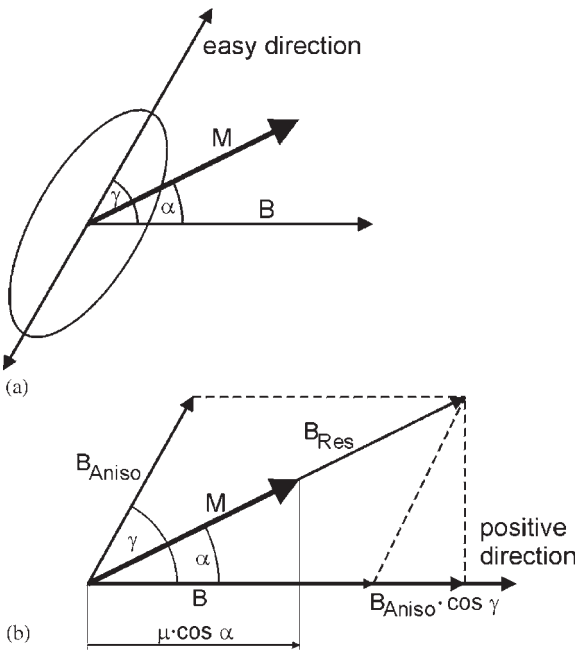

***Figure 2***
The vector model to explain the influence of the anisotropy after the PHFC process in the quasiparamagnetic state. (a) A Stoner–Wohlfarth particle with its easy direction, the external magnetic field $B$, and the equilibrium position of the particle's magnetization vector. (b) Here the anisotropy energy is replaced by an anisotropy field. The resulting magnetic field acting in the direction of the particle's magnetization vector can be calculated using Eqns. (5).

The anisotropy influence (after PHFC) is taken into account by an anisotropy field $B_{\mathrm{aniso}}$. The influence of the anisotropy energy is represented by two factors, the anisotropy field $B_{\mathrm{aniso}}$ and the angle $\gamma$ between the applied external magnetic field and the easy axis. The thermal fluctuation of the magnetization vectors will be described by a Langevin-like function $L^*(x)$ labelled with an asterisk. This asterisk means that this function is not identical to $L(x)$ defined in Eqn. (2). It is necessary to take into consideration thermal fluctuations of the magnetization vector within a limited range of angles due to the confinement of the magnetization vector in the potential minimum caused by the anisotropy energy. In addition, "back jumps" of the magnetization vector into the second energy minimum (where the magnetization vector has a negative component with respect to the applied magnetic field) must be considered.

In Fig. 3(a) calculated magnetization curves are presented using $L(x)$ instead of the analytically unknown $L^*(x)$. The experimental results presented

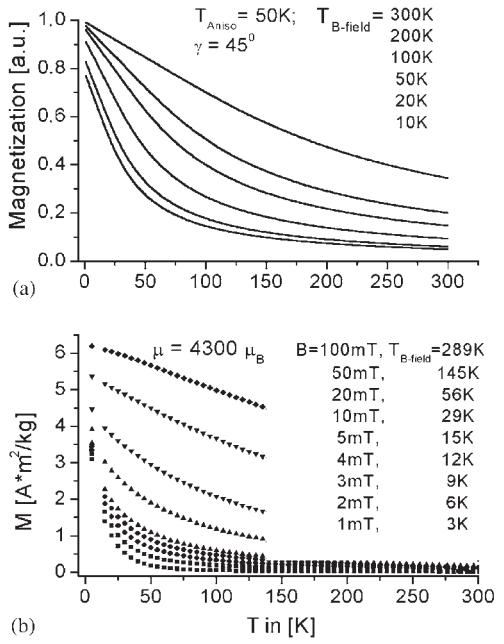

***Figure 3***
(a) Calculated magnetization $M$ versus temperature for a Stoner–Wohlfarth particle system with easy axes oriented at 45° with respect to the magnetic field applied. The field values and the particle anisotropy are given in equivalent temperatures as defined in the text. (b) The FW magnetization measured after PHFC on nickel nanoparticles in the fields indicated. $T_{\mathrm{B-field}}$ also is given calculated for particles with $\mu = 4300\mu_{\mathrm{B}}$. The offsets in the lowest temperature value of the magnetization due to the anisotropy can be observed. The sample details are described by Hesse *et al*. (2000).

in Fig. 3(b) prove the validity of this approach. A Stoner–Wohlfarth particle system with easy axes oriented at 45° with respect to the magnetic field applied was assumed. The field values and the particle anisotropy are given in equivalent temperatures as defined in the text. In the lower part of Fig. 3(b) the magnetization measured on nickel nanoparticles after PHFC in the fields indicated (and their equivalent temperatures) are presented. One can clearly observe offsets in the magnetization values due to the presence of anisotropy. Details are described by Hesse *et al*. 2000).

## 6. *The Hysteresis Loop*

Using the property that a Stoner–Wohlfarth particle has no explicit initial magnetization curve, Thamm and Hesse (1996) proposed an alternative method to the well known Henkel plot (Henkel 1964) in order to study the interactions between single–domain particles. This proposal is justified exactly for particles with uniaxial anisotropy. For such systems it is only necessary to measure first the initial magnetization curve of the completely demagnetized sample and then the hysteresis loop (see *Magnetic Hysteresis*). In an ensemble of a large number of spatially fixed noninteracting particles with uniaxial anisotropy and randomly distributed easy axes, there are always pairs of particles with magnetization vectors in opposite directions. The resulting normalized hysteresis loop of such a pair represents the mean value caused by the summation of the magnetization of each particle. As a consequence an initial curve $m_{\mathrm{IC}}$ will appear which is exactly half of the sum of the upper $m_{\mathrm{UC}}$ and the lower branch $m_{\mathrm{LC}}$:

$$m_{\mathrm{IC}} = \tfrac{1}{2}(m_{\mathrm{LC}} + m_{\mathrm{UC}})\Delta m = m_{\mathrm{IC}} - \tfrac{1}{2}(m_{\mathrm{LC}} + m_{\mathrm{UC}}) \quad (6)$$

$\Delta m$ is zero for noninteracting Stoner–Wohlfarth particles.

A finite value of $\Delta m$ may be caused by interactions between the particles or by the violation of the criteria for Stoner–Wohlfarth particles. An example presenting a measured initial magnetization curve together with the hysteresis loop is given in Fig. 4. The details are

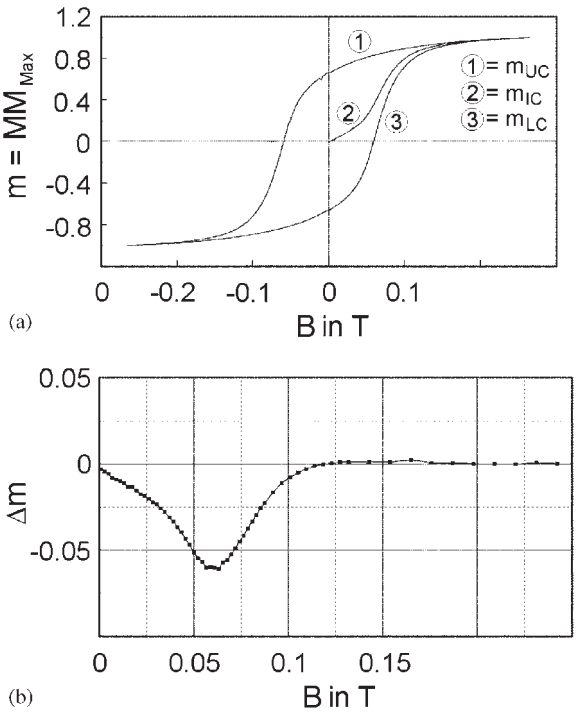

***Figure 4***
(a) Measured (normalized) initial magnetization curve together with the hysteresis loop. (b) The Thamm–Hesse plot as derived from the measurement in the upper part indicating particle–particle interaction.

described by Thamm and Hesse 1998. There is still no general theoretical justification for $\Delta m$ in the case of particles with multiaxial anisotropy energy. Nevertheless a nonzero deviation $\Delta m$ and its dependence on the applied magnetic field $\Delta m(B)$ will bear information about the particle–particle interaction. The dependence of $\Delta m(B)$ can be derived from one measured initial magnetization curve and the hysteresis loop, which is much faster and easier to do than the measurement of the rather popular Henkel plot (Henkel 1964), which hides the field dependence of $\Delta m$.

### 7. Concluding Remarks

Nanosized single-domain magnetic particles open new possibilities in performing and interpreting magnetization measurements. If the particles are fixed in space and exhibit magnetic anisotropy energy it is possible to bring them into a well-defined new low-temperature magnetic state. This can be achieved by the PHFC process. After that the particle's magnetization possesses a component pointing parallel to the applied magnetic field. This LTMS is called quasiparamagnetic. When measuring the magnetization versus temperature in a constant (weak) external magnetic field starting at low temperatures from a quasiparamagnetic state, the susceptibility exhibits a maximum. From the temperature of this maximum a direct determination of the (mean) particle magnetic moment is possible without any calibration. In the magnetization values measured for the LTMS in different (weak) magnetic fields the anisotropy becomes visible and can be determined. This new technique of performing magnetic measurements will enable experimentalists to distinguish between reversible superparamagnetic and irreversible or thermally stable behavior as reported by Chantrell *et al*. (2000).

All measurement procedures and considerations will hold for modern artificially produced arrays of particles or for systems exhibiting self-organized structures as well. Here a large variety of measurement possibilities will appear depending on the direction of the sample with respect to the magnetic field used for the PHFC process.

In the case when the hysteresis loop is measured at constant temperature it is recommended to start the measurement from a completely demagnetized state of the sample. Then the initial magnetization curve must be determined first and subsequently both branches of the hysteresis loop. A simple and useful criterion for the particle–particle interaction can be obtained by plotting the deviation $\Delta m$ vs. applied magnetic field.

## NDT Techniques: Magnetic

Recent years have seen rapid developments in the use of magnetic measurement techniques for materials evaluation. These range from the use of macroscopic hysteresis measurements through microscopic Barkhausen effect measurements down to nanometer scale magnetic force microscopy. Magnetic methods can be used to address two main classes of problems in materials evaluation: detection of defects, and determination of intrinsic properties. It is now one of the fastest-developing fields in materials evaluation due in part to the development of computer models that have made it possible to interpret the results of magnetic measurements in terms of changes in stress or in the structure of materials.

### 1. Macroscopic Scale: Magnetic Hysteresis

On the macroscopic scale, all ferromagnetic materials exhibit hysteresis in the variation of flux density $B$

with magnetic field $H$ (Jiles 1998). The hysteretic properties such as permeability, coercivity, remanence, and hysteresis loss are known to be sensitive to stress, strain, grain size, heat treatment, and the presence of a second phase. In addition, the measurement of hysteresis yields a number of independent parameters, each of which changes to some degree with stress, strain, and microstructure. Since several independent parameters are needed in general to separate effects of stress from microstructure, hysteresis measurements are ideally suited for materials evaluation because the necessary parameters can be obtained from a single measurement.

The effects of elastic stress on hysteresis have been reported by a number of investigators. Stress changes the shape of the hysteresis loop as shown in Fig. 1. However, interpretation of results is difficult without a working model of hysteresis, since none of the direct hysteresis parameters such as coercivity, remanence, initial permeability, or hysteresis loss is uniquely related to a single physical property. It is clear that any model used for interpretation of nondestructive evaluation results such as effects of stress, elastic and plastic strain, creep and fatigue should have as few parameters as is reasonably possible. The stress or strain dependence of these parameters can then be determined. Some success has been achieved with a magneto-mechanical model based on an effective field due to stress (Sablik *et al*. 1993) and this can be used to predict and interpret the magnetic hysteresis properties under stress.

## 2. Microscopic Scale: Barkhausen Effect

On the microscopic scale the magnetic Barkhausen effect (MBE) consists of discontinuous changes in flux density, known as Barkhausen jumps, as shown in Fig. 2. These are caused by sudden irreversible motion of magnetic domain walls when they break away from pinning sites as the magnetic field $H$ changes. There are five mechanisms by which MBE is caused: (i) discontinuous, irreversible domain wall motion; (ii) discontinuous rotation within a domain; (iii) appearance and disappearance of Néel peaks; (iv) inversion of magnetization in single-domain particles; (v) displacement of Bloch or Néel lines in two 180° walls with oppositely directed magnetizations.

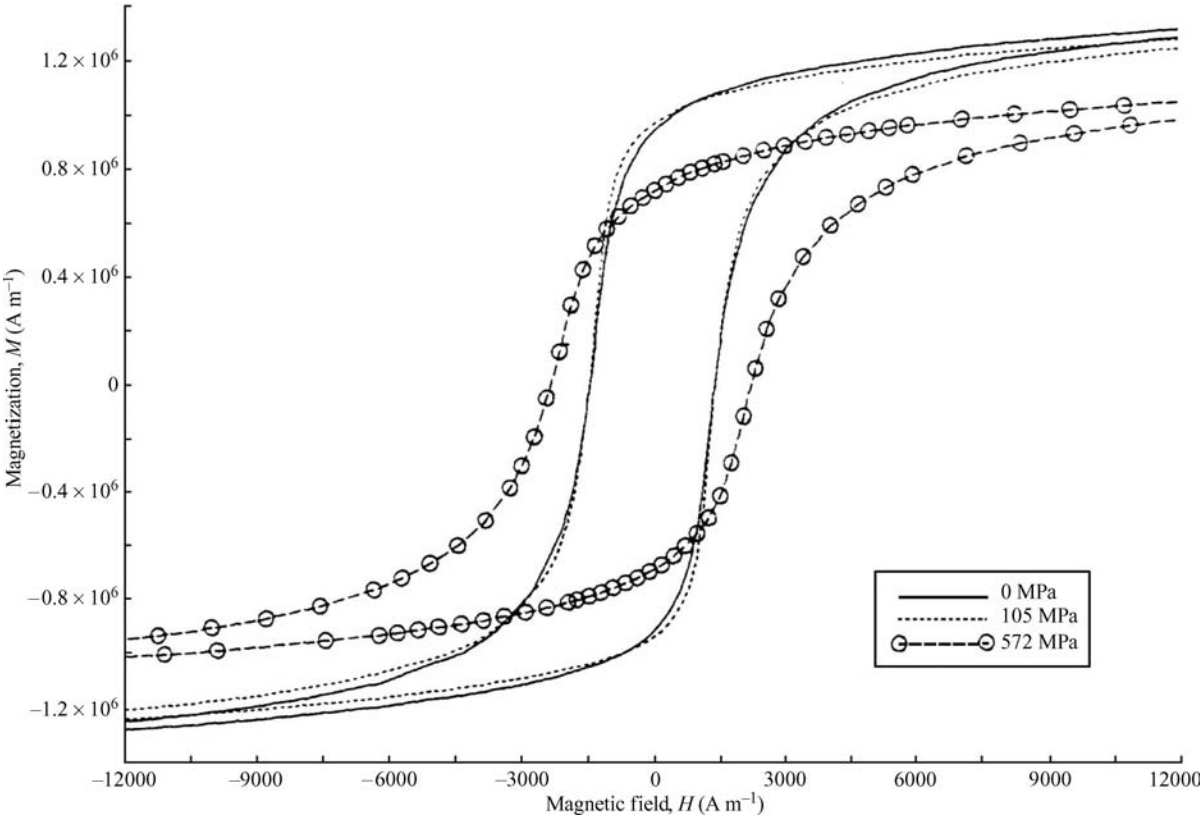

***Figure 1***
Changes in the hysteresis curve caused by stress (after Makar and Tanner 1998).

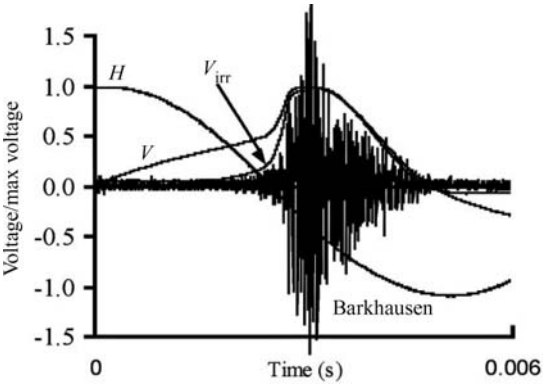

*Figure 2*
Barkhausen signal shown as voltage against time. The time dependence of magnetic field $H$, voltage in flux coil $V$, and envelope of irreversible component of voltage in flux coil $V_{irr}$ are also shown on the same time scale.

The Barkhausen pulse height distribution is dependent on stress and the number density and nature of pinning sites within the material (Mandal *et al.* 1999). The pinning sites are inhomogeneities in the material such as grain boundaries, dislocations, or precipitates of a second phase with different magnetic properties from the matrix material. Most Barkhausen activity occurs close to the coercive field $H_c$. Double peaks in the count rate can occur and the location and size of the peaks can shift as a result of changes in the defect distribution so that two specimens of the same material with different defect distributions have different Barkhausen spectra.

Barkhausen signals are sensitive to stress as shown in Fig. 3. MBE measurements are used for the nondestructive evaluation of stress. All ferromagnetic NDE methods are sensitive to both mechanical stress and the microstructure of the material and therefore, in order to determine stress, it is necessary to use several independent measurement parameters. It has been found that Barkhausen effect, incremental permeability, X-ray diffraction, and hardness measurements were successful in estimating residual stress. Changes in the density of dislocations affect the MBE signals and MBE can be used to distinguish between microstructures, which cannot be distinguished on the basis of optical microscopy.

The effect of fatigue by cyclic loading on the root mean square value of MBE signals has shown that residual strains in unloaded specimens could be identified, although changes occurring under fatigue cycling were complicated so that the Barkhausen signals could not be simply related to the applied load. However, the median Barkhausen pulse amplitude can be used to assess whether the applied stress amplitude is above or below the fatigue limit.

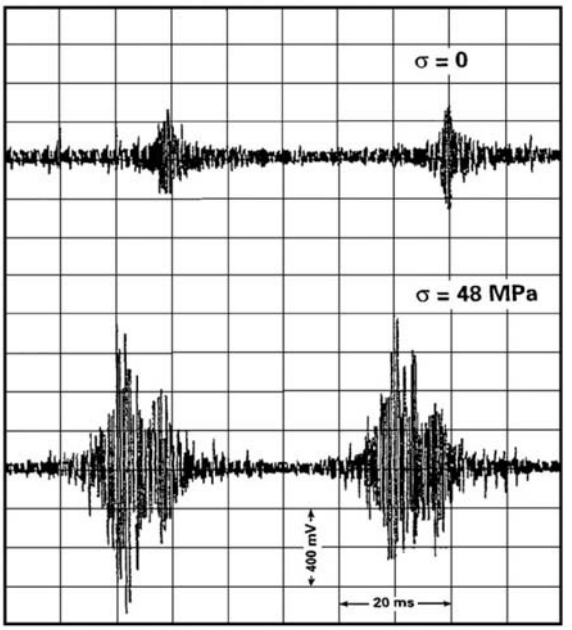

*Figure 3*
Changes in Barkhausen emissions as a result of applied tensile stress.

## 3. Nanoscopic Scale: Magnetic Force Microscopy

In order to evaluate the variation of materials properties from one location to the next, magnetic imaging techniques can be used. For example, the variation of magnetic field strength across the surface of a material can be used to produce a two-dimensional image. This could be used to identify unusual regions of a material, which may have defects or be otherwise damaged, or simply to investigate the spatial variation of magnetization.

The magnetic force microscope samples the magnetic field gradients close to the surface of the specimen over a scanning range of typically 10–100 μm. The method (see *Magnetic Force Microscopy*) is basically a scanning force probe technique detecting magnetic forces between the magnetized tip of the microscope and a test specimen, as shown in Fig. 4. The magnetic force microscope can be used to detect both static and dynamic magnetic fields on the surface of a specimen. In the original device, a spatial resolution of 100 nm was demonstrated. Today, spatial resolutions of 50 nm are routine, and claims of resolutions down to 10 nm are made in some cases (Dahlberg and Proksch 1999). This method is therefore useful for characterizing magnetic materials on length scales from typically 10 nm up to 100 μm.

The image formed as a result of magnetic force microscopy is obtained by measuring the force or the

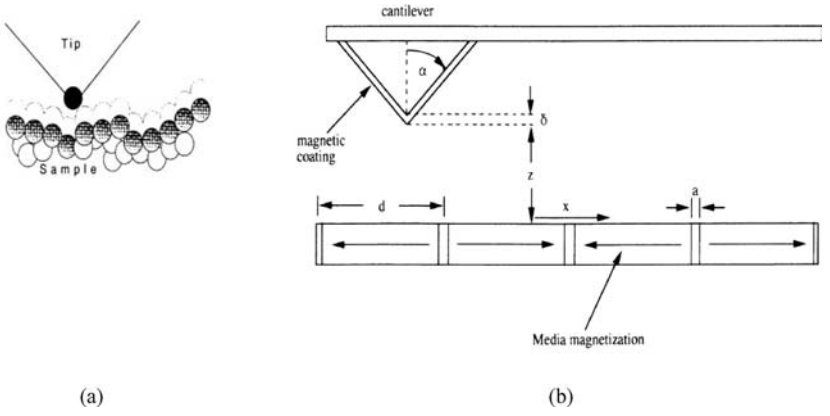

***Figure 4***
(a) Magnetic probe tip scanning over the surface of a material. (b) Schematic of the cantilever arrangement supporting the probe tip.

force gradient. The images formed can be used to study magnetic structures such as domain walls, closure domains, Bloch lines and, in the case of magnetic recording media, intentionally magnetized regions of a material. It is in the area of magnetic recording media that the magnetic force microscope is finding most applications. The ability to resolve features at length scales down to 50 nm, with little or no surface preparation required, and under ambient atmosphere conditions makes this technique ideal for practical high-resolution magnetic evaluation of material surfaces.

### *4. Conclusions*

The increasing demand for characterization of magnetic materials indicates that there will be a continual growth of interest in the available magnetic evaluation methods in the next few years. A variety of magnetic methods for characterization and evaluation of materials is available. Some techniques are designed to determine intrinsic properties of materials and these include the Barkhausen effect for surface characterization and hysteresis measurements for determination of bulk properties. These methods all offer wide scope for future development because of their sensitivity to material treatment, particularly the presence of different material phases, chemical composition and material deformation in its various forms: elastic and plastic strain, fatigue, dislocation density, and creep stress. Another major group of magnetic techniques has been developed to detect and characterize inhomogeneities, including defects, in materials. These techniques include such methods as magnetic particle inspection, magnetic flux leakage determination, and magnetic force microscopy. Magnetic force microscopy, an ultra high-resolution imaging method, can be used to produce an image of the magnetic field at the surface of a test specimen with resolutions down to 10 nm.

## Non-Fermi Liquid Behavior: Quantum Phase Transitions

The Landau theory of Fermi liquids has been very successful in describing even complex metals such as heavy-fermion systems. However, under certain conditions this model is not capable of explaining the observed thermodynamic and transport properties of metals. Several origins of such non-Fermi liquid behavior are possible, e.g., a magnetic instability leading

to a quantum phase transition, or single-ion effects as the multichannel Kondo effect or a distribution of Kondo temperatures.

## 1. Classical and Quantum Phase Transitions

Magnetic phase transitions—like many other types of phase transition (PT)—are usually observed by varying the temperature ($T$) and monitoring changes in thermodynamic quantities like the magnetic susceptibility, the specific heat, or other properties (see *Magnetism in Solids: General Introduction*). Second-order transitions where the first derivatives of the free energy (i.e., the magnetization or entropy) vary continuously are strongly influenced by thermal fluctuations. These fluctuations determine how, at the critical temperature ($T_c$), the system goes from a disordered state for $T > T_c$, to a magnetically ordered state at $T < T_c$. The fluctuations diverge spatially as $T_c$ is approached, as characterized by the correlation length ($\xi \sim |T - T_c|^{-\nu}$) with a critical exponent ($\nu$), and have a typical lifetime given by $\tau \sim \xi^z$, where $z$ is called the dynamical critical exponent.

Renormalization group theory predicts that the static properties near a PT depend only on a few parameters, namely the spatial dimension of the system ($d$), the symmetry of the order parameter (OP), and the range of the interaction leading to magnetic order. These parameters determine the universality class of the system. For magnetic systems, the OP is usually the spontaneous magnetization—for antiferromagnets and incommensurate magnets, the staggered magnetization—which is zero above $T_c$ and acquires a finite value below $T_c$. In many cases, e.g., when the magnetic moments are spatially localized, the symmetry of the OP is described completely by the number ($n$) of its components, i.e., $n = 1$ (Ising model), $n = 2$ (XY model), or $n = 3$ (Heisenberg model).

While the critical behavior of static properties such as the specific heat or magnetization for these examples is entirely determined by the universality classes, the dynamic behavior within a given class may differ depending on $z$. Fluctuations can actually suppress a PT altogether; the easier it is to generate fluctuations (i.e., the larger $n$ is), the more PT is suppressed. A PT to long-range order is only possible above a lower critical dimension ($d_L$) where $d_L = 2$ for $n = 3$, $d_L = 2$ for $n = 2$, and $d_L = 1$ for $n = 1$. (For $n = 2$ and $d = 2$ a special type of PT, the Kosterlitz–Thouless transition, exists.) On the other hand, there is an upper critical dimension ($d_U$) above which fluctuations in local-moment systems are deemed unimportant because they effectively average out (with $d_U = 4$ for a wide range of models). In general, for $d > d_U$, mean field theory (MFT) is sufficient to describe the PT.

In certain cases, $T_c$ can be driven to zero by some external parameter ($\delta$). The picture of a "classical" phase transition (CPT) has to be modified when $T_c$ vanishes at a critical value $\delta_c$. At $T = 0$, only quantum fluctuations are possible—for instance at the transition from a paramagnet to an ordered magnet. For such a quantum phase transition (QPT), the relevant length scales and time scales of these fluctuations are coupled via the uncertainty principle, leading to the time entering as additional $z$ dimensions. Formally, the inverse temperature corresponds to an imaginary time, hence the system acquires its full effective dimensionality ($d_{eff} = d + z$) only at $T = 0$ (Sondhi *et al.* 1997). The added time dimensions drive the system towards mean field behavior, where above $d_{eff} = 4$ only Gaussian fluctuations are observed and genuine critical behavior is absent. However, the static properties in all cases of a QPT are influenced by $z$. This leads to a behavior even at finite $T$ close to $\delta_c$, which is distinctly different from that at a CPT. A particularly interesting QPT is that depicted in Fig. 1 where an itinerant electron system is driven towards (or away from) magnetic order by $\delta$. While far from $\delta_c$, the low-temperature properties of the system can be described in the framework of a Fermi liquid (see *Heavy-Fermion Systems*), unusual "non-Fermi liquid" (NFL) behavior is observed at finite $T$ around $\delta_c$. This QPT has been observed in weakly magnetic transition metal compounds (Sect. 2.2) and in heavy-fermion systems based on rare earths or actinides (Sect. 2.3). On the other hand, NFL behavior in metals does not necessarily arise from proximity to a magnetic instability. Single-ion effects such as the multichannel Kondo effect (Sect. 3.1) or a distribution of Kondo temperatures (Sect. 3.2) may also lead to NFL-like properties.

An example of a QPT in an insulating solid is provided by the dipolar-coupled Ising magnet, e.g., $LiHo_xY_{1-x}F_4$, in a transverse magnetic field (Rosenbaum 1996).

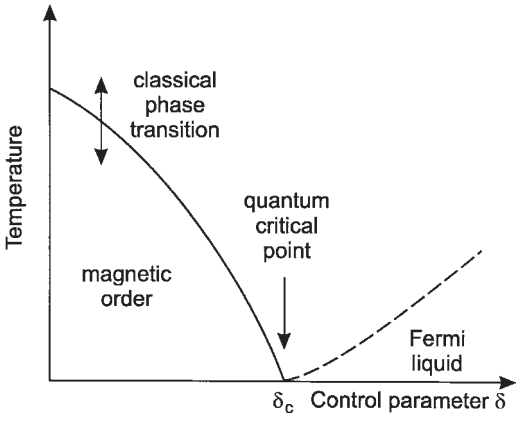

*Figure 1*

## 2. Quantum Phase Transitions and Non-Fermi Liquid Behavior in Metallic Magnets

### 2.1 Fermi Liquids

In a metal, the conduction electrons interact with each other due to their Coulomb repulsion. At the same time, there is a strong correlation by virtue of the Pauli priniciple, which states that two electrons (or, more generally, two indistinguishable fermions, i.e., particles with half-integer spin) cannot be in the same quantum state. Much of the complexity of the interacting system may be captured in terms of the physics of a non-interacting electron gas. For $kT \ll E_F$, the specific heat of a non-interacting electron system is given by $C = \gamma_0 T$ with $\gamma_0 = (\pi^2 k^2/3) N(E_F)$ where $N(E_F)$ is the density of levels at the Fermi energy $E_F$ and $k$ the Boltzmann constant.

The Pauli spin susceptibility is independent of $T$, $\chi_0 = \mu_0 \mu_B^2 N(E_F)$ where $\mu_0 = 4\pi \times 10^{-7}$ Vs/Am and $\mu_B$ is the Bohr magneton. The contribution to the electrical resistivity due to electron–electron (e–e) scattering is given by $\rho_{e-e} = c \times (kT/E_F)^2$ where $c$ is a microscopic scattering cross section.

Assuming a one-to-one correspondence between the excitations of an interacting electron system (termed "quasiparticles") and of the non-interacting electron gas, Landau postulated that the low-$T$ properties for the interacting system obey the same laws as for the Fermi gas, with a renormalized effective mass $m^*$ (with respect to the free-electron mass $m_0$) and a few additional parameters taking account of the residual interactions among the quasiparticles. This special case of an interacting electron system that can be obtained from the non-interacting Fermi gas by adiabatically turning on the interaction, is called a (Landau) Fermi liquid. In such a Fermi liquid (FL), the specific heat is given by $C = \gamma T = (m^*/m_0)\gamma_0 T$, the spin susceptibility by $\chi = \chi_0 (m^*/m_0)(1 + F_0^a)$ where $F_0^a$ is an additional Landau parameter, and the resistivity $\rho_{e-e}$ is again $\sim (kT/E_F)^2$ where $E_F$ may be modified due to the interactions.

### 2.2 Weak Itinerant Magnets

Besides the traditional itinerant magnets like Fe, Co, Ni with rather large Curie temperatures $T_c$ and ordered magnetic moments of the order of $1\mu_B$, there exist a number of intermetallic transition metal compounds and alloys with low $T_c$ and ordered moments of only a small fraction of $1\mu_B$ (see *Itinerant Electron Systems: Magnetism (Ferromagnetism)*). ExaN 1mples of these weak itinerant magnets are MnSi, $ZrZn_2$, and $YMn_2$. In some of these materials, the magnetic order can be suppressed by hydrostatic pressure ($p$) which serves as a control parameter (cf. Fig. 1). Figure 2 shows, as an example, resistivity data for MnSi, which at ambient pressure is an incommensurate magnet with $T_c = 30$ K. Because of the large $2\pi/Q$ ($= 190$ Å), MnSi is often described as an effective ferromagnet (FM).

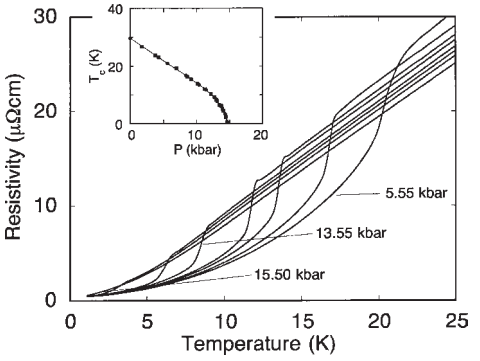

*Figure 2*
Resistivity $\rho(T)$ of MnSi at various pressures $p$. Inset shows the magnetic transitions temperature $T_c(p)$ as obtained from the kink in $\rho(T)$ (adapted by permission of American Physical Society from *Phys. Rev. B*, 1997, **55**, 8330–8).

The onset of magnetic order is seen as a kink in the electrical resistivity $\rho(T)$ (Fig. 2) (Pfleiderer *et al.* 1997). $T_c$ falls monotonically with $p$ and tends to zero at $p_c = 14.6$ kbar, the critical pressure of the magnetic QPT. For $p > p_c$, $\rho(T) = \rho_0 + \beta T^m$ with $m$ between 1.5 and 1.6 is observed over a large $T$ range. This NFL-like behavior ($m < 2$) arises from a long-range interaction between quasiparticles, mediated by overdamped spin fluctuations. Assuming a space- and time-dependent magnetization $\mathbf{m}(\mathbf{r}, t)$, which is treated as a molecular field, the imaginary part of the susceptibility is given by:

$$\chi''(\boldsymbol{q},\ \omega) = \omega \chi_{\boldsymbol{q}} \Gamma_{\boldsymbol{q}} / (\omega^2 + \Gamma_{\boldsymbol{q}}^2) \qquad (1)$$

where $\Gamma_{\mathbf{q}}$ describes the temporal relaxation rate of the Fourier component $\mathbf{m}_{\mathbf{q}}(t)$ of $\mathbf{m}(\mathbf{r}, t)$. For cubic, nearly ferromagnetic materials, $q = |\mathbf{q}|$ and:

$$\Gamma_{\boldsymbol{q}} = \gamma q^n (\chi^{-1} + cq^2) \qquad (2)$$

where $\gamma$ and $c$ are constants, and $\chi$ is the $T$ dependent uniform ($q = 0$) susceptibility.

The case $n = 1$ corresponds to damping by quasiparticles in a homogeneous FL. As the QPT is approached, $\chi^{-1} \to 0$ and $\Gamma_{\mathbf{q}} \sim q^3$, i.e., $z = 3$. Assuming that $\hbar \Gamma_q = kT$, the temperature dependence of $\rho$, varying as $T^m$, is given by $m = (d+2)/z$. This is in fair agreement with the behavior of MnSi. $T_c$ is predicted by this model to vary as $T_c \sim |p - p_c|^{3/4}$, which is consistent with experimental results not too close to $p_c$ (inset of Fig. 2). The stronger dependence of $T_c$ on $|p - p_c|$ in the vicinity of $p_c$ might signal a first-order transition, in which case the fluctuations are cut off.

In an antiferromagnet (AF), the critical fluctuations are not centered at $\mathbf{q} \approx 0$, but at the AF

***Table 1***
Predictions of the QGL model for the temperature dependence of the linear specific-heat coefficient $C/T$ and the electrical resistivity $\rho$ at the QPT.

| | $d=3$ | | $d=2$ | |
|---|---|---|---|---|
| | $z=3$ (FM) | $z=2$ (AF) | $z=3$ (FM) | $z=2$ (AF) |
| $C/T$ | $\sim -\ln(T/T_0)$ | $\sim \gamma - \beta\sqrt{T}$ | $\sim T^{-1/3}$ | $\sim -\ln(T/T_0)$ |
| $\rho$ | $\sim T^{5/3}$ | $\sim T^{3/2}$ | $\sim T^{4/3}$ | $\sim T$ |

wavevector $\mathbf{Q}$, which is of the order of the dimension of the Brillouin zone. Hence:

$$\Gamma_{\mathbf{Q}+\mathbf{q}} = \gamma_{\mathbf{Q}}(\chi_{\mathbf{Q}}{}^{-1} + c'q^2) \tag{3}$$

The exponent $n$ is effectively zero, and hence for $\chi_{\mathbf{Q}}{}^{-1} \to 0$ at the transition, $\Gamma_{\mathbf{Q}+\mathbf{q}} \sim q^2$ is obtained, i.e., $z=2$ leading to $m=d/z$. For the MFT described here, sometimes termed quantum Ginzburg–Landau (QGL) model, it is required that $d+z>4$.

The above description of a QPT involving long-range interactions between quasiparticles (Moriya 1985, Lonzarich and Taillefer 1985, Lonzarich 1997) can also be derived in a more sophisticated renormalization-group treatment (Hertz 1976, Millis 1993). The results for the limiting behavior of $\rho$ and $C$ in the QGL model are listed in Table 1.

There is an additional caveat for AF metals at the QPT. The simple expectation $m=1.5$ ignores the fact that the scattering of quasiparticles by fluctuations occurs only on those parts of the Fermi surface that are connected by $\mathbf{Q}$. However, this scattering may be "short-circuited" by quasiparticles on other parts of the Fermi surface. As was shown by Rosch (1999), an asymptotic FL-like $T^2$ dependence for $T \to 0$ is only obtained for extremely pure samples without impurity scattering. Impure samples yield $m=1.5$, while effective exponents $1 \lesssim m \lesssim 2$ can be obtained in a wide $T$ region for samples of moderate and high purity. The different $T$ dependences are due to the existence of two scattering processes with different $\mathbf{q}$ dependences—strongly anisotropic scattering by magnetic fluctuations and isotropic impurity scattering.

### *2.3 Heavy-fermion Systems*

Heavy-fermion systems (HFS), with an (often) regular sub-lattice of 4*f* or 5*f* atoms, notably Ce, Yb, or U, are close to a magnetic instability giving way to long-range magnetic order arising from the interaction between the 4*f* or 5*f* magnetic moments via the conduction electrons (see *Heavy-fermion Systems*). It is instructive to consider the case of an isolated magnetic impurity in a nonmagnetic metallic host where a strong hybridization between conduction electrons and *f* electrons may lead to a complete screening of the magnetic moment by the former, resulting in a singlet ground state. This can be described by the Kondo Hamiltonian $H=-J\mathbf{Ss}$ where $\mathbf{S}$ is the impurity spin and $\mathbf{s}$ the conduction-electron spin, with an effective antiferromagnetic exchange interaction ($J$) (see *Electron Systems: Strong Correlations*).

At sufficiently low $T$ well below the characteristic Kondo temperature $T_K$, a local FL is formed around the magnetic impurity. In a simplified picture, HFS can be thought of as a lattice-coherent superposition of these local FLs. Hence at low $T$, most HFS can be described within the framework of FL theory with, however, a very large effective mass $m^*$ derived from the huge linear specific heat coefficient ($\gamma := C/T$) and a correspondingly large Pauli susceptibility ($\chi$), both being only weakly dependent on $T$. The contribution $\rho_{\mathrm{el-el}} \sim (T/T_K)^2$ is observable in HFS because $T_K \sim 10\,\mathrm{K}$ is much smaller than $E_F$ in typical metals.

The competition between on-site Kondo interaction quenching the 4*f* or 5*f* localized magnetic moments and intersite Ruderman–Kittel–Kasuya–Yosida (RKKY) interaction between these moments via the conduction electrons allows for nonmagnetic or magnetically ordered ground states in HFS. This competition is governed by a single parameter, namely the effective exchange constant ($J$), which enters the characteristic energy scales $kT_K \sim \exp(-1/N(E_F)J)$ and $kT_{RKKY} \sim J^2 N(E_F)$ for Kondo and RKKY interactions, respectively. The strength of $J$ is usually tuned by composition or pressure. Because of the exponential dependence of $kT_K$ on $J$ (which depends on the hybridization), volume changes are often the dominant effect in producing the magnetic–nonmagnetic transition. The hybridization can of course be strongly affected when alloying with non-isoelectronic ligands.

A large number of investigations have been carried out on HFS close to the magnetic instability. NFL behavior, i.e., deviations from the FL predictions in the low-$T$ thermodynamic and transport properties has been reported for many systems. The main observations in many cases are a specific heat coefficient ($\gamma$) exhibiting a logarithmic $T$ dependence, saturating towards low $T$ in a number of systems, and a $T^m$ dependence of the electrical resistivity ($\rho$) with $m<2$. There are relatively few magnetization studies. The most decisive probe for magnetic fluctuations near a QPT, inelastic neutron scattering (INS), has only been employed for a few systems so far.

Since many of the HFS are driven through the QPT by changing the composition (hence introducing disorder), its effect on the critical behavior is an important issue. One has to distinguish between disorder by dilution of the 4*f* or 5*f* site as, e.g., in $Ce_{1-x}La_xRu_2Si_2$, or by altering the ligand configuration as for example in $CeCu_{6-x}Au_x$. In the first case, a "Kondo hole" introduced by dilution might lead to substantial quasiparticle scattering and ultimate loss of coherence. In the second case, the Ce atoms

experience different local environments and this may lead to different local Kondo temperatures. In $CeCu_{6-x}Au_x$, the QPT was tuned both by composition and pressure, with no difference in the functional $C(T)$ and $\rho(T)$ dependencies. Disorder may, however, play an important role in other systems (Sect. 3.2).

Practically, all HFS systems investigated so far are close to an AF instability (as opposed to a FM instability). A number of systems, notably $Ce_{1-x}La_xRu_2Si_2$, have been compared in detail with the QGL model (Table 1). Long-range AF is introduced into $CeRu_2Si_2$ by moderate La doping and is due to the concomitant lattice expansion. The behavior near the QPT, occurring for $x_c \approx 0.075$, is broadly consistent with expectation, although some differences between INS-derived and specific heat-derived parameters remain (Raymond *et al.* 1997). In $CeCu_{6-x}Au_x$ (the most extensively studied system up to now), the QPT can be tuned by the Au concentration ($x$), again by virtue of a weakening of $J$ upon expansion of the $CeCu_6$ lattice. At the critical concentration $x_c \approx 0.1$, NFL behavior occurs with $\gamma = a \ln(T_0/T)$ over nearly two decades in $T$ (Fig. 3), and $\rho \approx \rho_0 + AT$ between 0.02 K and 0.5 K.

These $T$ dependences can be understood in terms of the spin-fluctuation model when two-dimensional critical fluctuations coupled to quasiparticles with three-dimensional dynamics are assumed. Indeed,

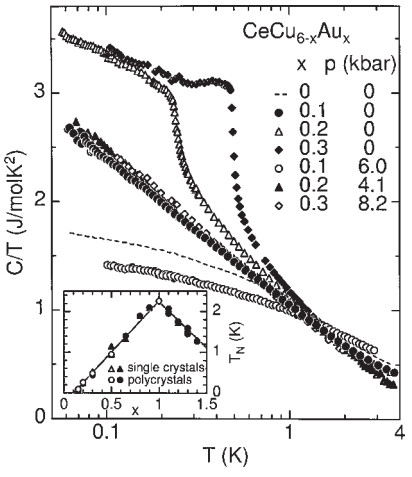

***Figure 3***
Specific heat $C$ of $CeCu_{6-x}Au_x$ plotted as $C/T$ vs. log $T$ for different hydrostatic pressures $p$. Note that when $T_N = 0$, i.e., for $x = 0.3$ at 8.2 kbar and for $x = 0.2$ at 4.1 kbar, the $C/T$ curve falls on the same "universal curve" as for $x = 0.1$ where $T_N = 0$ at ambient pressure. Here a pressure of 6.0 kbar leads to Fermi-liquid behavior $C/T \approx$ const. Dashed line indicates $C/T$ for $CeCu_6$. Inset shows the Néel temperature $T_N$ vs. $x$ at $p = 0$ (reproduced by permission of Elsevier Science from *J. Magn. Magn. Mater.*, 1999, **200**, 532–51).

INS experiments for $x = 0.1$ reveal quasi-one-dimensional features in the dynamical structure factor ($S(\mathbf{q}, E = \text{const.})$) which correspond to quasi-two-dimensional "rods" in real space (Stockert *et al.* 1998). Here the neutron energy transfer was $E = 0.15$ meV. For strictly two-dimensional fluctuations, the system would be at the upper critical dimension since $d_{\text{eff}} = d + z = 4$.

The energy dependence of the critical fluctuations measured at $\mathbf{Q} = (0.8, 0, 0)$ has revealed an anomalous scaling with $E$ and $T$ of the imaginary part of the dynamical susceptibility $\chi''(\mathbf{q}, E, T) = S(\mathbf{q}, E, T) \times (1 - \exp(-E/kT))$ (Schröder *et al.* 1998), i.e., $\chi''(E, T) = T^{-\alpha} g(E/kT)$ with $\alpha = 0.74$ (Fig. 4). The scaling function $g$ is consistent with a simple form of the dynamical susceptibility:

$$\chi(\boldsymbol{q},\ E,\ T) = c(f(\boldsymbol{q}) + (-iE + bT)^{\alpha})^{-1} \qquad (4)$$

where $c$ and $b$ are constants. The anomalous $T$ dependence of the uniform static magnetic susceptibility has initially been described as $\chi(0, 0, T) = \chi_0(1 - BT^{1/2})$ between 0.08 K and 3 K, but can be modeled up to 7 K by $\chi = c'(\chi_0^{-1} + b'T^{\alpha})^{-1}$ with $\alpha = 0.8$ (Schröder *et al.* 1998). The fact that $\alpha$ as obtained from INS for $\mathbf{Q} = (0.8, 0, 0)$ is equal to $\alpha$ ($q = 0$, $E = 0$) may imply that (i) the non local physics is contained in $f(\mathbf{q})$ which vanishes as $\mathbf{q} \to \mathbf{Q}$ where $\mathbf{Q}$ is a critical vector, i.e., belonging to the quasi-one-dimensional features of $S(\mathbf{q}, E = \text{const})$, and (ii) the anomalous scaling exponent is a local property since it appears to be independent of $\mathbf{q}$. This "local" behavior is, however, different from a simple local Lorentzian fluctuation spectrum that would be described by $\alpha = 1$.

The QPT in $CeCu_{6-x}Au_x$ has not only been tuned by $x$ but also by pressure. Fig. 3 shows that samples with $x > x_c$ can be driven to the QPT, i.e., $T_N = 0$ by appropriate hydrostatic pressure ($p$). Near the QPT, $C$

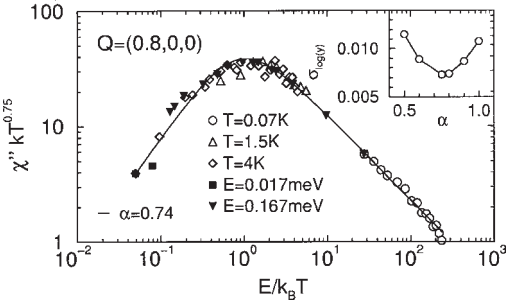

***Figure 4***
Scaling plot inelastic neutron-scattering data for $CeCu_{5.9}Au_{0.1}$ at $q = (0.8, 0, 0)$ vs. $E/k_BT$. The inset shows how the quality of the scaling collapse varies with $\alpha$ in Eqn. (5). Solid line in the main part corresponds to a fit with $\alpha = 0.74$ (reproduced by permission of American Physical Society from *Phys. Rev. Lett.*, 1998, **80**, 5623–6).

is identical for all samples. Likewise, the sample with $x = 0.1$ can be driven by $p$ away from the QPT towards FL behavior $C/T \approx$ const. approximately followed by pure $CeCu_6$. The linear $T_N(p)$ and $T_N(x)$ dependencies are in agreement with the scenario of two-dimensional fluctuations. The detailed mechanism of how local moments and long-range fluc tuations work together to produce the unique quantum-critical behavior of $CeCu_{6-x}Au_x$ has yet to be disentangled.

Tuning of the QPT in the related system $CeCu_{6-x}Ag_x$ by a magnetic field has been inferred from $C$ and $\rho$ (Heuser *et al.* 1998) with $T$ dependencies compatible with the QGL scenario with $d = 3$ and $z = 2$ (Table 1), although this scenario does not include a magnetic field.

A number of stoichiometric HFS where the QPT can be tuned by pressure have also been investigated, e.g., $CeCu_2Si_2$ with its intriguing—but not yet fully understood—interplay between superconductivity (SC) and magnetism (see *Heavy-fermion Systems*). A particularly interesting case is $CePd_2Si_2$ (Fig. 5), which in a small $p$ range where $T_N$ is suppressed to zero, exhibits SC below a large $T$-range of NFL behavior (Mathur *et al.* 1998). Analogous behavior was found for $CeIn_3$. This is suggestive of spin-fluctuation mediated SC. Up to now, however, only resistivity measurements have been reported, and the detailed interplay between superconductivity and AF order is not yet known. Even more intriguing is the recent observation of superconductivity in ferromagnetic $UGe_2$ (Saxena *et al.* 2000).

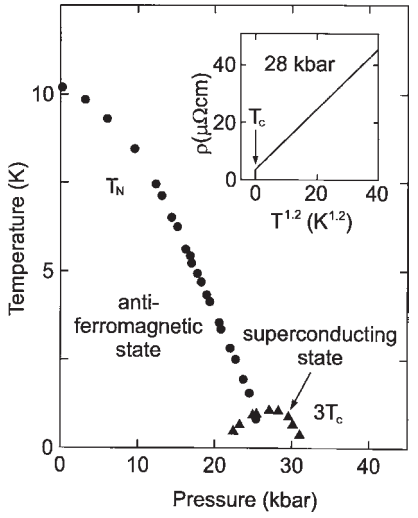

***Figure 5***
Temperature–pressure phase diagram of a high-purity $CePd_2Si_2$ single crystal. Superconductivity appears below $T_c$ in a narrow window where the Néel temperature $T_N$ tends to absolute zero. For clarity, the values of $T_c$ have been scaled by a factor of three, and the origin of the inset has been set at 5 K below absolute zero. The inset shows that the resistivity $\rho$ exhibits a $T^{1.2}$ dependence on temperature over a wide $T$ range (reproduced by permission of Macmillan from *Nature*, 1998, **394**, 39–43).

## 3. Non-Fermi Liquid Behavior due to Single-ion Effects

### 3.1 Multichannel Kondo Effect

Perfect screening of the magnetic moment via the Kondo effect leads to a local FL around a magnetic impurity in a metal. In general, however, several conduction-electron channels ($N$) may be present and the Kondo Hamiltonian reads $H = \Sigma_{\alpha=1}^{N} J_\alpha \mathbf{S}\mathbf{s}^\alpha$, where $\alpha$ is the channel index (Schlottmann and Sacramento 1993). For $N < 2S$, the screening is not complete; $N = 2S$ leads to perfect screening for $T \to 0$. In the case of degenerate channels, $J_\alpha = J$ for all $\alpha$, the impurity spin will be overscreened if $N > 2S$.

For the special case $S = 1/2$ and $N = 2$, NFL behavior is predicted with $C/T \sim \chi \sim -\ln(T/T_K)$ and $\rho \sim 1 - (T/T_K)^{1/2}$ for $T \to 0$. Up to now, the experimental evidence for NFL behavior by overscreening of the magnetic moment of an impurity has been scarce.

In a more general sense, the Kondo effect may also pertain to orbital degrees of freedom of an impurity acting as a pseudospin instead of the spin. This is discussed for the interaction of conduction electrons with tunneling states, first in amorphous metals and later in metallic nanoconstrictions (van Delft *et al.* 1998). In these cases, the two channels are provided by the spectator spin of the conduction electrons. For certain rare-earth and actinide metals, a quadrupolar Kondo effect (QKE) has been considered (Cox and Jarrell 1996), where the pseudospin of the impurity is the quadrupolar moment arising from the aspherical charge distribution of the 4*f* or 5*f* electrons.

Again, the two channels are provided by the spin degeneracy of the conduction electrons. Indeed, the NFL anomalies as first reported for $U_{0.2}Y_{0.8}Pd_3$ (Seaman *et al.* 1991) were suggested to arise from the QKE. Here, NFL anomalies persist to rather dilute U alloys (Maple *et al.* 1995), thus favoring the single-ion QKE model. On the other hand, the NFL behavior might be due to an AF instability (Andraka and Tsvelik 1991), supported by long-range AF order in $U_{0.4}Y_{0.6}Pd_3$. In addition, a divergence of the quadrupolar susceptibility for $T \to 0$ as predicted for the QKE scenario was not found. Hence the situation for $U_xY_{1-x}Pd_3$ is not clear.

The clearest signature of a QKE is found in $U_{1-x}Th_xBe_{13}$ (Aliev *et al.* 1996). In $U_{1-x}Th_xPd_2Al_3$, single-ion scaling of NFL properties compatible with the QKE is observed, while $U_{1-x}Y_xPd_2Al_3$ exhibits

signatures of a magnetic instability around $x_c = 0.7$ whence the NFL properties in this case might be due to a QPT (Maple *et al*. 1999).

### 3.2 Distribution of Kondo Temperatures

Features of NFL behavior may arise from a quite different single-ion scenario, i.e., a distribution of Kondo temperatures ($P(T_K)$) in disordered systems. Fluctuations in $J$ or the local $N(E_F)$ near a disorder-induced metal–insulator transition may lead to a wide distribution of $P(T_K)$. Indeed, the specific heat of heavily doped Si:P on the metallic side of the transition shows a contribution $\Delta C \sim T^{\alpha}$ with $\alpha \approx 0.2$, which is attributed to $P(T_K)$ (Lakner *et al*. 1994). Here the local moments arise from the statistical distribution of P donor atoms in the single crystalline host, with a distribution of hybridization strengths to the conduction electrons and hence of $J$. In the case of heavy-fermion solid solutions, the statistical distribution of atoms may lead to a distribution of $T_K$, as first put forward for the case of $UCu_{5-x}Pd_x$ ($x = 1$ and 1.5) on the basis of NMR measurements which directly showed a distribution of Knight shifts, viz., Kondo temperatures (Bernal *et al*. 1996). Even for a rather narrow distribution of $J$ and/or $N(E_F)$, a broad $P(T_K)$ with a finite value for $T_K \to 0$ may occur because of the exponential dependence of $T_K$ on $J$ and $N(E_F)$.

On the other hand, an interesting single-ion NFL scaling was found in the dynamic structure factor $S(q, \omega)$ determined from INS (Aronson *et al*. 1995). This system is also at the verge of a magnetic instability as evident from spin-glass behavior at the lowest temperatures (Vollmer *et al*. 1997). A model combining the proximity to a magnetic instability and disorder, the so-called Griffiths phase model, has been tested for a number of U systems (de Andrade *et al*. 1998).

# Nonlinear Magneto-optics

Just as linear magneto-optics describes the interaction of polarized light with magnetic (or magnetized) materials, nonlinear magneto-optics describes their nonlinear optical response. Physically, magneto-optical (MO) effects are related to the breaking of the time-reversal operation (see *Faraday and Kerr Rotation: Phenomenological Theory*). This leads to well-known phenomena such as the Faraday effect and magnetic circular dichroism in transmission and the magneto-optical Kerr effect (MOKE) in reflection. Similarly, nonlinear MO effects are related to a combination of time-reversal symmetry breaking with the breaking of space-inversion symmetry (at least within the electric dipole approximation).

The Faraday and Kerr effects have been known for over a century. However, the field of nonlinear magneto-optics started much more recently with the prediction (Pan *et al.* 1989) of magnetization-induced contributions to the nonlinear optical response of magnetic surfaces and interfaces. This was followed by experimental observation of such effects by Reif *et al.* (1991) for an Fe surface and by Spierings *et al.* (1993) for Au/Co interfaces. (Actually, first predictions of possible nonlinear MO effects were already published as early as 1967 by Lajzerowicz and Vallade (1967) for antiferromagnetic materials and by Akhemiev *et al.* (1985) for magnetic crystals. The ''revival'' and recent strong development of nonlinear magneto-optics is clearly related to the enormous interest in the study and applications of magnetic multilayers and nanostructures and by the development of solid state mode-locked femto second lasers that are particularly suitable for these kinds of studies (Rasing 1998).

Apart from the nonlinear optical equivalents of the Faraday and Kerr effects, the higher order optical response also leads to new nonlinear MO phenomena that have no equivalence in linear magneto-optics, e.g., transverse Faraday and Kerr effects that are linear in magnetization (Pavlov *et al.* 1997, Wierenga *et al.* 1995), the breaking of the equivalence between magnetization reversal, the change of light helicity (Kirilyuk *et al.* 2000b), and the sensitivity for antiferromagnetic ordering (Fiebig *et al.* 1995).

## 1. Theory

An incident electromagnetic wave can induce a polarization in a medium that serves as a source for the transmitted and reflected light. This polarization **P** can be written in the electric dipole approximation as an expansion in powers of the electric field $\mathbf{E}(\omega)$ of the incident wave:

$$P_i = \chi^{(1)}_{ij} E_j\,(\omega) + \chi^{(2)}_{ijk} E_j\,(\omega) E_k\,(\omega) + \cdots \qquad (1)$$

The tensor $\chi^{(1)}$ is the linear optical susceptibility, leading to the linear reflection and refraction of light. The second term describes nonlinear optical effects such as *second harmonic generation*. In the presence of a magnetization **M** both $\chi^{(1)}$ and $\chi^{(2)}$ should be further expanded in powers of **M**:

$$\chi^{(1)} = \chi^{(1)}_0 + \frac{\delta\chi^{(1)}}{\delta\mathbf{M}}\,\mathbf{M} + \cdots \qquad (2a)$$

$$\chi^{(2)} = \chi^{(2)}_0 + \frac{\delta\chi^{(2)}}{\delta\mathbf{M}}\,\mathbf{M} + \cdots \qquad (2b)$$

The first term in both Eqns 2(a) and 2(b) could be thought of as describing purely crystallographic effects while the second one only exists in the presence of magnetization. In principle in both cases the magnetic contribution is described by a higher rank tensor; in practice these magnetic contributions can be written as effective $\chi^{(1)}$ and $\chi^{(2)}$ components, respectively. For example, a nonzero magnetization along the $\hat{z}$-axis of an optically isotropic material yield nonzero components $\chi^{(1)}_{xy} = -\chi^{(1)}_{xy}$ that lead to linear MO effects that are proportional to the ratio $\chi^{(1)}_{xy}/\chi^{(1)}_{zz}$.

The crystallographic nonlinear optical tensor $\chi^{(2)}$ is only nonzero in media without inversion symmetry. Consequently, for isotropic media, $\chi^{(2)}$ only gives a contribution from surfaces and interfaces where the inversion symmetry is broken. The presence of a magnetization does not affect the inversion symmetry (as **M** is an axial vector) but does lower the symmetry of $\chi^{(2)}$ and consequently leads to new nonzero, nonlinear susceptibility components. These elements can be derived in a straightforward way and are summarized in Table 1 for the standard longitudinal, transversal, and polar MO configurations (Rasing 1998).

From Table 1, the effects of magnetization-induced second harmonic generation (MSHG) can directly be understood. For example, in the longitudinal configuration, an *s*-polarized (parallel to y) input

***Table 1***
The nonzero $\chi^{(2)}$ components for the longitudinal ($\mathbf{M}\|x$), transversal ($\mathbf{M}\|y$), and polar ($\mathbf{M}\|z$) MO configurations ($xz$ is the plane of incidence). For convenience, only the indices are indicated. The odd components are indicated in bold.

| | $P_{in}$ | $S_{in}$ | |
|---|---|---|---|
| $\mathbf{M}\|x$ | xxz, zxx, zzz | zyy | $P_{out}$ |
| | **yxx**, **yzz** | **yyy** | $S_{out}$ |
| $\mathbf{M}\|y$ | xzx, zxx, zzz, **xxx**, **xzz**, **zzx** | zyy, **xyy** | $P_{out}$ |
| | | | $S_{out}$ |
| $\mathbf{M}\|z$ | xxz, zxx, zzz | zyy | $P_{out}$ |
| | **yzx** | | $S_{out}$ |

beam will give rise to one even component ($\chi^{(2)}_{zyy}$) and one odd component ($\chi^{(2)}_{yyy}$). The even term will yield a *p*-polarized and the odd term an *s*-polarized field, respectively. Thus, the output polarization can be varied by changing the direction of **M**, yielding a nonlinear Kerr rotation $\theta_k^{(2)} \sim \arctan(\chi^{(2)}_{yyy}/\chi^{(2)}_{zyy})$ in the same way as in linear magneto-optics, but with values for $\theta_k^{(2)}$ that are three orders of magnitude larger than the linear equivalent (Koopmans *et al.* 1995). Similarly, it follows from Table 1 that in the transverse geometry both *s*- and *p*-polarized input beams will always generate a *p*-polarized output. Consequently, as in linear MOKE, there is no nonlinear Kerr rotation. However, in contrast to the linear case, there is a strong magnetization-induced intensity change, that is *linear* in the magnetization.

Table 1 shows another important difference between the linear and the nonlinear MO effects. Whereas in both cases the MO effects are proportional to a ratio between odd and even tensor components, in the linear case the odd components are small off-diagonal elements. In the nonlinear case the odd components are of a similar type as the even ones (compare the components in Table 1). This fact, which is also supported by calculations of $\chi^{(2)}$ based on spin-dependent band structure (Hübner and Benneman 1989) is responsible for the very strong nonlinear MO effects that have been observed in various experiments and that are typically three orders of magnitude larger than the linear equivalents.

The relation between the nonlinear MO susceptibility and the spin-dependent band structure can be written as:

$$\chi^{(2)}_{ijk}(2\omega) \propto \sum_{a,b,c} \frac{\langle a|i|c\rangle\langle c|j|b\rangle\langle b|k|a\rangle}{(2\hbar\omega - E_{ca} + i\hbar\Gamma_{ca})(\hbar\omega - E_{ba} + i\hbar\Gamma_{ba})} \quad (3)$$

Equation (3) shows that spectroscopic MSHG experiments in principle allow the probing of the spin-dependent surface or interface density of electronic states which is not only of fundamental interest but also highly relevant for the understanding of spin-dependent tunneling processes in magnetic tunnel junctions (de Boer *et al.* 1998).

All the effects so far have been described within the electric dipole approximation only. An extension to include higher order contributions to the nonlinear MO response can be found in Rasing (1998), whereas the application of magnetization-induced sum frequency generation can be found in Kirilyuk *et al.* (2000a).

## 2. *Experimental Considerations*

For each polarization combination, the total MSHG response from a magnetic material can be simplified by

$$\mathbf{P}(2\omega, \pm M) = (\chi^{even}_{eff}(\pm\mathbf{M}) \pm \chi^{odd}_{eff}(\pm M))E^2_{\omega} \quad (4)$$

where $\chi^{even}_{eff}$ and $\chi^{odd}_{eff}$ are effective tensor components that are even and odd in the magnetization and describe the crystallographic and magnetic contributions to the total response, respectively. As both these contributions are complex quantities, the total (MSHG) signal is thus given by

$$I(2\omega) \sim |\chi^{even}_{eff}|^2 + |\chi^{odd}_{eff}|^2 \pm 2|\chi^{odd}_{eff}||\chi^{odd}_{eff}|\cos\Delta\Phi \quad (5)$$

where $\Delta\Phi$ is the phase difference between the two contributions. The importance of the latter is obvious: when $\Delta\Phi = \Pi/2$, the interference term is zero and changing the magnetization direction will have no effect on the total MSHG signal.

Though generally phase information is lost in intensity measurements, fortunately $\Delta\Phi$ can be measured quite easily in nonlinear optics by using interference techniques (Stolle *et al.* 1997). The latter can also be exploited in the case where there is only a purely odd response by adding a nonmagnetic reference signal, as it is the interference between even and odd terms that gives rise to the nonlinear MO effects.

Though MSHG signals give large relative MO effects, being a nonlinear optical technique the absolute intensities are rather small ($10$–$10^4$ photons $\mathrm{sec}^{-1}$). However, they are easily detectable with modern photon counting or charge coupled devices (CCD), though care should be taken to filter out the two signal versus the much stronger fundamental signal at $\omega$ (see Fig. 1).

Because of the simplicity of the experimental configuration coupled with the large effects, the transverse geometry is often used for experimental studies. One can then define a magnetic contrast or asymmetry as:

$$A = \frac{I(2\omega, +\mathbf{M}) - I(2\omega, -\mathbf{M})}{I(2\omega, +\mathbf{M}) + I(2\omega, -\mathbf{M})} \quad (6a)$$

$$= \frac{2|\chi^{odd}_{eff}|/|\chi^{even}_{eff}|}{1 + |\chi^{odd}_{eff}\chi^{odd}_{eff}|^2}\cos\Delta\Phi \quad (6b)$$

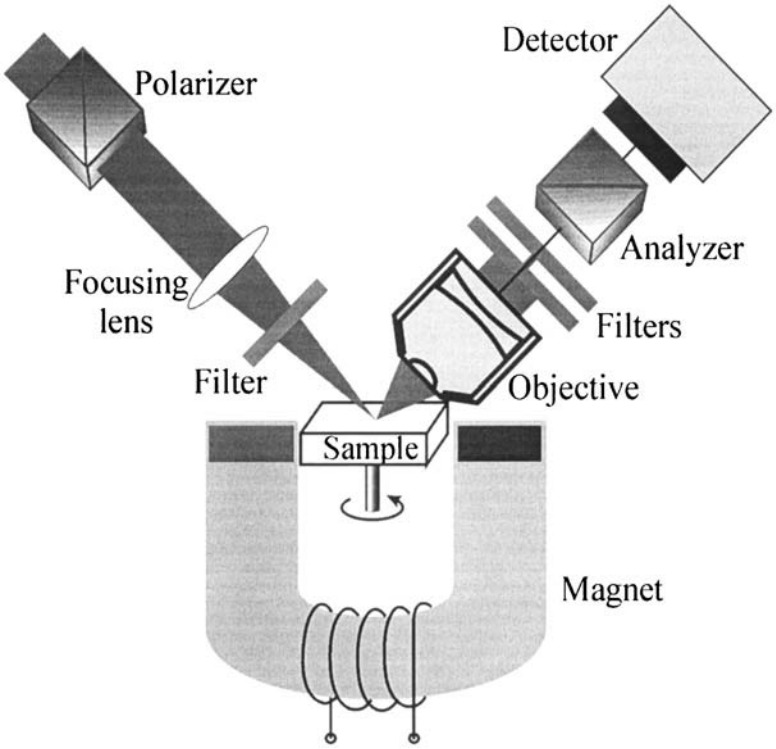

***Figure 1***
Schematic configuration for nonlinear MO experiments. Photomultipliers or CCD cameras (for domain imaging) can be used as detectors.

Because $A$ is normalized with respect to the total SHG intensity, it does not depend on the intensity or shape of the fundamental light pulses, nor on the spectral properties of optical components such as filters in the optical setup. Together with the already mentioned simplicity, this makes $A$ a useful parameter for quantitative investigations. One should, however, realize that the appearance of large effects that result from the large magnetic tensor components also means that, in contrast to most linear MO effects, the nonlinear effects are often not simply proportional to the magnetization as directly follows from Eqns (5) and (6). This can for example strongly affect the shape of MSHG loops (see Veenstra 2000).

## *3. Symmetry Considerations*

As a second-order nonlinear optical technique described by a third-rank tensor, MSHG can be exploited to probe other changes in symmetry, e.g., the appearance of steps on vicinal surfaces (Leermakers in press), magnetic moments at step edges (Jin *et al*. 1998), and the changes (phase transitions) in these properties. Because of the use of femtosecond laser sources for these experiments the latter can be performed with unprecedented time resolution. This has already led to exciting results, such as the disappearance of magnetic order within picoseconds, by using strong, but ultrashort, excitation pulses (Hohlfeld *et al*. 1999).

Since the MSHG response originates from the interference of both crystallographic (even) and magnetic (odd) contributions to the nonlinear optical response, a detailed analysis of the symmetry properties of the MSHG signal can provide deeper insight into both the crystallographic and magnetic symmetry of crystalline material. Experimentally this is done by using various polarization combinations (both circular and linear) in combination with azimuthal rotation dependence of the MSHG signal. These effects have been beautifully demonstrated for magnetic garnets (Pavlov *et al*. 1997, Kirilyuk *et al*. 1999) and for hexagonal manganites (Fiebig *et al*. 2000a), where in the last case even very complicated noncollinear spin structures could unambiguously be resolved. In both classes of material, the power of MSHG to probe the local spin structure, i.e., to do domain microscopy has been demonstrated as well (Fiebig *et al*. 2000b, Kirilyuk *et al*. 1997).

## 4. Concluding Remarks

Nonlinear Magneto-optics, or more specifically, MSHG has yielded an interesting and powerful new technique to investigate the magnetic structure of materials. The higher order optical response gives, in particular, the possibility of probing magnetic ordering in otherwise complicated or inaccessible structures (such as buried magnetic interfaces or antiferromagnetic materials) and has been shown to lead to intrinsically new effects. Therefore, this new area of magneto-optics is not only interesting from a fundamental point of view but it will also be quite important for applications such as the investigations of magnetic nanostructures and the spin dynamics in these systems.

# Nuclear Magnetic Resonance Spectrometry

Nuclear magnetic resonance (NMR) spectroscopy is an analytical technique used extensively in the molecular structure determination of organic, organometallic, biological, and inorganic materials. As the name implies, NMR is concerned with the magnetic properties of atomic nuclei, which give rise to the observed phenomenon. In an NMR experiment, samples are placed in a strong, homogeneous magnetic field and radio-frequency (RF) electromagnetic

energy is applied. Particular nuclei absorb this energy at sharply defined frequencies; this signal is then detected, amplified, and presented as a frequency spectrum. NMR of hydrogen nuclei in bulk materials was first observed in 1946 independently by the research groups of Bloch at Stanford and Purcell at Harvard, for which they received the 1952 Nobel Prize for Physics. It was quickly realized that liquid samples give much narrower peaks with significantly improved resolution of peaks in the spectrum.

The discovery of the *chemical shift*, i.e., the dependence of the resonance frequency of a given nucleus on its specific chemical environment in the molecule, established NMR as a fundamental tool for structure determination. The three most important types of information obtained in a high-resolution NMR spectrum are frequency, area, and multiplicity of the resonance lines. The exact resonance frequency of a nucleus is characteristic of its local electronic environment and is measured against a reference peak in the sample. The area under the resonance line can be integrated to give quantitative information about the relative number of nuclei giving rise to each peak. Peaks may be split into multiple lines owing to scalar (spin–spin) coupling with neighboring nuclei. This interaction occurs through the electrons of the bonding network and is due to the different combinations of spin orientations that neighboring nuclei can adopt. The splitting pattern indicates structural information about the neighboring nuclei.

Advances in instrument hardware since the late 1960s have significantly enhanced the sensitivity and resolution of NMR spectroscopy. As a result, spectra may be obtained of solutions of low concentration, nuclei may be observed that have very low natural abundance, and resolution of structural features is greatly improved. Whereas during the first 20 years after its discovery NMR applications were mostly limited to proton nuclei, modern spectrometers can in principle observe any nucleus, limited only by restrictions of its magnetic properties. Furthermore, developments in software and RF pulse sequence programming have dramatically extended the range and power of NMR experiments. Methods exist to map out fully by NMR the structure of an organic molecule for example. Although methods have also been established to obtain high-resolution NMR spectra of solid materials, the differences in the techniques are sufficient to require that this be a topic for a separate article (see *Solids, Nuclear Magnetic Resonance of*).

## 1. Principles

Both classical and quantum mechanical descriptions may be used to describe the NMR phenomenon. Since each approach has certain advantages, some features of each will be used in this discussion.

While all atomic nuclei possess charge and mass, some have magnetic moments and angular momentum and therefore behave as spinning bodies. Nuclei with even mass and atomic number have no nuclear spin and therefore do not exhibit the NMR phenomenon. These include the common isotopes $^{12}C$, $^{28}Si$, and $^{16}O$. Of the remaining nuclei, those with odd mass numbers and even nuclear charge numbers have spin quantum numbers, $I$, which are odd-integral multiples of $\frac{1}{2}$, whereas those with even mass numbers and odd nuclear charge have integral values of $I$. The nuclear angular momentum is given by $I(h/2\pi)$, where $h$ is Planck's constant. The magnetic moment, $\mu$, is proportional to the angular momentum by a factor $\gamma$, called the *magnetogyric ratio*, which is characteristic of a given nucleus:

$$\mu = \gamma hI/2\pi \tag{1}$$

A set of magnetic quantum numbers given by the series

$$m = I,\ (I-1),\ (I-2), \ldots, -I \tag{2}$$

describes the allowed values of the magnetic moment vector. Thus, there are $(2I+1)$ possible spin states for a given nucleus. For the simplest case of those nuclei with $I = \frac{1}{2}$ this corresponds to two spin states. These spin states are degenerate in the absence of a magnetic field, but they correspond to states of different potential energy in the presence of a uniform magnetic field, $H_0$. For spin-$\frac{1}{2}$ nuclei the two spin states correspond to the magnetic moment aligned either with or against the applied magnetic field ($m = +\frac{1}{2}$ or $m = -\frac{1}{2}$). Inducing and detecting transitions between these two states form the basis of NMR experiments.

The interaction between the applied magnetic field, $H_0$, and the nuclear magnetic moment, $\mu$, causes precession of the nucleus about the direction of the applied field. The frequency of precession is given by the Larmor equation:

$$\nu_0 = \gamma/2\pi H_0 \tag{3}$$

where $\nu_0$ is the Larmor frequency of a nucleus and is linearly dependent on the strength of the magnetic field, $H_0$. If a small magnetic field, $H_1$, is applied perpendicular to $H_0$, and made to rotate at a frequency of $\nu_0$, energy is absorbed from the $H_1$ field into the spin system. This is the resonance condition. If $H_1$ is rotating at any frequency other than $\nu_0$, no net absorption of energy occurs. The Larmor frequency is very different for individual nuclei. For example, in a magnetic field of 11.75 T the Larmor frequencies are 500.10 MHz for $^{1}H$, 470.48 MHz for $^{19}F$, 125.75 MHz for $^{13}C$, 50.67 MHz for $^{15}N$, 99.35 MHz for $^{29}Si$, and 202.44 MHz for $^{31}P$. Although there are a few nuclei whose Larmor frequencies are close enough to overlap frequency ranges, in

general only one nuclear species at a time is observed in a given spectrum.

The separation of the energy levels is small, and at equilibrium there is only a slight excess of nuclei in the lower energy spin state as given by the Boltzmann population distribution. Since NMR experiments are dependent on this small population to produce a signal, NMR is relatively insensitive compared with some other spectroscopic techniques. Once energy transfer occurs into the spin system, the process by which the nuclei re-establish a Boltzmann population distribution is called spin–lattice relaxation. This process is dependent on the presence of fluctuating local magnetic fields. Several common mechanisms of spin–lattice relaxation include interactions with neighboring magnetic nuclei, free rotation of a functional group or molecule, the presence of significant anisotropy in the chemical shift (see Sect. 3), and interactions through scalar coupling (see Sect. 4) with another rapidly relaxing nucleus. Spin–lattice relaxation times, $T_1$, for most common nuclei are in the range 0·1–20 s, but much smaller or greater $T_1$ values are also possible.

The ease of observing NMR signals for different nuclei is dependent on $I$, $\gamma$, and the natural abundance of the isotope. In general, nuclei with $I = \frac{1}{2}$ produce spectra with the narrowest lines. Nuclei with $I > \frac{1}{2}$ possess electric quadrupole moments which can significantly shorten relaxation times and broaden resonance lines. For this reason these nuclei are generally less suitable for traditional NMR experiments. The magnetogyric ratio is a fundamental constant of the nucleus, which determines the frequency and inherent sensitivity of the nucleus to the NMR experiment. In general, spin-$\frac{1}{2}$ nuclei with a high $\gamma$ value and reasonable natural abundance are easily observed by NMR spectroscopy. Examples of nuclei with 100% natural abundance which fit this description are $^{1}H$, $^{19}F$, and $^{31}P$.

## 2. *Instrumentation and Experimental Details*

Figure 1 shows a block diagram of a typical NMR spectrometer. In most modern NMR spectrometers the magnetic field is generated by a superconducting magnet. The sample is placed into the NMR probe which is located in the center of a homogenous region of the magnet. The spectrometer console provides at least three RF channels which are transmitted into the probe. The *observe channel* supplies the observe RF for the nucleus of interest and receives the signal back from the sample. The decoupler channel is used to irradiate another nucleus in the sample other than the one being observed. The *lock circuit* conducts a separate NMR experiment that continually measures another resonance, typically deuterium ($^{2}H$), and adjusts for minor drift in the magnetic field. This ensures long-term stability of high-resolution NMR experiments. Modern spectrometers typically employ two computers, one for data acquisition and processing and another for spectrometer control.

Both liquid and solid samples are normally dissolved in a deuterated solvent such as chloroform-d which provides a signal for the lock circuit. The liquid sample is placed in a capped, thin-walled glass tube, which is typically either 5 mm or 10 mm in diameter, although microsample probes are also available.

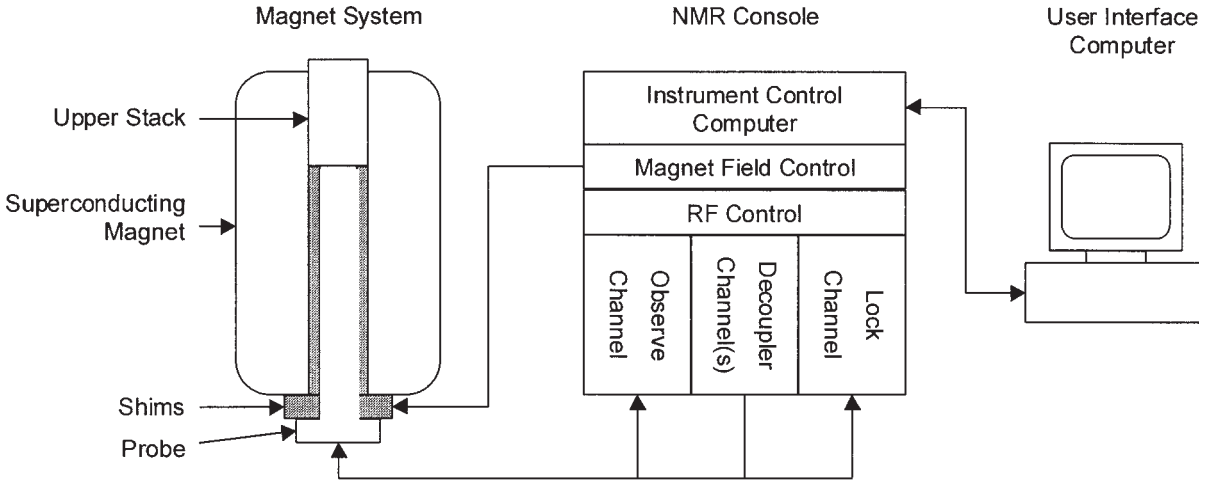

***Figure 1***
Block diagram of a typical NMR spectrometer. The sample is introduced through the upper stack of the magnet into the probe. The shims are used to optimize the homogeneity of the magnetic field around the sample. Instrument operation is carried out from the NMR console through the user interface computer.

## 3. Chemical Shifts

As mentioned above, nuclei of a given type do not all exhibit transitions at exactly the same frequency. Each nucleus is surrounded by an electron cloud, and the motion of these electrons creates a secondary magnetic field which tends to oppose the applied magnetic field; chemical shift differences arise because this local electron density varies depending on the electronegativity of the atoms attached to the nucleus and the type of bonding in which it is involved (e.g., single vs. multiple bonds). Thus, the higher the electron density about a nucleus, the greater the secondary magnetic field, or *shielding* effect. The effect of the nearest neighboring atoms or functional groups is usually most important. It is these small differences in resonance frequency among the chemically different nuclei in a sample that help identify the specific structures present.

The peak positions are determined using an internal standard which may be either a peak from another material added to the sample or from the deuterated solvent in the case of $^{13}C$ or $^{1}H$ NMR. These positions are reported relative to the position of a reference material. Although NMR data are measured in frequency units, Hz, they are usually reported in the dimensionless units of ppm which is independent of the magnetic field strength. Since the resonance frequencies are directly proportional to magnetic field strength, this is achieved by taking the difference in frequency between the peak and the standard (in Hz), multiplying by $10^6$ and dividing by the operating frequency of the spectrometer, $\nu_0$. This dimensionless chemical shift is given the symbol $\delta$:

$$\delta = 10^6(\nu_{\text{sample}} - n_{\text{ref}})/\nu_0 \qquad (4)$$

Using these chemical shifts permits comparisons to be made of data acquired on instruments of different magnetic field strength. As an example of a typical spectrum, Fig. 2 shows the $^{1}H$ NMR spectrum of ethylbenzene. It contains four sets of resonance lines from *low field* to *high field*, or left to right: a singlet, a quartet, and another singlet. The last singlet is due to the protons of tetramethylsilane (TMS), $(CH_3)_4Si$, which is commonly used as the standard for $^{1}H$, $^{13}C$, and $^{29}Si$ NMR. By convention, the chemical shift for the standard is set to 0 ppm.

## 4. Proton NMR

Consider the $^{1}H$ NMR spectrum shown in Fig. 2. The dominant features of the spectrum are the presence of the singlet at $\delta = 7.2$ ppm (phenyl ring protons), triplet at $\delta = 1.2$ ppm (methyl protons), and quartet at $\delta = 2.6$ ppm (methylene protons). The neighboring group affects more than just the chemical shift of a peak: in the case of the methyl group, for example, the neighboring methylene group not only affects the position of the resonance line but causes the peak to be split into a triplet as well. The explanation for this phenomenon, called spin–spin splitting, lies in the fact that the neighboring protons may also be in different orientations with respect to the applied magnetic field. Since the proton is a nucleus with $I = \frac{1}{2}$, two possible spin states exist for each proton. Depending on whether the neighboring nuclear spin is aligned with (parallel) or opposed to (antiparallel) the proton at resonance, it will either increase or decrease the net magnetic field experienced by the observed proton. This gives rise to slight differences in energy levels and thus different resonance lines. In the case of the methylene protons of ethylbenzene, three combinations of the orientations ($\uparrow\uparrow$, $\uparrow\downarrow = \downarrow\uparrow$, $\downarrow\downarrow$) of the two spins are possible for the neighboring nuclei producing a 1:2:1 triplet for the methyl protons. Spin–spin splitting is a primary characteristic of $^{1}H$ NMR. These interactions are said to be electron coupled since they operate through the bonding network; the effect is quite strong over the first few bonds but diminishes greatly thereafter.

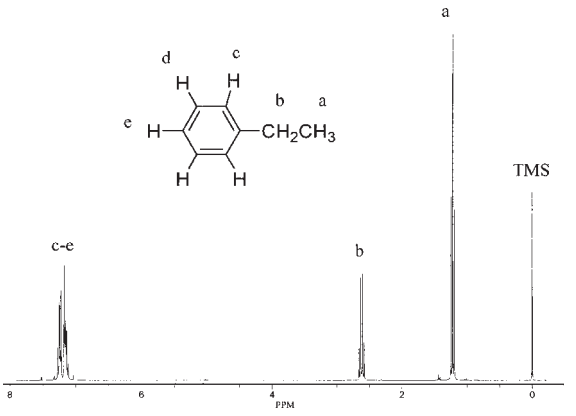

***Figure 2***
Proton NMR spectrum (300 MHz) of ethylbenzene. Assignments to the protons in the structure are shown. The internal standard is TMS, which is set to a chemical shift of 0 ppm.

The number of lines produced by spin–spin coupling is given by

$$\text{Multiplicity} = 2nI + 1 \qquad (5)$$

where $n$ is the number of protons in the neighboring group and $I$ is the spin quantum number. The separation between the lines of a multiplet is referred to as the coupling constant, $J$. This value, expressed in frequency units (Hz), reflects the magnitude of the spin–spin interaction and is independent of the applied magnetic field. Characteristic coupling constants are of great value in structure elucidation. Factors that influence the magnitude of the coupling

constant include bond order, electronegativity of the substituents on the coupled nuclei, and bond angles.

To determine if two nuclei are coupled to each other, a double resonance experiment can be performed. In this type of experiment, two RF fields are simultaneously applied to the sample: one is used to observe the spectrum in the normal manner, and the other is a perturbing field applied at the resonance frequency of another nucleus that is suspected to be coupled to the one of interest. If the perturbing (or *decoupling*) field is sufficiently strong the nucleus of interest appears as if it is no longer coupled. In the spectrum of ethylbenzene, for example, if the decoupling field is applied at the resonance frequency of the methylene protons, the methyl proton triplet collapses to a single peak. Similarly, irradiating at the center of the methyl proton resonance causes the methylene proton quartet to collapse to a singlet. The perturbation of coupled spins to determine connectivity in a molecule is a key feature in a number of more advanced NMR techniques.

## 5. Carbon-13 NMR

The sensitivity of the $^{13}C$ nucleus is a factor of approximately 6000 lower than that of $^{1}H$ owing to its smaller magnetogyric ratio and low natural abundance of 1.1%. Although $^{13}C$ spectra were obtained as early as the 1950s (Lauterbur 1957), significant growth in the application of $^{13}C$ NMR and other low-sensitivity nuclei did not occur until after the introduction of the pulsed Fourier transform method (Ernst and Anderson 1966).

The resulting dramatic reduction in the amount of time necessary for data acquisition allowed $^{13}C$ NMR spectroscopy to become a routine tool for probing molecular structure. The rare occurrence of the isotope greatly simplifies $^{13}C$ NMR spectra by eliminating the spin–spin coupling ($^{13}C$–$^{13}C$) that is so dominant in $^{1}H$ NMR spectra.

Further simplification of $^{13}C$ spectra is achieved by removing the scalar coupling between $^{13}C$ and $^{1}H$ by double-resonance decoupling over the $^{1}H$ chemical shift range. In the resultant spectrum, each line corresponds to a magnetically unique carbon atom in the sample. The relatively large $^{13}C$ chemical shift range, which is about 20 times that of $^{1}H$, affords excellent resolution of even structurally quite similar atoms. As an example of a typical spectrum, Fig. 3 shows the $^{13}C$ spectrum of ethylbenzene. Note that all six structurally unique carbon atoms give resonances that are well resolved from each other.

The ability to differentiate structures in $^{13}C$ NMR is facilitated by the fact that the major factors governing $^{13}C$ nuclear shieldings are well established. Experimentally, it has been found that substituent effects on $^{13}C$ chemical shifts are largely additive. Semiempirical methods, therefore, are usually successful in predicting these shifts. The largest variation in $^{13}C$ chemical shifts occurs with direct substitution by highly electronegative elements such as oxygen and fluorine. The hybridization at carbon also strongly affects the position of the resonance line. Carbon–carbon double bonds (C=C), for example, typically appear in the region 90–160 ppm from TMS, whereas carbon–carbon single bonds (C–C) usually occur in the range 0–90 ppm from TMS.

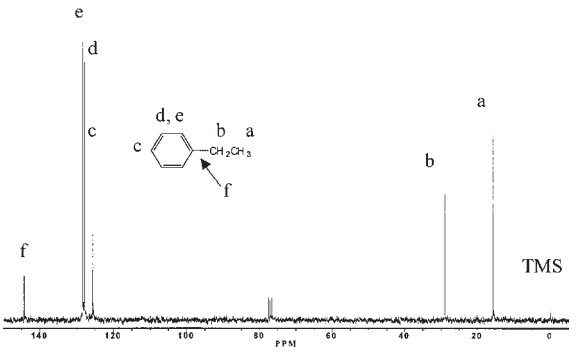

***Figure 3***
Carbon-13 NMR spectrum of ethylbenzene with assignments of the peaks to the carbons in the structure. Note that each unique carbon atom produces a different peak in the spectrum.

## 6. Other Nuclei

Prior to 1970 the bulk of NMR studies concerned the proton. The rest of the interest at that time was divided among the high-sensitivity nuclei $^{19}F$, $^{31}P$, and $^{11}B$. Since then, studies involving virtually all observable NMR nuclei have been carried out. Extensive compilations of chemical shift data can be found for the nuclei mentioned above as well as $^{14}N$, $^{15}N$, $^{17}O$, $^{29}Si$, $^{195}Pt$, $^{119}Sn$, among others.

## 7. Quantitative NMR

NMR can be readily made quantitative since there are no response factors or matrix effects that need to be considered. In principle this means that the area under each peak in a spectrum is proportional to the number of nuclei of that type that are present in the molecular structure. In practice, however, several factors must be taken into account to obtain quantitative data.

In the data acquisition parameters, a sufficiently wide spectral width needs to be used to ensure a uniform level of RF power has been applied across the range of interest. Two other factors can distort the intensities of the peaks in the spectrum. Perturbations of the populations can occur when nuclei other than protons are observed and proton decoupling is used.

This is called the nuclear Overhauser effect (NOE). The NOE can be eliminated by turning the proton decoupler *off* during the delay between RF pulses (*gated decoupling*) to allow the normal equilibrium populations to be established. The second factor that must be considered is the spin–lattice relaxation time of the nuclei. For quantitative analysis it is necessary to use a sufficient delay between RF pulses to ensure that all nuclei are fully relaxed before the next RF pulse is applied. This may be seconds, or even minutes, and could hinder rapid acquisition of spectra. A small amount of a *paramagnetic relaxation reagent*, such as tris(acetylacetonato) chromium(III), is added to shorten the relaxation times of nuclei other than protons. Relaxation reagents provide an extremely efficient pathway for nuclear spins to return to the ground state through electron–nuclear dipole–dipole relaxation produced by the unpaired electron of the reagent. Thus, for quantitative analysis by NMR of nuclei other than protons, a small amount (50–75 mg) of a relaxation reagent should be added to the solution if possible to reduce $T_1$, gated decoupling should be used to eliminate any residual NOE, and a sufficiently long relaxation delay must be employed to permit complete relaxation of the nuclei. For protons it is sufficient simply to use a relaxation delay of appropriate length. Frequently the $T_1$ values of the nuclei of interest are measured and a relaxation delay of five times the largest $T_1$ is used.

## 8. Two-dimensional NMR

A major development in NMR was the introduction of the concept of two-dimensional NMR spectroscopy (2D NMR) in the early 1970s (Jeener 1971). In the standard one-dimensional NMR experiment the application of a RF pulse results in the nuclear magnetic moments precessing about the direction of the magnetic field. This response to the RF pulse induces a signal in the receiver coil of the probe which is monitored for a period of time (the *acquisition time*). Thus, the detected NMR signal (or *free-induction decay*, *FID*) is a function of a single time variable. Fourier transformation of this signal produces the normal one-dimensional frequency spectrum.

If the spin system is allowed to evolve under another set of experimental conditions (e.g., the length of time the proton decoupler is on) for a period of time prior to detection of the FID, and if this *evolution period* is varied systematically, the NMR signal is now a function of two time variables. The data are collected as a series of FIDs, each of which has the same acquisition time, $t_2$, but a different evolution period, $t_1$. Two Fourier transformations are performed on this data matrix, one on the rows of the matrix ($t_1$), and the second on the columns of the data ($t_2$). The result of this process is now a matrix (the two-dimensional spectrum) which is a function of two frequencies, $\nu_1$ and $\nu_2$, and for which the intensity of the signal at each pair of frequencies is a third dimension. The specific identity of these frequencies depends on the two-dimensional experiment performed. Some of the applications include *heteronuclear and homonuclear correlation spectroscopies* in which pairs of coupled nuclei are identified through scalar coupling (both short and long range), *J-resolved spectroscopy* in which the coupling patterns and chemical shifts are separated and shown on different axes, and *exchange spectroscopy* in which nuclei involved in chemical exchange can be identified.

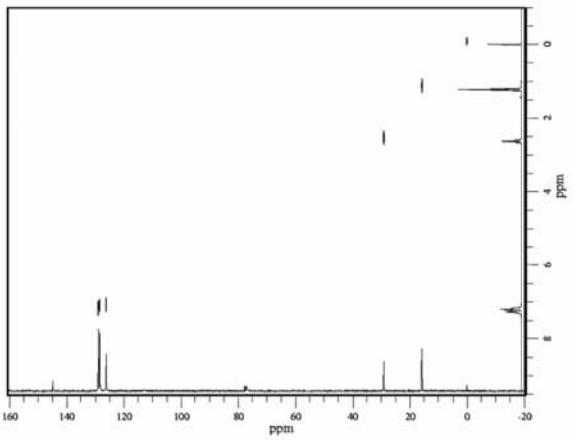

***Figure 4***
Two-dimensional heteronuclear ($^1$H–$^{13}$C) chemical shift correlation (HETCOR) plot showing connectivities between carbon nuclei and their directly bonded protons.

An example of a two-dimensional heteronuclear ($^1$H–$^{13}$C) chemical shift correlation (HETCOR) spectrum of ethylbenzene is shown in Fig. 4. The proton spectrum is shown on the *y*-axis and the carbon spectrum is shown along the *x*-axis. The two-dimensional contour plot shows peaks at the intersections of directly coupled carbon and proton nuclei. Note that the $^{13}$C resonance at 145 ppm has no directly bonded proton so there is no peak at that position in the two-dimensional plot.

# Nuclear Resonance Scattering

Nuclear resonance scattering (NRS) with synchrotron radiation combines the outstanding properties of Mössbauer spectroscopy (see *Mössbauer Spectrometry*) with those of synchrotron radiation. Since its first observation in 1984 (Gerdau *et al.* 1985) a rapid development of the technique and its applications followed which has just been reviewed (Gerdau and de Waard 2000). Thanks to the outstanding properties of third generation synchrotron radiation sources, NRS has nowadays become an established spectroscopy on an atomistic scale which is element and even isotope sensitive and nondestructive. Applications comprise two main fields, "hyperfine spectroscopy" and "structural dynamics." In hyperfine spectroscopy NRS is complementary to other nuclear techniques and yields useful information on atomic, magnetic, and electric properties and structures. Those fields of applications benefit most which exploit the specific properties of synchrotron radiation: applications to high pressure, to grazing incidence geometry (surfaces and multilayers), to single crystals, and to very small samples. Structural dynamics on a ps to μs timescale as free or jump diffusion as well as rotational motions can directly be measured in the time domain by nuclear quasi-elastic scattering techniques. On the fast timescale the (partial) density of phonon states is directly accessible by nuclear inelastic scattering.

## 1. Principles of Nuclear Resonance Scattering

Nuclear resonance scattering is a resonant x-ray scattering technique in the time domain. It is based on the Mössbauer effect and the scattering proceeds via the Mössbauer level whereas Mössbauer spectroscopy is an absorption spectroscopy and is normally carried out in the energy domain. Both are, in principle, connected by the Heisenberg uncertainty principle.

In case of Mössbauer spectroscopy (see *Mössbauer Spectrometry*) a radioactive source provides the $\gamma$-quanta which are very sharp in energy (neV-μeV) and by varying the energy one measures absorption spectra behind the sample. In nuclear resonance scattering an x-ray pulse from a synchrotron radiation source which is very sharp in time ($\sim$100 ps) and very broad in energy (white radiation) excites the nuclear levels in the sample. The successive decay of these levels gives rise to an exponential intensity decay in time. This decay corresponds to the Lorentzian line in Mössbauer absorption spectroscopy.

There are several techniques utilizing nuclear resonance scattering: nuclear forward scattering (NFS), nuclear quasi-elastic scattering (NQES), nuclear Bragg diffraction (NBD), nuclear reflectometry (NR, for the investigation of surfaces and multilayers), nuclear small angle scattering (NSAS, measuring for example, magnetic domain structures), nuclear inelastic scattering (NIS), and synchrotron radiation-based perturbed angular correlation (SRPAC). In the following a short introduction will be given to the main fields: nuclear forward scattering, nuclear quasi-elastic scattering, and nuclear inelastic scattering (see Fig. 1).

### 1.1 Nuclear Forward Scattering

Nuclear forward scattering (and nuclear reflectometry) has the closest analogy to Mössbauer spectroscopy; in fact, it is its scattering variant. The main domain is the determination of hyperfine parameters such as internal magnetic fields (magnetic hyperfine field), electric field gradients, isomer shifts, and the Lamb-Mössbauer factor ($f_{LM}$).

The setup for NFS (see Fig. 1) also looks very similar to a standard set-up for Mössbauer spectroscopy (see *Mössbauer Spectrometry*). However, while Mössbauer spectroscopy is an absorption spectroscopy (one $\gamma$-quantum is absorbed by one nucleus)

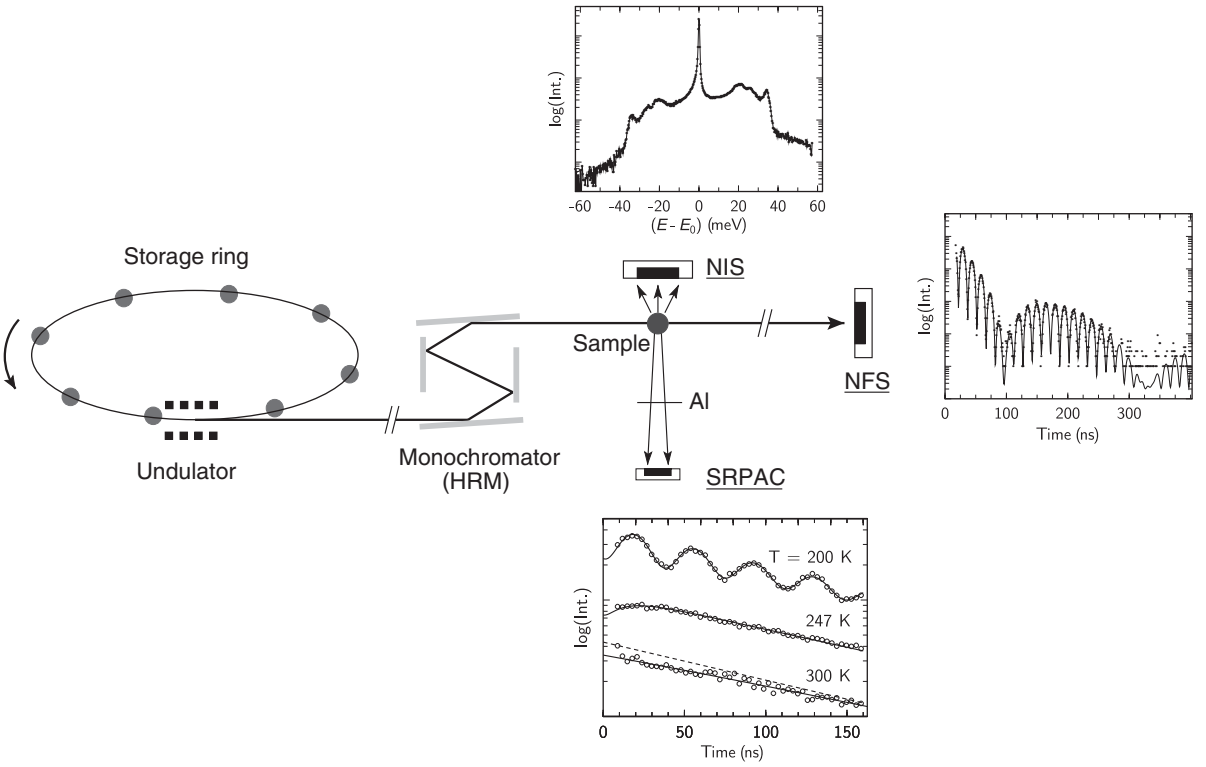

***Figure 1***
Scheme of the setup for some techniques in NRS: NFS, NIS, and SRPAC. Furthermore, the corresponding time and energy spectra are schematically shown measured by the detectors for NFS, SRPAC, and NIS. The storage ring is operated in "few bunch" mode with e.g. 176 ns spacing between adjacent buckets (red bullets). The undulator produces the well-collimated synchrotron radiation which is monochromized at the nuclear resonances by a high resolution monochromator, HRM (bandwidth $\Delta E \approx$ meV). Finally the radiation impinges the sample. Depending on the scattering process and the scattering geometry different techniques are exploited. Variable sample environments allow for the combination of high/low temperature, high pressure, and external magnetic field.

NFS is a scattering spectroscopy. The "white" synchrotron radiation excites all Mössbauer levels in the sample and creates a "coherent collective nuclear state". In the static case this nuclear state will decay in the forward direction giving rise to an excess of intensity at delayed times (see Fig. 1, NFS). The timescale is determined by the lifetime $\tau_0$ of the involved nuclear level. Multiple scattering may influence the measured time response giving rise to "dynamical beats." Furthermore, in case of split nuclear levels due to hyperfine interaction (electric, magnetic) an additional interference pattern, the so-called "quantum beat" structure is superimposed.

### *(a) Dynamical beats*

For samples with a large effective thickness, $t_{\mathrm{eff}} = n_{\mathrm{MB}} d \sigma_0 f_{\mathrm{LM}}$, with $n_{\mathrm{MB}}$ the density of Mössbauer nuclei, $d$ the geometrical thickness, $\sigma_0$ the resonant Mössbauer cross section, and $f_{\mathrm{LM}}$ the Lamb–Mössbauer factor, a speed-up effect is observed and dynamical beats (Bessel beats) show up in the time spectra.

In Fig. 2 the situation is shown for Mössbauer and NFS spectra. For a thin sample, $t_{\mathrm{eff}} = 1$, we have a single Lorentzian line in the Mössbauer spectrum which corresponds to an exponential decay in the NFS spectrum (Fig. 2(a),(b), dotted lines). Increasing the effective thickness ($t_{\mathrm{eff}} = 25$) the Mössbauer line becomes much wider and non-Lorentzian (Fig. 2(a), solid line). In the NFS spectrum (Fig. 2(b), solid line) we observe two features: (i) a speed-up, showing up as an increase in intensity at early times (from $10^7$ to $10^9$ units in the present example) and (ii) a dynamical beat structure is superimposed to the decay. From this beat structure the effective thickness and by this $f_{\mathrm{LM}}$ can very precisely be determined.

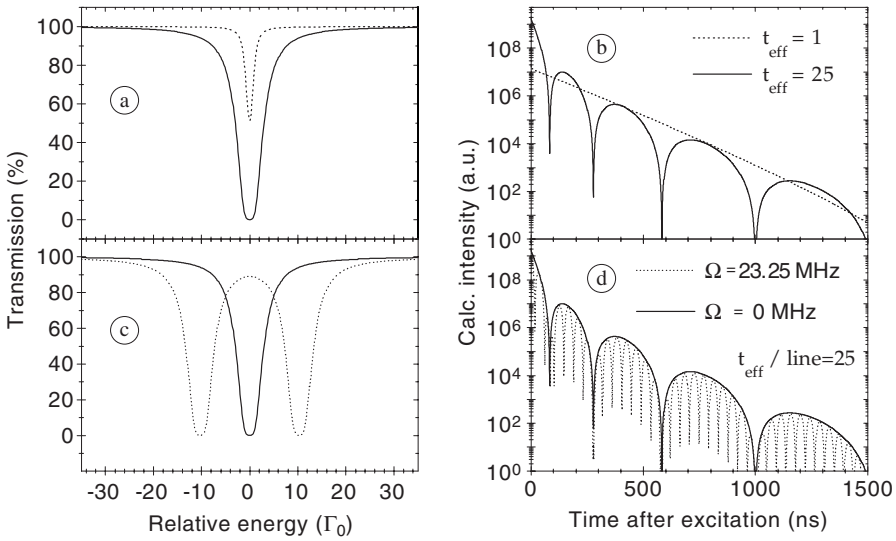

***Figure 2***
Simulations of corresponding spectra of Mössbauer spectroscopy (left panel, with $\Gamma_0 = \hbar/\tau_0$) and NFS (right panel) for thin ($t_{\mathrm{eff}} = 1$) and thick ($t_{\mathrm{eff}} = 25$) samples. For the single lines (panel a) the thin sample leads to an exponential decay whereas the spectrum from the thick sample is further modulated by the dynamical beats (panel b). In panel c the energy spectra of a thick sample ($t_{\mathrm{eff}} = 25$) with one (solid line) and two (dotted line) transition lines, respectively, are shown. In panel d the corresponding time spectra are shown. The sample with the two lines shows in addition to the dynamical beats the fast, equidistant quantum beat structure with frequency Ω superimposed (from Grünsteudel 1998).

*(b) Quantum beats*

As is well known (see *Mössbauer Spectrometry*) hyperfine interaction might split the nuclear levels. In Mössbauer spectroscopy several absorption lines reveal this splitting whereas in NRS an interference pattern, the quantum beat structure, shows up.

In case of quadrupolar interaction the excited nuclear state (e.g., in case of $^{57}$Fe) splits to the $\pm 3/2$ and $\pm 1/2$ levels. This gives rise to two absorption lines in Mössbauer spectroscopy (see dotted line in Fig. 2(c)). The corresponding spectrum in NFS shows up as an interference pattern of these two transitions with a single frequency Ω of the quantum beats (see dotted line in Fig. 2(d)). Due to the thick sample with an effective thickness $t_{\mathrm{eff}} = 25$, the dynamical beat structure strongly modulates the quantum beats as an envelope. It is clearly seen that the quantum beat structure is equidistantly spaced whereas for the dynamical beat structure the distance of the minima increases with time. This can be described in a good approximation by

$$I_{\mathrm{NFS}}(t) \propto \frac{t_{\mathrm{eff}}}{t/\tau_0} \cos^2\left(\frac{\Omega t}{2}\right) \mathrm{e}^{-t/\tau_0} \cdot J_1\left(\sqrt{4 t_{\mathrm{eff}} t/\tau_0}\right)^2 \quad (1)$$

The term $\cos^2(\frac{1}{2}\Omega t)$ describes the quantum beats and the Bessel function $J_1$ the dynamical beats. For comparison the unsplit case is shown as solid lines in the same figures. Changing the strength of the hyperfine interaction will result in a different splitting and correspondingly in a different quantum beat frequency Ω.

In the case of magnetic hyperfine interaction, full splitting of the nuclear levels occurs giving rise to six nuclear transitions and correspondingly to six absorption lines in Mössbauer spectroscopy with $^{57}$Fe (see *Mössbauer Spectrometry*). In NRS spectroscopy a more detailed interference pattern will result. Contrary to Mössbauer spectroscopy where the $\gamma$-rays from the radioactive source are normally unpolarized now the x-rays from the synchrotron radiation source are highly linearly polarized. This feature strongly modifies the time spectra which are displayed in Fig. 3. The important parameters are the orientation of the three vectors with respect to each other, the wave vector $\vec{k}$, the polarization vector $\vec{E}$, and the hyperfine field vector $\vec{H}$.

If all three vectors are perpendicular to each other a simple quantum beat pattern with one single frequency and high contrast results originating from the two $\Delta m = 0$ transitions (Fig. 3a).

A similar spectrum with only one frequency, however, with less contrast appears when $\vec{H} \| \vec{k}$. In this case the two $\Delta m = +1$ and the two $\Delta m = -1$ transitions interfere independently giving rise to left and right hand circular polarization (Fig. 3c).

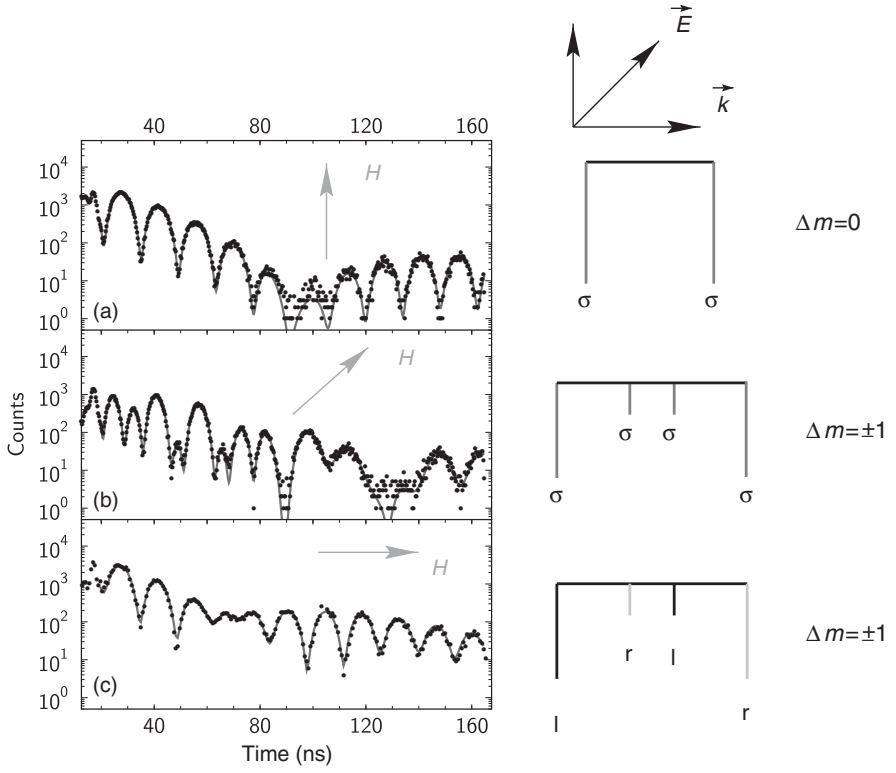

***Figure 3***
Left panel: Measured time spectra of iron (NFS) in case of magnetic hyperfine interaction for various alignments of the hyperfine field $\vec{H}$ with respect to the wave vector $\vec{k}$ and the polarization $\vec{E}$. Solid lines are fits according to the full theory. Right panel: nuclear transition lines with their polarization state, $\sigma-\sigma$ linearly polarized, l and r left- and right-hand circular polarized, respectively. $\Delta m$—change of magnetic quantum number (reproduced with permission from Leupold *et al*. (2003); © Kluwer Academic Publisher).

Finally, for $\vec{H} \| \vec{E}$ all $\Delta m = \pm 1$ transitions interfere giving rise to a more complicated spectrum which is sigma polarized (Fig. 3b). The slow overall modulation is caused by dynamical beats due to the finite effective thickness.

### *1.2 Nuclear Quasi-elastic Scattering*

Nuclear quasi-elastic scattering measures structural dynamics on a ps to μs timescale. The coherent and the incoherent channel can be utilized. In the first case, the coherent channel, the Lamb–Mössbauer factor has to be greater than zero ($f_{\mathrm{LM}} > 0$). The setup is the same as in NFS (see Fig. 1). The incoming x-ray pulse creates a coherent collective nuclear state which decays in the static case in forward direction. Dynamics, for example, the jump of a Mössbauer nucleus from one atomic site to another (in space and angle, see Dattagupta (1976) for example), destroys this state. As a consequence no x-ray is scattered in forward direction, i.e., the measured intensity in the NFS detector is decreased at later times. We will get an "accelerated decay" or a "damping" of the NFS intensity $I_{\mathrm{NFS}}(\mathrm{t})$ which might be described in a simplified picture by

$$I(\mathrm{t}) \propto I_{\mathrm{NFS}}(\mathrm{t}) \mathrm{e}^{-2\lambda_{\mathrm{t}} t}\, \mathrm{e}^{-\lambda_{\mathrm{r}} t} \qquad (2)$$

The first exponential is related to the van Hove self-intermediate function with $\lambda_{\mathrm{t}}$ being the translational relaxation rate and the second one to the rotational correlation function with $\lambda_{\mathrm{r}}$ being the rotational relaxation rate. In the second case, the incoherent channel, the scattering is independent of the Lamb-Mössbauer factor, $f_{\mathrm{LM}}$. The setup (see Fig. 1) is similar as in traditional time differential perturbed angular correlation (see *Perturbed Angular Correlations (PAC)*) spectroscopy. Therefore the technique is called synchrotron radiation-based perturbed angular correlation, SRPAC. The incoming x-ray pulse selectively excites a single nucleus which decays in the static case with an angular distribution according to the anisotropy parameter, $A_{22}$. Dynamics, for

example, rotational motion monitored by the electric hyperfine interaction $\hbar\Omega$, changes this distribution and gives rise to a damping of the intensity signal. The scattering intensity can be written as

$$I = I_0\, \mathrm{e}^{-t/\tau_0}\{1 - A_{22}G_{22}(t)\} \tag{3}$$

with $A_{22}$ the anisotropy and angular term and $G_{22}$ the perturbation factor. It reduces in the slow approximation to

$$G_{22}(t) \propto \mathrm{e}^{-\lambda_r t}\ \cos^2\left(\frac{\Omega t}{2}\right) \tag{4}$$

and in the fast approximation to

$$G_{22}(t) \propto \mathrm{e}^{-(\Omega^2/\lambda_r)t} \tag{5}$$

Combining both techniques the translational and rotational relaxation rates can be separately extracted.

### *1.3 Nuclear Inelastic Scattering*

Nuclear inelastic scattering is a very recent method in order to measure directly the (partial) density of phonon states (Seto *et al*. 1995; Sturhahn *et al*. 1995; Chumakov *et al*. 1995). The principle setup is shown in Fig. 1. The synchrotron radiation is monochromized by a scanning high resolution monochromator (HRM) with (sub-)meV (1 meV = 0.24 THz) energy resolution. At resonance the x-ray pulse creates a coherent collective nuclear state as in NFS which decays either in forward direction or incoherently, due to internal conversion, spin flop etc., in the entire solid angle of $4\pi$. This feature gives a simple and effective method at hand to measure the instrumental function (detector NFS) in parallel with the inelastic spectrum (detector NIS). While scanning the HRM the nuclear resonance can only be excited when at the same time a phonon is excited or annihilated. In NIS this is a purely incoherent process with the consequence of a perfect averaging over the momentum $\vec{q}$. The successive nuclear decay proceeds as a single exponential in the entire solid angle covered by the "$4\pi$"-detector (detector NIS). In practice only a solid angle of about $\pi$ can be achieved.

As an example the energy dependence of nuclear inelastic scattering of synchrotron radiation in a polycrystalline $\alpha$-iron sample at room temperature is shown as a function of energy of the incident radiation (Fig. 4). The central peak corresponds to elastic scattering. The structure beyond the central peak shows the energy spectrum of inelastic scattering, accompanied either by creation ($E>0$) or by annihilation ($E<0$) of phonons. At ambient temperature one may recognize various contributions to the energy spectrum, which correspond to inelastic scattering accompanied by excitation or annihilation of different number of phonons. The normalized probability

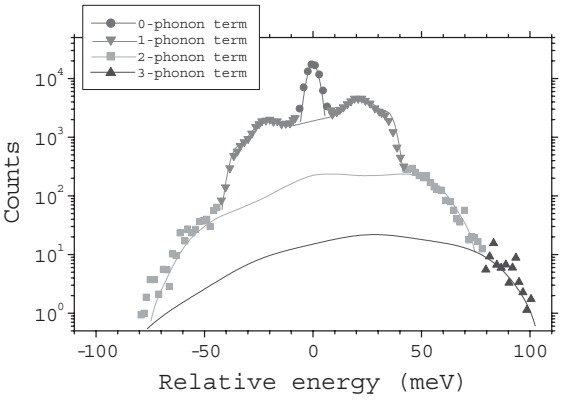

***Figure 4***
Expansion of the energy spectrum of nuclear inelastic scattering of synchrotron radiation in $\alpha$-iron in multiphonon terms. The data were taken at room temperature. Different symbols show the regions of the spectra, where the corresponding contributions are dominant. The lines are the calculations according to Eqns. (6)–(8) and convoluted with the instrumental function of the monochromator (reproduced with permission from Chumakov and Sturhahn (1999); © Kluwer Academic Publisher).

of nuclear inelastic scattering $W(E)$ can be decomposed in terms of a multiphonon expansion (Singwi and Sjölander 1960)

$$W(E) = f_{\mathrm{LM}}\left(\delta(E) + \sum_{n=1}^{\infty} S_n(E)\right) \tag{6}$$

The Dirac $\delta$-function $\delta(E)$ describes the elastic part of scattering (zero-phonon term), and the $n$th term of the series $S_n(E)$ represents the inelastic scattering accompanied by creation (annihilation) of $n$ phonons. The one-phonon term is given by

$$S_1(E) = \frac{E_{\mathrm{R}} \cdot g(|E|)}{E \cdot (1 - \mathrm{e}^{-\beta E})} \tag{7}$$

and the subsequent terms under harmonic approximation may be found through the recursive relation:

$$S_n(E) = \frac{1}{n}\int_{-\infty}^{\infty} S_1(E')S_{n-1}(E - E')\mathrm{d}E' \tag{8}$$

Here $\beta = (k_{\mathrm{B}}T)^{-1}$ with $k_{\mathrm{B}}$ the Boltzmann constant, $T$ the temperature, $E_{\mathrm{R}} = \hbar^2k^2/2M$ the recoil energy of a free nucleus, $k$ the wave vector of the x-ray quantum, $M$ the mass of the atom. The function $g(E)$ is the normalized density of phonon states

$$g(E) = V_0\frac{1}{(2\pi)^3}\sum_j \int \mathrm{d}\vec{q}\,\delta[E - \hbar\omega_j(\vec{q})] \tag{9}$$

where $V_0$ is the volume of unit cell, index $j$ numerates the branches of the dispersion relation $\hbar\omega_j(\vec{q})$, $\vec{q}$ is the phonon momentum, and the integral is taken within the first Brillouin zone. The detailed theory of nuclear inelastic scattering has been published by several authors (Singwi and Sjölander 1960; Kohn *et al.* 1998, Sturhahn and Kohn 1999).

From the density of phonon states other (thermo)dynamic quantities can be derived as the vibrational contribution to the internal energy, lattice specific heat at constant volume and pressure, vibrational entropy. From the sum rules (Lipkin 1999) the density of phonon states, $f_{\mathrm{LM}}$ and the mean square displacement, the mean kinetic energy, the mean force constant, and the second order Doppler shift can be determined.

In summary, NIS gives direct access to the density of phonon states and various (thermo)dynamic quantities. It is complementary to methods as inelastic neutron, x-ray, and light scattering. In those techniques mainly dispersion relations which are fitted to a model are measured and in a final step the density of phonon states can be derived.

## 2. *Applications*

### *2.1 Applications to High Pressure*

High-pressure applications are one of the domains which benefit most from the outstanding properties of synchrotron radiation. The small beam size allows one to work with samples much smaller than 100 μm in diameter. In that case state-of-the-art diamond anvil cells (DAC) are able to reach pressures far above the 100 GPa regime, those pressures which are common in the center of the Earth. The small divergence of the beam allows sophisticated sample environments, *in situ* pressure calibration and diffraction studies for the determination of the induced volume change with pressure. In the following example iron metal has been investigated by NFS and NIS in order to follow over the pressure-induced phase transition magnetic order (via the hyperfine field) and structural dynamics (via the partial phonon DOS).

#### *(a) Iron metal*

Recently, the high-pressure behaviour of iron gained much interest due to unusual superconductivity and due to simulations of the inner core of the Earth and improved technical developments in high-pressure research. It is well known that α-iron undergoes under pressure a magnetic and structural phase transition to the hexagonal closed-packed (h.c.p.) phase of iron (ε-iron) in the pressure range of 10–22 GPa at ambient temperature.

A 2.5 μm thick iron foil enriched to 95% in $^{57}$Fe was pressurized in a DAC (Grünsteudel 1997). Figure 5 shows the NFS spectra for various pressures. A small external magnetic field (0.6 T) aligned the internal field perpendicular to the incoming wave vector $\vec{k}$ and the polarization $\vec{E}$ (the case discussed in Fig. 3a). At 3 GPa the spectrum reveals iron in the pure α-phase. The regular quantum beat pattern shows a single frequency from which a hyperfine field

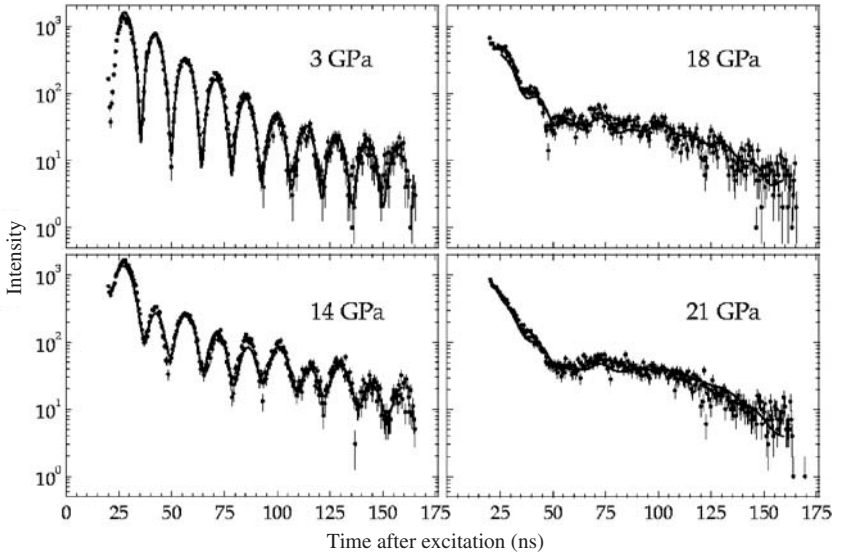

***Figure 5***
Time spectra of NFS from the pressure induced α→ε transition in Fe at various pressures (from Grünsteudel 1997).

of 32.4 T can be derived. Taking into account the polarizing external field of 0.6 T the internal field becomes 33.0 T (in case of iron the external and internal field align antiparallel). At 14 GPa the influence of the $\varepsilon$-phase is already quite pronounced. With a further increase in pressure the influence of the nonmagnetic $\varepsilon$-phase becomes dominant. At 21 GPa the sample is almost completely in the $\varepsilon$-phase. Now the NFS spectrum is modified only by a single Bessel minimum at 50 ns which originates from the increased effective thickness in comparison to that of the magnetically split one.

With the same sample, NIS spectra have been recorded and the densities of phonon states have been extracted (Lübbers *et al.* 2000b). Examples at ambient pressure and at 42 GPa are displayed in Fig. 6. All spectral features of the density of phonon states of $\varepsilon$-Fe are shifted to higher energies with respect to $\alpha$-Fe revealing a hardening of the lattice vibrations. Several thermodynamical properties have been derived as $f_{\mathrm{LM}}$ and the mean-square displacement, respectively, the mean phonon energy and the corresponding Debye temperature, the lattice contribution to the specific heat $c_V$, the internal energy, entropy, and the mean force constant. Finally, from the low-energy part of the density of phonon states the average velocity of sound $v_{\mathrm{av}}$ (Fig. 6 inset) has been derived according to the relation

$$g(E) = \frac{V}{2\pi^2\hbar^3 v_{\mathrm{av}}^3} E^2 \qquad (10)$$

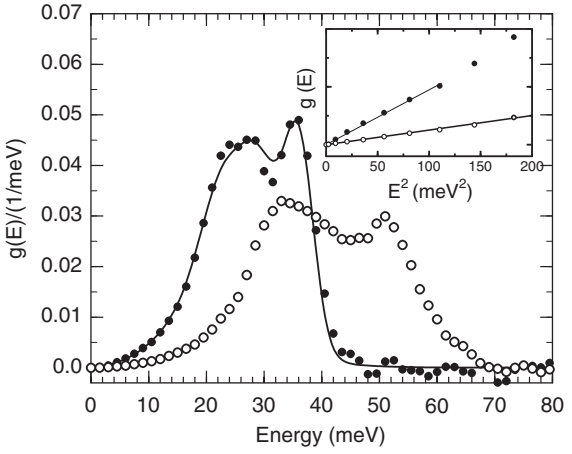

***Figure 6***
Phonon density of states from the pressure induced $\alpha \rightarrow \varepsilon$ transition in Fe at ambient pressure (solid circles) and 42 GPa (open circles). The solid line represents the DOS from neutron scattering. The inset displays the corresponding low energy part for the determination of sound velocities. Here the solid lines represent a linear fit to the data (reprinted with permission from Lübbers *et al.* (2000b); © AAAS).

with $V$ the volume per Fe atom. Extensions to higher pressures have been reported (Mao *et al.* 2001) and investigations undertaken to account for anisotropies (Lübbers *et al.* 2000a). These sound velocity data have been complemented by recent data-from inelastic x-ray scattering and in the very high-pressure regime by those from shock waves and in the low-pressure regime by those from neutron scattering.

### *2.2 Applications to Nano-structured Material*

The understanding of magnetism of self-organized nano-structures and clusters gained much attention because of fundamental aspects of nanoscale magnetic ordering in general and possible applications in high-density magnetic storage and magnetoelectronics.

#### *(a) Iron on W (110)*

As an example the perpendicular spin orientation in ultrasmall Fe islands on W (110) will be discussed (Röhlsberger *et al.* 2001). Ultrasmall pseudomorphic Fe islands on an atomically clean W (110) crystal have been prepared by thermal evaporation of Fe enriched to 95% in $^{57}$Fe. The coverage of the Fe islands was 0.57 which is slightly below the percolation limit. Their average diameter was determined to be 2.0 nm. A coating of five monolayers of Ag prevents the sample from contamination. Figure 7 left panel displays the time spectra taken in grazing incidence geometry between 300 K and 4.5 K. The right panel of Fig. 7 shows the determined weight of the magnetic component. It increases with decreasing temperature. This can be attributed to superparamagnetic relaxation of the magnetic moments. At high temperatures the magnetization of small particles is subject to fast thermal fluctuations so that the effective magnetic hyperfine field averages to zero. The transition from the fast relaxation regime to the magnetically ordered state occurs at about 50 K. However, it is a very broad transition certainly due to the size distribution of the islands. The modulation in the time spectra is characteristic for a perpendicular magnetization. This result is quite remarkable because Fe films on W (110) are known to be magnetized in-plane for coverages of more than 0.6.

#### *(b) Exchange-coupled thin films*

Exchange-coupling between soft- and hard-magnetic phases (see *Multilayers: Interlayer Coupling*) plays an important role in the engineering of novel functional magnetic nanostructures. There exist some micromagnetical models describing this behavior (see *Magnets: Remanence-enhanced*), however, due to methodological difficulties there exist nearly no direct measurements of the actual spin structure. Utilizing the technique of probe layers, i.e., inserting $^{57}$Fe in various depths of the thin film (see Fig. 8),

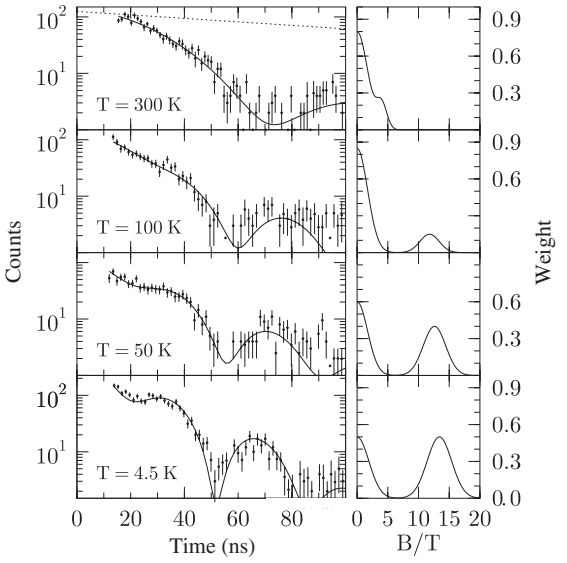

***Figure 7***
Time spectra of nuclear resonant grazing-incidence reflection from ultrasmall $^{57}$Fe islands on W (110). The modulation of the intensity is attributed to a perpendicular magnetization of the Fe islands. The solid lines are the results of simulations. The right panel displays the probability density for the hyperfine field distribution that was obtained from the simulations (reprinted figure with permission from Röhlsberger *et al.* (2001); © by the American Physical Society).

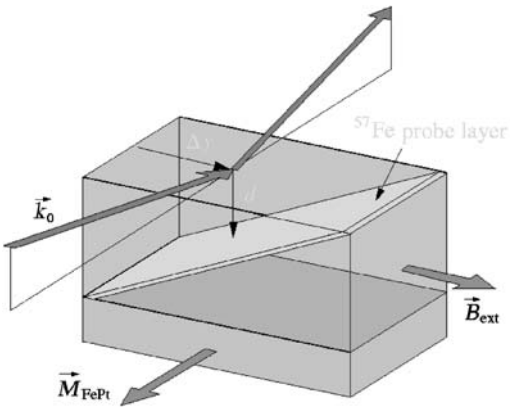

***Figure 8***
Scattering geometry of the sample (11 nm Fe on FePt). The incoming x-ray beam with wavevector $\vec{k}_0$ impinges the sample at a lateral position $\Delta y$ probing the spin structure via the wedge-shaped $^{57}$Fe probe layer (0.7 nm) at depth $d$ (reprinted figure with permission from Röhlsberger *et al.* (2002); © by the American Physical Society).

NRS directly probes the actual spin structure in various depths by selectively exciting the $^{57}$Fe layer at various lateral positions (Röhlsberger *et al.* 2002). The sample investigated here is a bilayer system consisting of 11 nm Fe on 30 nm $Fe_{55}Pt_{45}$ in the hard-magnetic tetragonal $L1_0$ phase. A wedge-shaped 0.7 nm thick $^{57}$Fe film with a slope of 0.5 nm/mm has been produced. Different depths d in the sample can thus be probed by adjusting the displacement $\Delta y$ of the sample transversely to the incident beam. The sample was magnetically saturated in an external field of 2.3 T so that the remanent magnetization $\vec{M}_{FePt}$ of the $Fe_{55}Pt_{45}$ layer was oriented along $\vec{k}_0$, as shown in Fig. 8. Time spectra at 4 K with selected in-plane external fields $\vec{B}_{ext}$ perpendicular to $\vec{k}_0$ were taken at various displacements of $\Delta y$. Evaluation of the spectra reveals the depth dependence of the rotation of the magnetization in the Fe film (see Fig. 9).

### *2.3 Applications to Disordered Systems*

NRS techniques are well suited for the investigation of the dynamics of disordered systems over a huge timescale. Whereas NIS covers the fast regime of phonons, NQES techniques complement the investigations to the slow time regime ($10^5$–$10^{10}$ Hz). The technique of probe molecules allows for the investigation of glasses which do not contain Mössbauer atoms and, furthermore, when carefully chosen, allows for mode selectivity as collective and noncollective modes, respectively. In the following example, the glass forming dibutyl phthalate (DBP), with a glass temperature $T_g = 178$ K, was investigated by NFS (sensitive to translational and rotational dynamics) and SRPAC (sensitive only to rotational dynamics) (Sergueev *et al.* 2003). Ferrocene was used as probe molecules. NFS spectroscopy is applicable as long as the Lamb–Mössbauer factor $f_{LM}$ is greater than zero, which holds in this case up to 210 K. SRPAC, on the other hand, does not depend on $f_{LM}$ and can be applied in the entire temperature regime (see Fig. 10). At the lower temperatures, the SRPAC intensity follows an exponential decay modulated by quantum beats. In the regime of slow relaxation, the beats are damped at a rate proportional to rotational relaxation (see Eqn. (4)). Similar quantum beats modulate the decay of the NFS intensity, where the damping depends on the sum of rotational and translational relaxation (see Eqn. (2)). At higher temperatures, in the regime of fast relaxation, only SRPAC spectra can be measured. From these spectra relaxation rates have been determined. Below 190 K the data sets from both techniques coincide, which means that translational dynamics is absent in the experimental time window. Above 190 K the NFS data begin to deviate from the SRPAC data because translational dynamics is activated. From these results the pure translational relaxation rates have been derived.

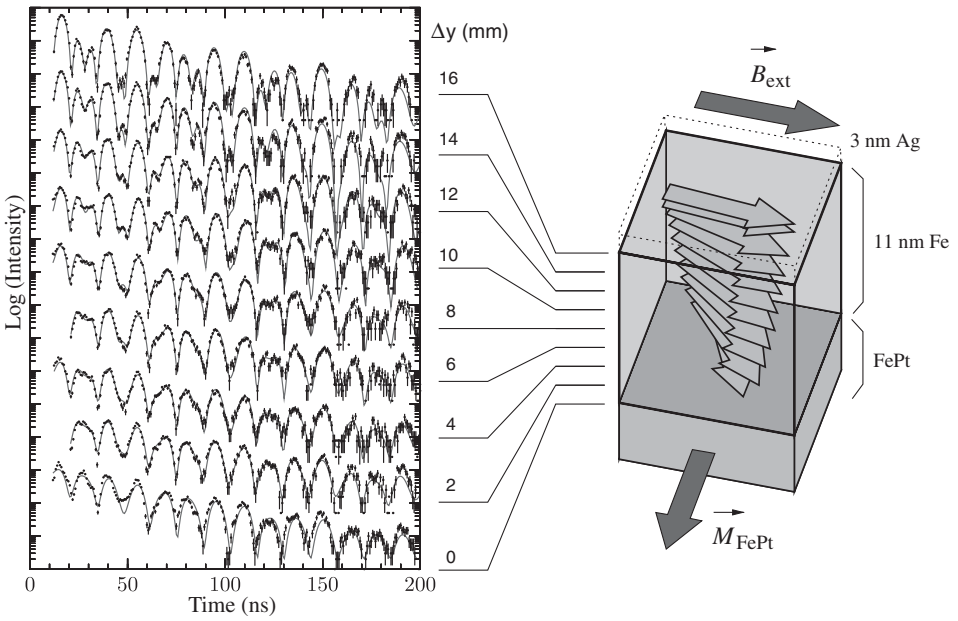

***Figure 9***

### *2.4 Summary*

With the advent of powerful synchrotron radiation sources around the world as APS (Argonne, USA), SPring-8 (Harima, Japan), and ESRF (Grenoble, France) nuclear resonance scattering techniques became a rapid growing spectroscopy with unique applications in various fields. The probe molecule/layer technique, the application of sophisticated sample environments, and the possibility of applying various NRS techniques simultaneously makes this spectroscopy a unique tool. The previous typical examples demonstrate the versatility and huge potential of the technique. Even when these examples focused on $^{57}$Fe for the sake of simplicity the tunable (in energy) synchrotron radiation allows for a convenient and routine access to various Mössbauer isotopes.

## Optical and Magneto-optic Data Storage: Channels and Coding

The data path of an optical recording system is effectively a communications channel with certain bandwidth and noise characteristics. Data to be recorded must pass through this channel and, on replay, must emerge unaltered. The vehicle to navigate the data through the channel is a recording code (also known as a modulation code or channel code). The recording code converts data to an appropriate format to pass through the channel and be recovered as the original data on replay.

The frequency response of the channel falls off sharply at high frequencies. Therefore, if the signal representing "raw" data contains high-frequency components then these will not be recorded. Because the binary data to be recorded cannot be predicted it is likely that the signal representing the data contains a broad spectrum of frequencies ranging from very low to very high. Consequently, the recording code converts the frequency spectrum of the signal to be recorded to a form that matches the response of the recording channel.

An important function of a recording code is to enable the regeneration of a timebase for effective re-timing of the signal during playback. There will be differences between the speed of the disk during record and playback. It is essential, therefore, to have a timebase signal that is accurately synchronized to the rate at which data are read from the disk. In effect, the recording code combines the data to be recorded with a clock signal on recording. At replay the clock signal is extracted and used to control a phase-locked-loop circuit that provides the timebase.

For a given channel bandwidth the correct choice of code can increase storage density above that of an uncoded system. A common coding technique is "non return to zero immediate" (NRZI): binary one is represented as a signal-level transition and zero as no transition. However, there is a limit to how close transitions can be packed together in an attempt to increase storage density. Too close and their mutual proximity begins to affect the ability of the detection scheme to resolve them. The recording code introduces constraints that define the separation of transitions. Consequently, for a given track length, a greater number of code bits can be stored compared to data bits. Although it takes more code bits to represent a given number of data bits, i.e., the code rate is less than one, the result is a higher data-recording density.

### *1. Bandwidth*

The upper cut-off frequency of an optical-disk channel is a function of the laser wavelength ($\lambda$), the track velocity ($v$) and the numerical aperture (NA) and is given by $2\mathrm{NA}v/\lambda$, (Heemskerk and Immink 1982). Since the laser-spot diameter ($D$), is equal to $0.5\,\lambda/\mathrm{NA}$ (Bouwhuis *et al.* 1985) the cut-off frequency becomes $v/D$. The number of bits that can be stored on a disk depends on the size of the laser-spot and is approximately equal to $nA/D^2$, where $A$ is the area of the disk and $n$ is the number of bits that can be resolved within the spot. This latter variable can be maximized through proper selection of recording code.

Whilst, in principle, the channel response extends down to d.c. it is prudent to limit its response at the lower frequencies. This minimizes the adverse effect that the low-frequency power components in the replayed signal may have on the laser servo system. Also, to reduce the effect of disk-surface blemishes, which can detrimentally affect the replay signal, it is necessary to employ a high-pass filter in the replay channel that removes the lower frequencies. Other considerations are the use of transformers, which do not pass d.c. levels, in the replay channel.

### *2. d, k Constraint*

One function of the code is to ensure that there are never long periods of time during which there are no transitions or that transitions do not occur too close together. These codes are classed as run-length limited (RLL).

The minimum distance between two transitions is the $d$ constraint, whilst maximum distance is $k$. The $d$ and $k$ values determine the performance of the code. Ideally $d$ should be low to permit high-density recording but, given a finite laser-spot size, $d$ cannot be so low that it cannot be resolved. Also, intersymbol interference (ISI) and inter-track cross-talk increase with reducing $d$. The constraint value $k$ cannot be too large since frequent changes in the replayed signal are necessary to synchronize a timebase that re-times the replayed data.

The $d$,$k$ constraints of a code can be represented by a finite-state transition diagram (FSTD) (Shannon 1948; Franaszek 1970). Figure 1 is an FSTD for a code with constraint 1,3. The dotted paths in the diagram represent no level change in the code; solid lines represent a level change, either zero to one or one to zero. In moving from one state to another it is seen that there must be at least one zero and a maximum of three zeros between two changes.

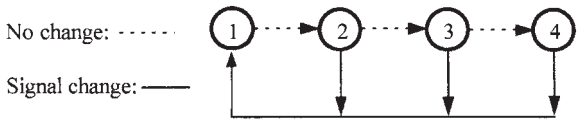

***Figure 1***
Finite-state transition diagram for 1,3 *d*,*k* constraint.

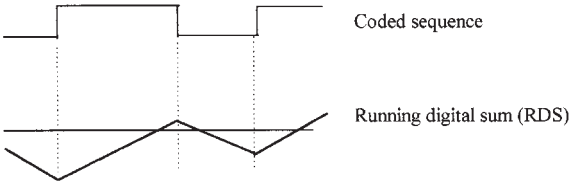

***Figure 2***
Running digital sum (RDS) of coded sequence.

## 3. Channel Capacity

The maximum rate, $R$, at which information can be transmitted reliably through a channel is limited by the channel capacity $C$. The capacity of a channel perturbed by white noise is given by Shannon (1948):

$$C = W\log(1 + P/N)\text{bits}\,\text{s}^{-1} \qquad (1)$$

Where $W$ is bandwidth and $P/N$ is signal-to-noise ratio. For $R < C$, information may be transmitted at an arbitrarily low error rate. The actual error rate for high $R$ is governed by the quality of the channel and the ingenuity of the coding scheme employed.

Shannon also defined capacity for a discrete noiseless channel in units of user bits per channel bit (Shannon 1948):

$$C = \lim_{T\to\infty} \log_2 \frac{N(T)}{T} \qquad (2)$$

where $N(T)$ is the number of allowed signals of duration $T$. This reduces to $\log_2 \lambda$ where $\lambda$ is the largest root of the equation $\lambda^{k+1} - \lambda^{k-d} - x + 1 = 0$ and $d$ and $k$ are the constraint parameters of the code defined above. The equation is derived from a consideration of the finite-state-timing diagram (FSTD) of the code and its associated state transition matrix (Siegel 1985, Immink *et al*. 1998).

In a recording code, $m$ data bits are mapped into $n$ code bits to give a code with rate $R = m/n$, where $m/n \leqslant 1$. The maximum theoretical code rate is known as the capacity of the code. The efficiency of a code is usually measured in terms of how near to $C$ the actual rate is.

## 4. Code Spectra/Equalization

Data to be recorded will be derived from a number of diverse sources and, as such, cannot be predicted. The various patterns of bits that are likely can be simulated, however, using a pseudorandom binary sequence (PRBS). If the PRBS is long it will contain virtually all the binary combinations that the recording system is likely to encounter. Assuming such a random sequence of data, the frequency spectrum of the ensuing coded sequence is useful in assessing code performance. Since the optical channel response falls off rapidly at high frequency, the high-frequency components of a code's spectrum should be low. Also, the low-frequency components should have low amplitude with a null at d.c.

Some codes are not absolutely d.c.-free: there may be a slight dc component that will vary with the sequence of the signal being recorded. A measure of the d.c.-content in the coded signal is the running digital sum (RDS). The RDS is the running integral of the coded signal, assuming $+1$ is integrated when the signal is high and $-1$ when it is low (Fig. 2). The RDS is effectively the arithmetic sum of the area under the graph of the integral; this should be kept low for efficient operation. The digital sum variation (DSV) represents the limits of the RDS graph. The d.c. content of a code is said to be bounded provided the DSV does not extend to infinity.

A closer match between the response of the channel and the spectrum of the code may be achieved through equalization. Equalization is the process of modifying the channel's frequency response or changing the spectral content of the signal to be recorded to more closely match the response of the channel. Here, the channel is taken to include the write and read electronics. One technique is to include a filter in the channel to shape the spectrum of the code.

## 5. Examples of Code

In the two-thirds rate code of Horiguchi and Morita (1976) two data bits are represented by three code bits. The *d*,*k* value is (1,7), which gives a code capacity of 0.679.

The code adopted for the audio compact disk (CD) specification (and for the mini-disk) is known as eight-to-fourteen modulation (EFM) (Heemskerk and Immink 1982). In EFM, eight data bits are coded into 14 code bits. However, in order to control the d.c. content of the code, three merging bits are added after the coding process to produce a coded symbol 17 bits long—hence the true rate is 8/17. Whilst the merging bits minimize the DSV, the *d*,*k* value of (2,10) is maintained.

An improved version of EFM, EFMPlus (Immink 1995) has been adopted for the digital versatile disk (DVD). This has the same *d*,*k* value as EFM but the rate is higher at 8/16. Eight data bits are coded into codewords of 16 bits using a look-up table of

codewords. Rather than using merging bits to control d.c. content, substitute codeword sequences are available at the encoder as an alternative to the main table of codewords. During the encoding process, codewords are taken either from the main look-up table or from the substitute table in order to keep the DSV at a minimum. The reduction of one bit in the codeword yields an improvement of 6–7% in information density compared to the EFM code.

## 6. Signal Detection

The basic method of determining the binary value of the replayed analogue signal is to employ peak detection. With peak detection the replayed signal is compared with a level threshold and a binary value registered accordingly. This is satisfactory for low to medium density systems but if the storage density was to be increased, inter-symbol interference would cause signal distortion in the replayed signal. This distortion would severely impair the detection process. For very high-density systems, therefore, partial response maximum likelihood (PRML) (Siegel 1991) is usually employed. In a PRML scheme the channel response is tightly controlled. This tight control permits the ISI-induced signal distortion to be predicted, thus enabling the corresponding binary values to be determined in line with the replayed signal.

With peak detection a great deal of information is wasted once the decision process is made. A more effective, albeit more complex, method is maximum likelihood detection. The principle behind maximum likelihood detection is that all possible sequences of replayed signal are known to the detector. As each sequence is replayed it is compared to all the known sequences: the one with the best match is the one most likely to be the correct one. A disadvantage is that for a reasonably long replayed sequence the detection process would take too long. Viterbi detection (Viterbi 1967) is a maximum likelihood detection algorithm that reduces detection time by comparing the replayed signal sequence ''on-the-fly.'' Reserved judgements are made on sections of the replayed signal as to the likelihood of it representing a certain bit pattern. The decision to incorporate certain combinations of bits in the detected sequence depends not only on the current signal being decoded but also on previous evaluations: the $k$ constraint of the recording code can be used to force decisions. The result is a detector that gives superior performance compared to peak detection.

## 7. Comments

The classical work on communications channels by Shannon can be applied to optical recording systems, since the latter is effectively a transmit-now, receive-later communications system. Unlike a communications system, however, the signal power of a recording system cannot be increased indefinitely in order to improve performance.

A binary-data signal comprises two related components: amplitude and time. These must be replicated faithfully on replay to reconstitute the recorded signal: this is a function of the recording code. A further requirement of a code is to increase storage density. However, the dual goals of achieving high density together with reliable timebase regeneration are contradictory. Hence, many codes have been developed in an attempt to resolve these contradictions. The code designer must balance the storage gains to be delivered by a code against the need for reliable operation and cost of implementation.

The signal that is ultimately recorded is derived from the information data, to which has been added data for error correction, timing, synchronization, and sundry other purposes. There is no one ''supreme'' code with all the best characteristics: many different recording codes are in use, each designed for a specific application. No small consideration is the practical implementation of a code.

The recording codes in general use are single-dimension codes, where a serial sequence of data is coded. In an attempt to resolve the contradictory requirements of a code, two-dimensional codes have been examined (Davey *et al*. 1998). These codes capitalize on the areal format of recorded data. Mutually related information is encoded in two dimensions. This information is recovered at replay to support effective detection. This concept can be extended further to a third dimension. Such codes may be suitable for application to multilayer disks such as the current DVD, which has two layers, and future generations that may possibly have many layers.

## Permanent Magnet Assemblies

Modern permanent magnets are ideally suited to generate magnetic fields of magnitudes comparable to their spontaneous polarization, $J_s$. These fields can be static or variable, uniform or nonuniform. They are generated by permanent magnet structures that demand no continual expenditure of energy for their operation, and dispense with the elaborate cooling systems required by resistive or superconducting electromagnets. Furthermore, the permanent magnet assemblies are compact and can offer the significant advantage of flux confinement in the region of interest. Permanent magnets are now competitive with electromagnets for generating fields of up to about 2 T. More generally, when a high field with a rapid spatial variation is required, they may offer the only practicable solution.

The polarization, $J$, of a modern hard magnet (Skomski and Cugat 1999) deviates little from its remanent or saturation value, $J_s$, far into the second quadrant of the hysteresis loop, before switching at the coercive field, $H_c$ (see *Rare Earth Magnets: Materials*, *Magnets: Sintered*). The plot of the polarization of the magnet as a function of the magnetic field, $H$, acting on it is almost rectangular in shape, as indicated in Fig. 1. The intrinsic spontaneous polarization of $SrFe_{12}O_{19}$ is 0.47 T, for example, and that of $Nd_2Fe_{14}B$ is 1.61 T. Values of the remanent polarization of typical sintered magnets are given in Table 1. They are typically 10–20% less than the spontaneous polarization of the pure hard phase due to imperfect crystallite alignment and the presence of secondary phases necessary to develop coercivity. The magnetic flux density, $B$, is related to the $H$-field (magnetizing force) and polarization by $B = \mu_0 H + J$ so that in free space, where $J = 0$, the relation between $B$ and $H$ is simply $B = \mu_0 H$.

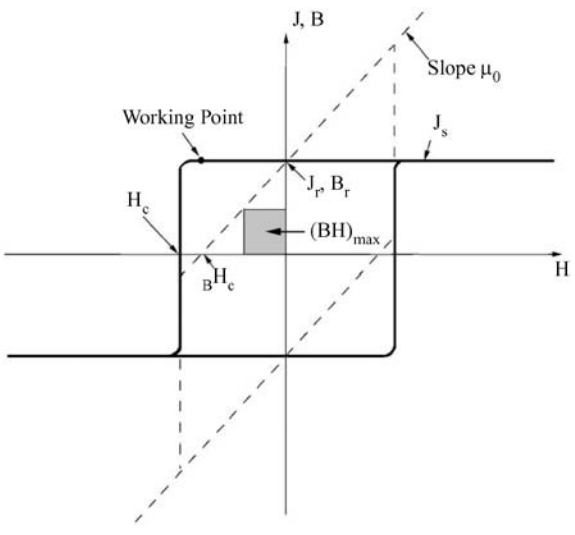

***Figure 1***
The $J(H)$ hysteresis loop of an ideal permanent magnet. The corresponding $B(H)$ loop is shown by the dotted line. $(BH)_{max}$ is indicated by the area of the shaded region.

The purpose of any permanent magnet assembly is to deliver magnetic flux into a region of space adjacent to the magnet known as the *airgap*, creating a magnetic field, $B_g(r)$, in this region. Maximum energy product, $(BH)_{max}$, defined on the $B$:$H$ loop of Fig. 1, is equivalent to twice the energy stored in the field in the airgap, $(1/2\mu_0)\int B_g^2 d\tau$. The energy product provides a convenient measure of the efficiency of the magnet material for generating airgap fields. In the case of an ideal rectangular hysteresis loop with $\mu_0 H_c > J_r/2$, the maximum possible energy product, $(BH)_{max}$, is $J_r^2/4\mu_0$.

In the structures described below, the airgap is often a cylindrical cavity surrounded by magnets. The fields achieved in the airgap scale with, but are not limited by the polarization of the magnets. Ideally, the field generated is the product of a geometric constant, $K(r)$, for the structure and the remanence of the magnet, $J_r$.

$$K(r) = B_g(r)/J_r \tag{1}$$

When $K > 1$, the magnetic structure achieves flux concentration.

Permanent magnet structures are produced by assembling blocks of rare-earth magnets (see *Magnets: Sintered*) or ferrite magnets (see *Alnicos and Hexaferrites*; *Ferrite Magnets: Improved Performance*) in any desired orientation. These magnets with their wide, rectangular hysteresis loops have the property that the field of one magnet does not significantly perturb the magnetization of its neighbors. The magnet blocks behave essentially as if they are rigid and transparent. This follows because the longitudinal susceptibility is zero for a rectangular hysteresis loop; the slope of the $B(H)$ curve is $\mu_0$, as for free space.

The transverse susceptibility, $J_s/\mu_0 H_a$, is only of order 0.1, since the anisotropy field, $H_a$, is much greater than the magnetization (Table 1). Hence, for example, the directions of magnetization of two blocks of $SmCo_5$ in contact with their easy-axes perpendicular will deviate by less than a degree from the easy-axes. The assumption of rigidity and transparency of the magnetization greatly simplifies the design of magnetic circuits. Errors in the calculated airgap

***Table 1***
Properties of typical oriented sintered ferrite and rare earth magnets.

| Compound | $T_C$ (°C) | $H_a$ (MA m$^{-1}$) | $J_r$ (T) | $H_c$ (MA m$^{-1}$) | $(BH)_{max}$ (kJ m$^{-3}$) | $T_{max}$ (°C) |
|---|---|---|---|---|---|---|
| $BaFe_{12}O_{19}$ | 450 | 1.1 | 0.41 | 0.27 | 34 | 300 |
| $SmCo_5$ | 720 | 32 | 0.88 | 1.70 | 150 | 250 |

flux density arising from this approximation are usually no more than a few percent.

Permanent magnet structures have been devised to generate fields that are uniform, nonuniform, or time varying.

### *1. Uniform Fields*

It is not quite obvious that a permanent magnet can be used to generate a uniform field, as the magnetic field produced by a small bar magnet or point dipole of moment, $m$ (A m$^2$), is nonuniform and anisotropic as shown in Fig. 2(a). This field at a general point $r(r, \theta, \phi)$, relative to the axis of the dipole is given in polar co-ordinates as

$$H_r = 2m\cos\theta/4\pi r^3; H_\theta = m\sin\theta/4\pi r^3; H_\phi = 0 \quad (2)$$

Both the magnitude and direction of $H$ depend on $r(r,\theta,\phi)$. Nonetheless, a uniform field may be achieved over some region of space by assembling segments of magnetic material, each magnetized in a different direction, such that their individual contributions combine to yield a field which is uniform in some confined region.

One approach is to build the structure from long segments whose fields approximate those of line dipoles of length, $L$, and dipole moment, $\lambda$ (A m), per unit length. The field due to such a line dipole, in the limit of infinite length, is given by

$$H_r = \lambda\cos\theta/2\pi r^2; \; H_\theta = \lambda\sin\theta/2\pi r^2; \; H_\phi = 0 \quad (3)$$

Thus the magnitude of $H$, $\sqrt{(H_r^2 + H_\theta^2 + H_\phi^2)}$, at a distance, $r$, from each segment is actually independent of $\theta$, while its direction everywhere makes an angle, $2\theta$, with the orientation of the magnet as shown in Fig. 2(b).

By assembling a long, cylindrical magnet with a hollow bore from many individual segments, it is possible to create a field which is uniform within the bore. By choosing the orientation of each segment appropriately, their individual fields will all add at the center of the bore. Such segments can be assembled according to many different prescriptions. Some designs are shown in Fig. 3. The efficiency, $\varepsilon$, of a particular cylindrical magnet structure generating a uniform field in an airgap of cross-section, $A_g$, is defined as

$$\varepsilon = K^2 A_g / A_m \quad (4)$$

where $A_m$ is the magnet cross-section and $K$ (Eqn. (1)) is now independent of $r$. A reasonably efficient structure has $\varepsilon \approx 0.1$. The theoretical limit on $\varepsilon$ is 0.25 (Jensen and Abele 1996).

In the transverse field design shown in Fig. 3(a), the outer surface is an equipotential with no perpendicular stray field outside the surface and the flux density in the airgap is $0.293B_r$ provided $t/r = \sqrt{2}-1$. Multiples of this field can be obtained by nesting similar structures, each with the same $t/r$ ratio, one inside the other. These designs find application in nuclear magnetic resonance imaging (MRI). Highly homogeneous fields (better that one part in $1 \times 10^5$) are required for NMR applications. The generated fields must be shimmed with small magnets or pieces of soft ferromagnetic material in order to meet this specification. Also popular for NMR applications is the design shown in Fig. 3(b), which consists of two flat cuboid magnets and a soft iron return path (such a return

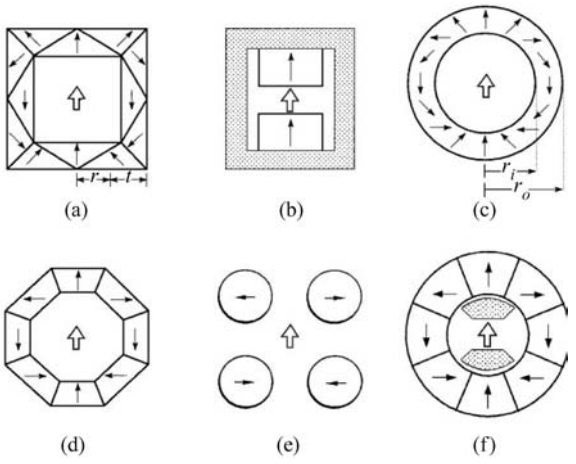

***Figure 3***

path is often referred to as a *yoke*). Permanent magnet flux sources supply fields of order 0.3 T in whole-body scanners for medical imaging. NMR spectrometers with permanent magnets flux sources are also beginning to be used for quality control in the food, polymer, and construction industries.

Figure 3(c) illustrates another design, known as the *Halbach cylinder* or *dipole ring*, where the direction of magnetization at any point in the cylinder is at $2\theta$ from the vertical axis, and its magnitude remains constant at all points. In the case of a cylinder of infinite length, this configuration yields a uniform magnetic field in the $y$ direction within the cylinder bore. The flux density in the airgap is given by Eqn. (1) with

$$K = \ln (r_o/r_i) \tag{5}$$

where $r_i$ and $r_o$ are the inner and outer radii of the cylinder, respectively. Unlike the structure of Fig. 3(a), the radii, $r_i$ and $r_o$, can take any values without creating a stray field outside the cylinder.

In practice a continuously varying magnetization pattern is not easily achieved. A more common approach is to approximate the ideal configuration with a finite number, $N$, of uniformly magnetized segments as illustrated in Fig. 3(d) for $N = 8$. In this case, the field is reduced by a factor, $[\sin(2\pi/N)]/(2\pi/N)$, which is included on the right-hand side of Eqn. (5). However, cylinders with as few as eight segments can still generate 90% of the ideal field.

As a further approximation to the ideal design, the cylinders are never infinitely long; their length, $z$, is typically comparable to their diameter. The geometrical constant, $K$, in Eqn. (4) is further reduced by an amount (Zijlstra 1985)

$$\Delta K = (z/2)[1/z_o - 1/z_i] + \ln ((z + z_o)/(z + z_i)) \tag{6}$$

where $z_o = (z^2 + r_o^2)^{1/2}$ and $z_i = (z^2 + r_i^2)^{1/2}$. For example, the flux density at the center of an octagonal cylinder with $r_i = 12$ mm, $r_o = 40$ mm, and length 80 mm made of a grade of Nd–Fe–B having $B_r = 1.20$ T is actually 1.25 T, compared to the value of 1.44 T calculated from Eqns. (1) and (5). Note that the flux in the airgap exceeds the remanence in a circuit which uses no iron, which illustrates the idea of magnetic flux concentration.

These cylindrical structures are useful for producing fields in bores ranging in diameter from a few millimeters to several hundred millimeters. Large structures, like that shown in Fig. 4, are used for industrial-scale materials processing and space-based experiments.

Soft iron can be introduced into a permanent magnet circuit either to provide a return path for the flux (Fig. 3(b)), or to concentrate the flux in the airgap (Fig. 3(f)), thereby creating a larger uniform field in a smaller volume. The field generated by the permanent magnet structure should be sufficient to saturate the soft segments. Pure iron ($J_s = 2.15$ T) or permendur ($J_s = 2.43$ T) may be used. In no case can the additional flux density exceed the polarization of the soft material, and in typical structures it will only be a fraction of this value, depending on the segment shape.

Assemblies composed of pairs of magnetized wedges allow great flexibility in the shape of the cavity while offering efficiencies comparable to those of Halbach cylinders (Jensen and Abele 1999).

A different simplification of the basic structure uses transversely magnetized cylindrical rods, as shown in Fig. 3(e) (Coey and Cugat 1994). This allows both longitudinal and transverse access to the cavity. The geometrical constant at the center for a set of $n$ rods, which are just touching, is

$$K = (n/2)\sin^2(\pi/n) \tag{7}$$

By increasing $n$, the central region in which the field is uniform is enlarged, but the magnitude of the field itself is reduced.

Uniform fields can also be generated in spherical cavities using the same principles as for cylindrical cavities (Leupold 1996). A uniform field is generated in a spherical cavity when the magnitude of the polarization of a volume element in a hollow spherical magnet structure is kept constant, but its orientation varies as $(2\theta,\phi)$ where $(r,\theta,\phi)$ are its polar

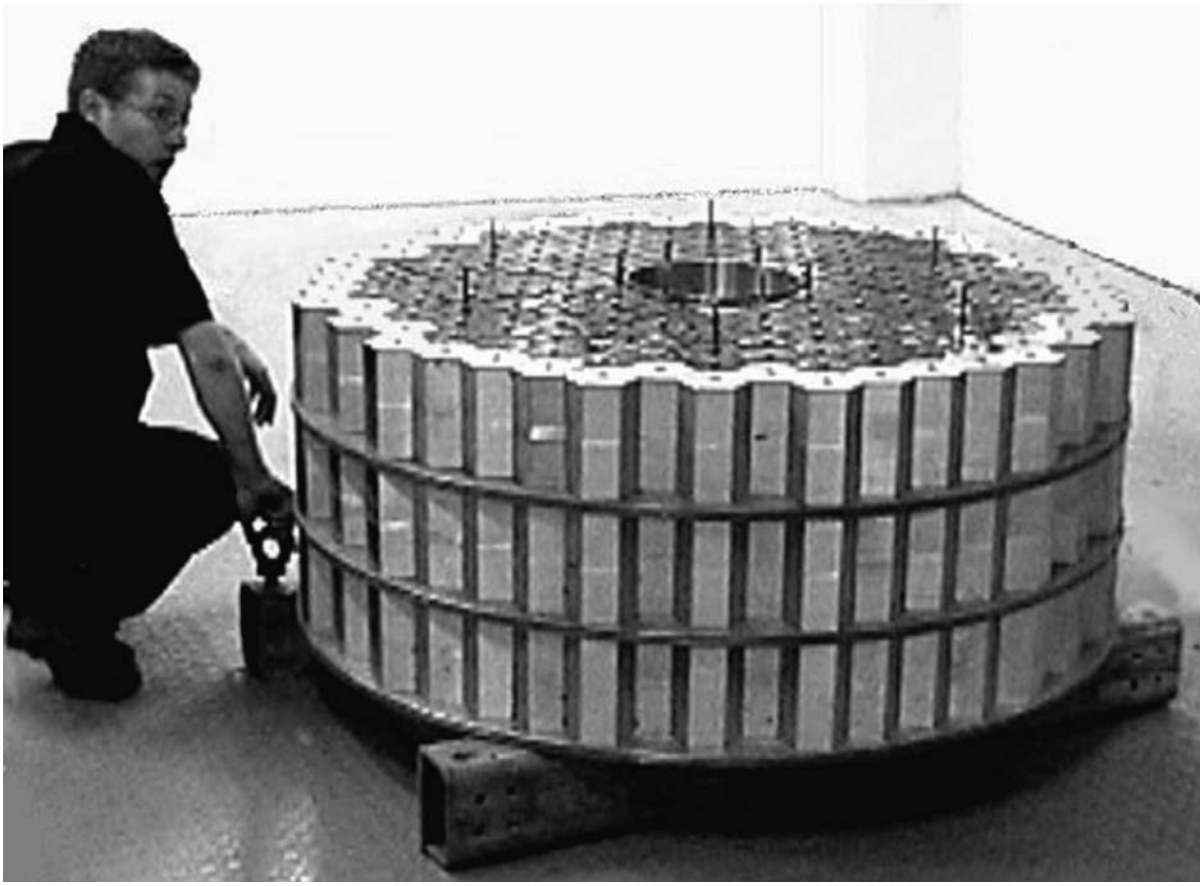

***Figure 4***

coordinates. The resulting geometric constant is

$$K = (4/3)\ln(r_o/r_i) \tag{8}$$

The field is one-third higher than for a Halbach cylinder of comparable dimensions. Access to the field is by diametral holes bored into the central space, which do not perturb the field significantly provided their radius is less than $r_i/4$. An example is illustrated in Fig. 5.

The upper limit to the fields that can be generated using permanent magnets is about 5 T. This is set in part by the coercivity of the material, as the vertical segments in Fig. 3 are subject to a reverse $H$-field equal to the field in the bore. But there is also a practical size limitation imposed by the exponential increase in dimension of Eqn. (5). Admitting a material existed with $B_r = 1.5\,\mathrm{T}$ and $\mu_o H_c = 5\,\mathrm{T}$, the outer diameter required to achieve 5 T in a 25 mm bore would be 700 mm. Such a structure of 400 mm in height would weigh about 1 t.

## 2. *Nonuniform Fields*

The ability of rare-earth permanent magnets to generate complex flux patterns with rapid spatial variation ($\nabla B > 100\,\mathrm{Tm}^{-1}$) is unsurpassed by any electromagnetic device. The solenoid needed to generate a field equivalent to that of a long magnet with $J \sim 1\,\mathrm{T}$, would require an Amperian surface current of about $800\,\mathrm{kAm}^{-1}$. Whether resistive or superconducting, it would have to be several centimeters in diameter in order to accommodate the requisite ampere-turns. No such limitations exist for permanent magnet dimensions.

The cylindrical configurations of Fig. 3 may be modified to produce a variety of inhomogeneous

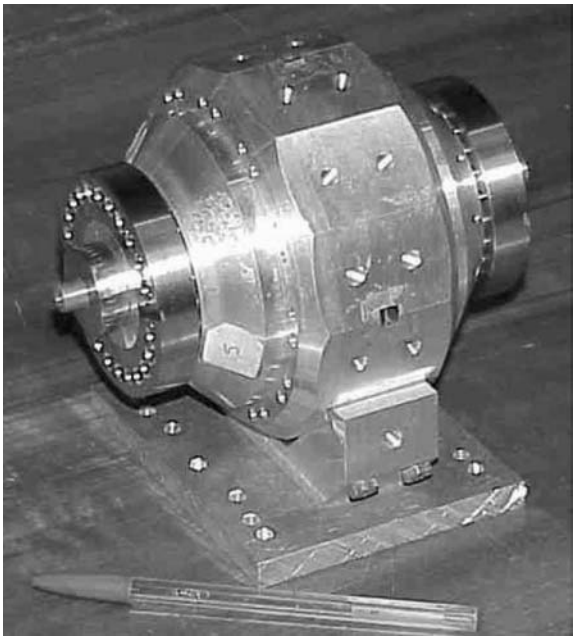

*Figure 5*
A spherical permanent magnet structure that produces a field of 4.5 T in a spherical cavity of diameter 2 mm (after Cugat and Bloch 1998).

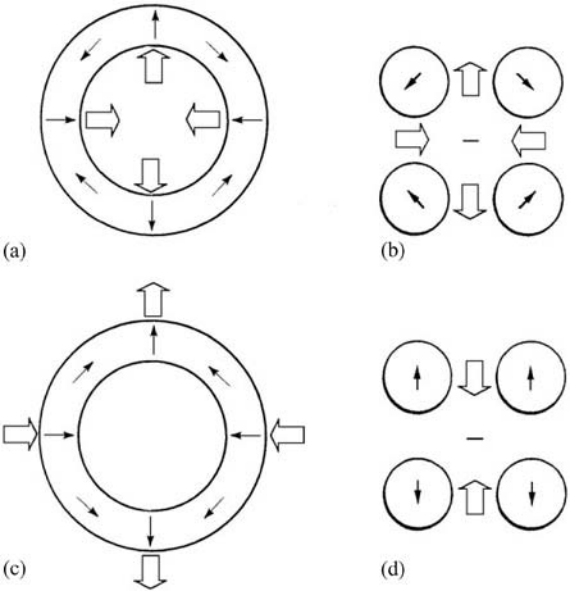

*Figure 6*
Cross-sections of some permanent magnet structures that generate nonuniform magnetic fields: (a) and (b) a quadrupole field, (c) an external quadrupole field and, (d) a field gradient.

fields. Some examples are shown in Fig. 6. Multipole fields such as quadrupole fields are particularly useful for charged-particle beam control (Halbach 1980). Various multipole fields are generated by having the orientation of the magnets in the ring vary as $(1 + (n/2))\theta$, where $n = 2$ for a dipole field (Fig. 3(c)), $n = 4$ for a quadrupole field (Fig. 6(a)), $n = 6$ for a hexapole field and so on. The field at the center of the quadrupole is zero, but whenever the particle beam deviates it experiences an increasing field which causes its trajectory to curve back to the center. A simplified four-rod structure, which also produces a quadrupole field, is shown in Fig. 6(b).

A different type of permanent magnet structure creates an inhomogeneous magnetic field along the axis of the magnet, which may be the direction of motion of a charged particle beam. Microwave power tubes such as the travelling wave tube are designed to keep the electrons moving in a narrow beam over the length of the tube and focusing them at the end while coupling energy from an external helical coil. Originally this was achieved by applying a uniform axial field from a resistive solenoid, but the design with permanent magnets focusing by a periodic axial field in Fig. 7(a) is just as effective, and represents a great saving in weight and power when $SmCo_5$ magnets are used.

One period of the structure in Fig. 7(a) generates an axial gradient field, also known as a *cusp* field.

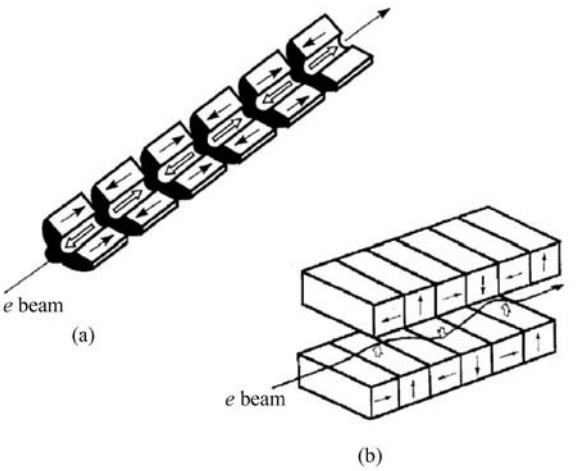

*Figure 7*
Permanent magnet structures that create spatially varying magnetic fields for particle beam control. (a) A microwave power tube and (b) a wiggler magnet for synchrotron radiation.

Uses of these fields include the stabilization of molten metal flows.

Insertion devices for generating intense beams of hard radiation (UV and x-ray) from energetic

electron beams in synchrotron sources use a periodic transverse field. These devices are known as *wigglers*, since they cause the electrons to travel in a sinuous path. Similar assemblies are used in free-electron lasers. A design, which includes segments alternately magnetized in parallel and antiparallel directions to concentrate the flux, is shown in Fig. 7(b).

A variant of the normal multipole Halbach configuration is the external Halbach configuration where the orientation varies as $(1-(n/2))\theta$. The multipole field is then produced outside the cylinder. The case of $n=4$ (illustrated in Fig. 6(c)) produces a quadrupole field outside the cylinder and zero field inside. The external Halbach designs are useful for the rotors of permanent magnet electric motors.

Other arrangements of cylindrical magnets (Fig. 6(d)) produce a uniform magnetic field gradient along a particular direction. Field gradients are especially useful for exerting forces on other magnets, or on paramagnetic or diamagnetic material. The force on a magnet of moment, $m$, is $F=-\nabla(m.B)$ whereas the expression for a nonferromagnetic material is $F=-(1/2\mu_0)\chi V\nabla B^2$, where $V$ is the sample volume and $\chi$ is the susceptibility. Field gradients of the order of $100\,\mathrm{Tm}^{-1}$ producing separation forces of the order of $1\times10^8\,\mathrm{Nm}^{-3}$ are used in open gradient magnetic separators to sort ferrous and nonferrous scrap or select minerals from crushed ore on the basis of their magnetic susceptibility.

Some magnetic levitation schemes exploit the nonuniform fields produced by permanent magnets. Diamagnetic material can be levitated against gravity when $\nabla B^2$ is of the order of $100\,\mathrm{T}^2\mathrm{m}^{-1}$, which can be achieved with permanent magnets in volumes of the order of $1\,\mathrm{mm}^3$. A magnet can remain suspended in the vertical field gradient of another magnet provided it lies between two horizontal diamagnetic plates.

Many types of contactless bearings and couplings use permanent magnet structures (Yonnet 1996). The linear bearing illustrated in Fig. 8(a) provides levitation along a track, but lateral constraint of the suspended member is required. It is impracticable to equip a great length of track with permanent magnets. Thus, levitation of vehicles may be provided by repulsion from eddy currents generated in a track of metal plates, or by attraction of the magnets on the vehicle to a suspended iron rail. The simplest rotary bearings are made of two ring-shaped magnets in repulsion. Some configurations (Fig. 8(b)) provide radial restoring force provided the axis is prevented from shifting or twisting. Others support a load in the axial direction (Fig. 8(c)), but must be prevented from moving in the radial direction. Magnetic bearings are simple, cheap, and reliable. They are best suited to high-speed rotary suspensions as in flywheels or turbopumps.

Figure 8(d) shows the design of a simple rotary coupling and Fig. 8(e) is a magnetic gear. These are useful for transmitting motion across the wall of a chamber operating in vacuum or in an aggressive environment. Forces in bearings and couplings depend quadratically on the remanence of the magnets, so it is advantageous to select material with a large polarization and a large coercivity, in case of slippage. Torques of the order of 10 Nm may be achieved in couplings a few centimeters in dimension.

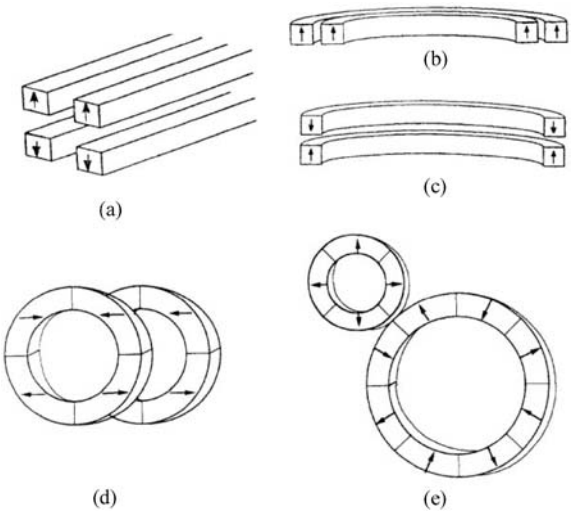

***Figure 8***
Some magnetic bearings and couplings: (a) is a linear bearing, (b) and (c) are rotary bearings, (d) is a rotating coupling, and (e) is a magnetic gear.

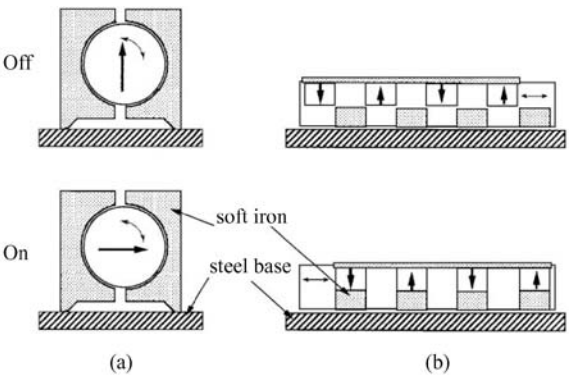

***Figure 9***
Two designs for switchable magnets.

## *3. Variable Fields*

Fields can be varied by changing the airgap, or by some movement of the magnets in a structure with respect to each other. The working point is displaced

as the magnets move. A simple type of variable flux source is a switchable magnet (Fig. 9). These are often used in holding devices, where a strong force is exerted on a piece of ferrous metal in contact with the magnet. The working point shifts from the open circuit point to the remanence point where $H = 0$ as the circuit is closed. The maximum force that can be exerted at the face of a magnet of area $A_m$, where the flux density is $B_m$, is $A_m B_m^2/2\mu_0$. Forces of up to $40\,N\,cm^{-2}$ can be achieved for $B_m = 1\,T$.

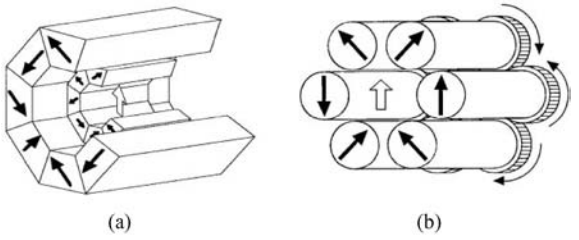

***Figure 10***
Structures for producing continuously variable magnetic fields. (a) A nested pair of Halbach cylinders and (b) a rotating mangle.

Simple force applications in catches and closures consume large amounts of sintered ferrite. Polymer bonded ferrite magnetized in strips of alternating polarity with a pitch of about 2 mm is widely used for fixing signs and light objects to steel panels.

To create a variable uniform field, two Halbach cylinders of the type shown in Fig. 3(d) each with the same radius ratio can be nested one inside the other, as shown in Fig. 10(a) (Leupold 1996). Then by rotating them through an angle, $\pm\alpha$, about their common axis, a variable field, $2\cos\alpha J_r \ln(r_o/r_i)$, is generated. There would be no torque needed to rotate two ideal Halbach cylinders, but in practice some torque arises from the segmented structure and end effects (Ní Mhíocháin *et al*. 1999).

Another solution is to rotate the rods in the device of Fig. 3(e), as demonstrated in Fig. 10(b) (Cugat *et al*. 1994). By gearing a mangle with an even number of rods so that the alternate rods rotate clockwise and anticlockwise through an angle, $\alpha$, the field varies as $B_{max}\cos\alpha$. Further simplification is possible with a magnetic mirror, a horizontal sheet of soft iron containing the axis of symmetry that produces an inverted image of the magnets, halving the number of rods required. The torque needed to vary the field in a mangle increases with a decreasing

***Figure 11***
A 2.0 T permanent magnet flux source based on the structure of Fig. 10(a) (photo by courtesy of Magnetic Solutions Ltd).

number of rods. A movable axial field gradient can be achieved with nonuniformly magnetized rods (Grönefeld 1998).

These permanent magnet variable flux sources are compact and particularly convenient since they can be driven by stepping or servo-motors and they have none of the high power and cooling requirements of a comparable electromagnet. For example, the flux source illustrated in Fig. 11 uses 20 kg of Nd–Fe–B magnets of the design shown in Fig. 10(a) to generate fields up to 2.0 T in a 25 mm bore. Large rotating or alternating fields can be generated by continuously rotating the magnets. Permanent magnet variable flux sources are expected to displace resistive electromagnets to generate fields of up to about 2 T, but they cannot compete with superconducting solenoids in the higher field range.

### *4. Concluding Remarks*

Permanent magnet structures are well suited to generate uniform fields, which are static or variable, as well as multipole field patterns and field gradients with rapid spatial variation. The advantages of permanent magnets are their compactness and energy efficiency—no power supplies or cooling systems are required. Their limitations lie in the maximum fields that they can generate which are determined by the remanence and coercivity of existing permanent magnet materials. Remanences of currently available grades of rare-earth magnets are in the range 0.9–1.4 T. There is little prospect that future materials development will extend the upper limit beyond 2 T.

The field produced by any permanent magnet structure scales with remanence from Eqn. (1). Designs with $K \sim 1$ are compact and efficient, and can achieve flux concentration, but designs with $K > 1.5$ are inefficient in the sense that the ratio of the volume of the magnet to the volume of the cavity increases exponentially with $B_g$.

The practical limit to the fields that can be generated with permanent magnets is about 5 T. For fields in the range 2 mT to 2 T, a permanent magnet assembly is often the best solution. Fields variable in both magnitude and direction are obtained by somehow rotating the magnets, as in the nested Halbach cylinder systems or in the magnetic mangle. In this field range, permanent magnet flux sources are set to replace the venerable iron-core electromagnet.

As regards spatially varying fields, static field gradients, $\nabla B$, of up to 100 $\mathrm{T\,m^{-1}}$ or more can be achieved with permanent magnets in very small volumes. Here there is no electrical solution to rival the Amperian surface currents associated with a magnetization of order 1 $\mathrm{MA\,m^{-1}}$.

## Permanent Magnet Materials: Neutron Experiments

The crystallographic and magnetic properties of materials exhibiting hard magnet characteristics can be simultaneously analyzed by the use of neutron scattering techniques. After an introduction to the different structural, microstructural, and magnetic parameters that are determining factors for optimal intrinsic and extrinsic magnetic properties, the main principles of neutron scattering, both nuclear and magnetic aspects, are discussed in detail in this article. Specific techniques are reviewed, together

with pertinent examples underlining the advantages of neutron scattering.

Modern, powerful hard magnetic materials are of metallic type. They are based on compounds combining the magnetic characteristics of transition metals and rare-earth metals, mainly cobalt or iron combined with samarium, neodymium, or praseodymium. In the crystal structures of these magnetic compounds, the densest sublattice (d elements) provides a high magnetization and supports strong exchange forces, resulting in a high Curie temperature. As important is the less dense rare-earth metal sublattice that couples ferromagnetically with cobalt or iron in the case of the light 4f elements and which provides strongly anisotropic crystal electric field (CEF) parameters, forcing to a marked easy axis behavior of the magnetic structure (see *Localized 4f and 5f Moments: Magnetism* and *Alloys of 4f (R) and 3d (T) Elements: Magnetism*).

In all cases, more than these two elements are needed to stabilize the hard magnetic main phase (e.g., boron in $Nd_2Fe_{14}B$, nitrogen in $Sm_2Fe_{17}N$, etc.) or to stabilize a highly coercive microstructure (e.g., multiphase systems as in the complex Sm(Co–Fe–Cu–Zr)$_{8.5}$ magnets) (see *Rare Earth Magnets: Materials*). Either the atomic long-range ordering that defines the crystal structures or the microcrystalline aspects of the multiphase systems must be measured in combination with the magnetic structure ordering parameters (strength and orientation of the moments, crystal field terms, etc.) and critically analyzed before the highest level of properties can be developed.

Many different techniques are used systematically to obtain the best knowledge of both the intrinsic and the extrinsic properties of the intermetallic or interstitially modified materials showing potentially good magnetic performances. These techniques are chosen specifically, over a wide range of analyses, to characterize bulk magnets (material at gram and centimeter scales), to check the micrometric to submicrometric range of properties (multiphase structures, domain structure), to study the impact of dense arrangements (atoms, coordination) from the nanoscale to the bond scale, or to perform spectroscopic analysis of the orbital (ground) states. Indeed there are many more possible investigation methods, tools, and techniques that can be used to characterize magnetic materials. However, because of wide application ranges, neutron scattering techniques appear to be highly valuable for the systematic characterization of the crystal as well as the magnetic ordering parameters, on the basis of the typical and multipurpose aspects of the interaction of neutrons with atoms and their magnetic moments.

## 1. Neutron Scattering, Sources, Principles, and Characteristics

Two main types of generators have been developed for the production of intense neutron beams (typically $10^{10}$–$10^{14}$ neutrons $s^{-1}$). The so-called conventional reactor is based on the continuous fission process of $^{235}U$ nuclei ($\sim 2$ MeV) with an excess of neutrons of about 1 for 2.5 emitted if a critical mass of fissile core is used. In the pulsed type of source, neutrons are produced from heavy atoms (Pb, $^{238}U$, etc.) by strongly accelerated ($\sim 1$ GeV) pulses of protons (spallation source). For example, very short pulses (100 μs) of 20–40 neutrons per proton are radiated periodically (10 ms). In all cases, the neutron energy (velocity) is moderated within appropriate materials. Reactor-type neutron sources are installed worldwide.

The most powerful one is the European HFR-ILL at Grenoble, France. Only a few machines of the pulsed type are operating (in the USA, the UK, Russia, and Japan), with ISIS at Didcot, UK, being the most powerful one. In this article, rather than focusing on the respective merits of each type of neutron generator, the critical differences in the use of neutrons for scattering within materials are discussed. From the Maxwellian shape of the energy spectrum issued from the source, in most cases a monochromatic neutron beam has to be selected by using crystalline monochromators or by creating kinetically controlled pulses by speed selectors (e.g., wheel-choppers). The multifaceted nature of the neutron takes advantage of the physical characteristics as expressed in Table 1.

Owing to these fundamental equivalences, for a neutron beam of wavelength $\lambda = 1.8$ Å, i.e., suitable for scattering in crystalline compounds (interatomic distances of 1–2 Å), the neutron speed is 2200 $ms^{-1}$ and the energy is 25 meV, corresponding to an equivalent temperature of 300 K. Hence, these neutrons are called thermal neutrons. At low temperature ($T \sim 20$ K) a moderator placed close to the reactor core allows for the use of so-called cold neutrons with a longer wavelength of 30–50 Å. A high-temperature ($T > 2000$ K) target allows for neutrons with a shorter wavelength of less than 0.4 Å.

The first interaction of neutrons with matter (which is not the most interesting one from the point of view of magnetic properties) consists of a nuclear

resonance and capture phenomenon, represented by an absorption cross-section, $\sigma_a$. Except for some isotopes ($^{113}$Cd, $^{157}$Gd, $^{164}$Dy, etc.), for most elements the corresponding cross-section remains negligible. It should be noted that the absorption is minimal far from the resonance energy.

The two main scattering processes of thermal neutrons in solid-state materials that exhibit magnetic properties are of the dipolar type.

The first process is nuclear scattering. This results from the interaction of the neutron spin, $n_s = \frac{1}{2}$, with the nuclear spin, $I$. The corresponding nuclear potential is effective at a distance of the same magnitude as that of the nucleus dimensions. Two intermediate scattering lengths, $a_+$ and $a_-$, are associated with the final states $I+\frac{1}{2}$ and $I-\frac{1}{2}$. Together they establish the coherent part of the scattering length $b_c = a_+(I+1)/(2I+1) + a_-(I)/(2I+1)$ and the incoherent part $b_i = (a_+ - a_-)/(2I+1)$. Practically, the coherent scattering process in combination with structured multicentered materials yields discrete intensities depending on the structure factor that is determined by the atomic arrangement. These scattering intensities can interfere constructively, whereas the incoherent scattering, which has isotropically distributed diffuse intensities, cannot interfere. However, considering the dynamic diffusion of a light element (e.g., hydrogen as a proton), incoherent scattering by this particle can be analyzed using a time and position resolving technique.

The second process is magnetic electron scattering. This results from the interaction of the neutron spin with the spin, **s**, and orbital, **l** (if any), vectors attached to the electrons. It can be described in terms of the total atomic spin, $S$, and orbital, $L$, components. The diffusion length is $f_M = 2m/\hbar^2(\mathbf{M}_n \wedge \mathbf{e}) \cdot (\mathbf{M}_e \wedge \mathbf{e})$, where **e** is the unit vector and $\mathbf{M}_n$ and $\mathbf{M}_e$ are the magnetic moments of the neutron and the electron, respectively, along the scattering vector (e.g., perpendicular to the diffraction plane). The magnetically scattered amplitude strongly depends on the orientation of the easy magnetic axis in relation to the normal of the diffraction plane (in-plane vs. out-of-plane components of the moments). If the magnetic field is strong enough to align the moments along the scattering vector, the magnetic contribution to diffraction can vanish.

If the neutron beam polarization level is $\boldsymbol{\sigma}_n$ (e.g., as diffracted on a ferromagnetic single-domain single crystal), coherency effects can be observed between both the nuclear and the magnetically scattered waves. This can be expressed by the total cross-section:

$$\sigma_t = b_c^2 + p_M^2 q^2 - 2 b_c p_M \mathbf{q} \cdot \boldsymbol{\sigma}_n$$

where $p_M$ is proportional to $f_M$ and **q** is the scattering vector.

There are several important peculiarities to point out. Because of the point-type potential of the nuclear interaction, the nuclear cross-section of diffusion results in a quasi-constant diffusion (Fermi) length. Since it is a nuclear characteristic (isotope characteristic), very large differences exist between the elemental Fermi lengths, revealing marked contrasts, e.g., for crystal structure determination. Successive d (and f) metals are different from each other and, in the same manner, most of the interstitial light elements are good scatterers. Table 2 compares selected cross-section amplitudes (Sears 1984).

Contrary to the nuclear scattering, the magnetic scattering related to the magnetic electron density, i.e., the magnetic scattering cross-section, decreases with the momentum transfer, $Q$, well approximated by Gaussian profiles (Brown 1992), which may reveal localized to itinerant aspects of the electron density. For a completely disordered moment distribution (paramagnetic state with no short-range correlations), independent of the initial polarization state of the beam, a diffuse magnetic (incoherent) scattered intensity is found that adds to the nuclear contribution. For a polarized neutron beam, successive measurements of the scattered intensity for two states of polarization (up and down, the scattering vector being horizontal) allow one to determine very accurately the spatial spin density, if the nuclear crystal structure is known. It should be noted that, if the magnetic structure exhibits unpolarized components, a depolarization effect is induced that can be successfully adopted in the polarization analysis technique to detect weak deviations from ferromagnetism.

The scattering processes as described above are of the elastic type (no energy exchange). Since the kinetic energy of thermal neutrons is of the same order of magnitude as that of the excitation processes of matter (phonons, atom diffusion, magnons, crystal field levels, etc.), inelastic scattering experiments can provide valuable information on the correlation energies or the dynamics of atom movements. Inelastic scattering leads to a change (initial to final states) of the neutron energy, where the opposite energy corresponds to the phonon or magnon frequency change $h\omega$. $\mathbf{Q} = \mathbf{k}_f - \mathbf{k}_i = 2\delta\mathbf{R} + \mathbf{q}$ allows one to localize scattered neutrons with a typical intensity given by a double differential (space and energy resolved) scattering cross-section. **Q** is the scattering vector, **R** a reciprocal lattice vector, **q** the wave vector of the excitation, and $\mathbf{k}_i$ and $\mathbf{k}_f$ are the initial and final wave vectors. For such purposes, an analyzer is placed behind the sample to check the spatial and energy dispersion profile.

## 2. *Applications of Neutron Scattering to Hard Magnetic Materials*

Except for anomalously absorbing nuclei, the penetration depth of neutrons is particularly large (a few centimeters), several orders of magnitude larger than

for x rays (micrometers). It is worth noting that large samples and thick-walled sample holders and vessels can be used, for example, to investigate fundamental as well as extrinsic magnetic properties, even those sensitive to external pressure, high temperature, corrosion, etc. Examples selected from the literature are discussed below, in order to illustrate the multiple applications of neutron scattering to magnetic materials.

### *2.1 Crystal Structure Determination*

#### *(a) Powder diffraction*

Neutron diffraction on powdered samples is a powerful technique that allows in most cases for the determination of the crystal structure of the compound more easily than by using x-ray powder diffractometry, owing to the excellent contrast in the scattering cross-sections, as shown in Table 2. For such purposes, it is recommended to use a high-resolution neutron diffractometer that consists of banks of a large number of individual detectors equipped with selective collimators. The crystal structure of $Nd_2Fe_{14}B$, especially the position of the light boron, was solved for the first time (Herbst *et al*. 1984) using neutron diffraction on a powdered sample. Parallel to this, the crystal structure was also solved by using x-ray single-crystal four-circle diffractometry (Shoemaker *et al*. 1984, Givord *et al*. 1984). The location of light hydrogen (deuterium) atoms inserted in four types of adjacent tetrahedral sites in $Y_2Fe_{14}BD_{4.8}$ was determined by means of a good-resolution position-sensitive neutron detector (Fruchart *et al*. 1984).

The scheme of the successive filling of the sites, that was found later to depend on the nature of the rare-earth element, was determined using a geometrical model that allowed the prediction of the maximum hydrogen uptake. When the interstitial ternaries $R_2Fe_{17}X_x$ (R = rare earth; X = C, N, H) were found to exhibit potentially high magnetic performances, neutron diffraction on powdered samples was the unique technique to ascertain the position and the stoichiometry ($x$) of the light element. From volumetric or barymetric gas absorption experiments, it was suggested for a long time that particularly large amounts of X elements (up to nine for hydrogen, up to six for carbon and nitrogen) can be inserted into the 2-17 metal lattice to improve the Curie temperature, the magnetization, and other magnetic properties. From neutron diffraction experiments, it was definitively shown that, at maximum, three carbon or nitrogen and 5 (= 3 + 2) hydrogen atoms per formula unit occupy well-defined 2R–4Fe octahedral sites,

two extra hydrogen atoms occupying smaller 4R–3Fe tetrahedral sites (Isnard *et al.* 1990).

This was confirmed by Koyama and Fujii (2000) for $N_2Fe_{17}N_3$. It is also of interest to analyze the cell parameter expansion, not only on light element insertion but also when other elements are substituted for iron in order to modify the bond lengths. The location of these elements as a function of their concentration provides interesting arguments for a better understanding of the modification of the bulk magnetic characteristics that are volume dependent. This has been systematized for titanium, cobalt, manganese, gallium, silicon, etc., establishing reliable schemes of substitution (Mishra *et al.* 1996).

For some resonantly absorbing elements (dysprosium), either the use of a two-wall cylindrical sample holder at $\lambda = 1-2.5$ Å or the use of very short wavelengths ($\lambda = 0.5$ Å) gives the most convenient conditions to record rather good data on powdered samples, e.g., gadolinium or samarium.

### *(b) Single-crystal diffractometry*

The most precise technique to use for crystal structure determination is four-circle diffractometry. However, this requires rather large single crystals. Spheres of 1.5–2.5 mm in diameter of $R_2Fe_{14}B$ (R = Y, Nd, Ho, Er) have been cut by spark erosion from large crystals and systematically studied by neutron diffraction. Precise information about the atomic positions and interatomic distances has been obtained for these dense iron compounds (Wolfers *et al.* 1996). Ancillary equipment can be used to perform experiments under special external conditions, e.g., very low or high temperatures, uniaxial stress, or high pressures.

### *(c) Small-angle and diffuse scattering*

The small-angle neutron scattering (SANS) technique using long neutron wavelengths (10–20 Å) allows one to investigate intermediate-size domains in the structure, for example, as formed by segregation effects. Only a few examples using SANS have been reported, e.g., the segregation rates of cobalt and copper in $Sm(Co–Cu)_5$ alloys that markedly influence the intrinsic and extrinsic hard magnetic properties of the binaries. In the $RFe_5Al_7$ series, a clustering tendency of iron is evident from classical powder diffraction experiments by the analysis of diffuse scattering phenomena, since the atomic clustering influences the magnetic correlation scheme (Schäfer *et al.* 1994).

## *2.2 Magnetic Structure Determination*

Neutron powder diffraction is a convenient technique for the measurement of the local magnetic moment characteristics. The higher the counting rate, the better are the refined values. For such a purpose, an instrument typically has a position-sensitive detector (PSD) providing a high counting rate at a sufficiently long wavelength that enables one to record the significant magnetic source signal within the aperture of the detector array. At HFR-ILL, Grenoble, and at LLB, Saclay, there are optimized instruments allowing one to measure diffraction patterns with a high statistic in the time range of minutes up to a few hours. It is recommended to record at least one high-resolution diffraction pattern in a large range of **Q** spacings using a dedicated diffractometer that provides precise crystal structure parameters. Moreover, the excellent counting rate of the banana-type PSD allows one to perform time- and temperature-resolved experiments in order to determine accurately the changes in the magnetic moments, e.g., for $R_2Fe_{14}B$ (R = Nd, Ho, Er), as well as for $RFe_{12-x}T_x$ (R = Dy) in the range of the Curie temperature or possible spin reorientation temperatures (SRTs).

When single crystals are available, the four-circle technique remains by far the best for detailed crystal and magnetic structure determinations, as demonstrated for the $R_2Fe_{14}B$ series (R = Y, Nd, Ho, Er) (Wolfers *et al.* 1996). After appropriate corrections (e.g., absorption or multidomain corrections), precise fittings to the data (several thousand recorded Bragg peaks) lead to detailed pictures of almost ferromagnetic but noncollinear magnetic structures accompanied by the small-atom displacements (and crystal symmetry lowering) related to the important magnetoelastic forces existing in these compounds.

Another method, polarized neutron diffraction (PND), can be used to investigate the magnetic structure of truly ferromagnetic and very large single crystals, e.g., $Y_2Fe_{14}B$ (Givord *et al.* 1985). With this technique, and in the case where the data collection statistics are good enough, a Fourier transformation allows one to plot spin density projections, thus revealing local but weak magnetic polarization effects or temperature-induced changes of density moment setting on cobalt atoms in $ThCo_5$ (Givord *et al.* 1977).

Using thermal neutrons it seemed impossible to analyze the magnetic structures of one of the archetypal magnetic compounds, $SmCo_5$. However, using short wavelengths of 0.4–0.5 Å, in order to reduce the nuclear absorption, precise PND experiments have allowed the calculation of the magnetic form factors of cobalt and samarium, the latter being very different at 4 K and 300 K: the samarium moment is much smaller at room temperature than at low temperature (Givord *et al.* 1979). Further analyses show that the form factors of $L$ and $S$ type show quite different radial shapes for samarium. Accounting for the opposite orbital and spin contributions in the magnetic moment of samarium yields an anomalous thermal behavior with a crossover temperature estimated as 350 K. Modeling of the appropriate Hamiltonian, considering the large exchange forces and the mixed

CEF multiplets of the samarium ground state, allows one to determine exchange and CEF parameters from a fit to the experimentally obtained form factors. Furthermore, the exchange field and the second-, fourth-, and sixth-order CEF parameters have been calculated, respectively, as $175 \pm 25$ K, $-200 \pm 50$ K, $0 \pm 50$ K, and $50 \pm 50$ K (Givord *et al.* 1979), which are in good agreement with values deduced from magnetization experiments and corresponding calculations.

For the parent compound $YCo_5$, a PND study has permitted the determination of the origin of a very large magnetocrystalline anisotropy, which is not related to the nonmagnetic yttrium but to one of the two cobalt sites ($Co_{II}$), which exhibits a particularly high orbital contribution and is attributed to its peculiar and asymmetric environment (Schweizer and Tasset 1980).

### 2.3 Magnetic Excitations

Dynamic excitation spectra have been recorded for different series of intermetallics belonging to the different classes of hard magnetic materials. For the $R_2Fe_{14}B$ series of materials, inelastic neutron scattering (INS) was first performed on powder samples (Loewenhaupt *et al.* 1988). For R = Y and Ce, only phonon scattering is identified. For R = Nd, Dy, and Er, resonances of magnetic origin are observed. These are attributed to magnon-like excitations for the latter two compounds, since they markedly increase with temperature (dominant Zeeman field, negligible CEF). For the neodymium compound, two well-defined and equivalent peaks (22 meV and 36 meV) are assigned to the two nonequivalent neodymium sites in terms of CEF effects. From the thermal dependence, it is concluded that the neodymium moment corresponding to the larger CEF signature is poorly affected by the SRT, contrary to the other neodymium site that is sensitive to SRT conditions as sharing the weakest CEF level. This approximate model cannot be considered to agree well with the accurate magnetic structure determination (Wolfers *et al.* 1996) refined from single-crystal data collection.

Subsequent INS experiments on $Nd_2Fe_{14}B$ single crystals (Mayer *et al.* 1992) did not show the existence of lines at 22–36 meV. However, low-energy lines (magnon dispersion) were analyzed on the basis of torque effects acting on the magnetic moments driven by effective exchange and anisotropy fields. The authors proposed a strong influence of long-range interactions in relation to an itinerant character of the iron magnetism.

The $R_2Zn_{17}$ compounds are isotypic with the magnetic $R_2Co_{17}$ compounds. However, owing to the simplest magnetic situation (here only R is magnetic), the CEF excitations were analyzed first (Garcia-Landa 1994). In the low-energy region ($< 15$ meV) several peaks were confirmed to be of CEF origin; then the noninteracting spins were described using a pure CEF model. For R = Er, ($T_{SR} = 1.4$ K, $T_N = 1.6$ K) a set of CEF parameters was determined, of which the dominant one is the negative second-order term of less than 2 K, thus agreeing with a magnetically easy plane behavior.

Magnetic excitations have been investigated in detail in some $R_2T_{17}$ compounds (T = transition metal) (Clausen and Lebech 1982). The spin wave dispersion relationships have been interpreted with a linear spin model comprising a Heisenberg exchange term and single-ion CEF anisotropy terms. Experiments performed on $Dy_2Co_{17}$ single crystals using the IN8-ILL spectrometer (Colpa *et al.* 1989) have been analyzed using a complete Hamiltonian with respect to the R–R exchange interaction, which is often considered negligible if compared to the T–T and R–T ones. Since there are some discrepancies between the assignment of a highly dispersive mode that is associated with the Co–Co exchange forces, both the exchange and the CEF characteristic energies have been deduced. For $Dy_2Co_{17}$, the values are: $J_{TT} \sim 200$ K, $J_{RT} \sim 25$ K, $J_{RR} \sim 0.2$ K, $CEF_R$ parameters $\sim 28$ to 6 K, and T-anisotropy parameter $\sim 6$ K. They are in good agreement with the high-field magnetization fittings (Givord *et al.* 1977) as compared to those obtained by NPD for $SmCo_5$.

### 2.4 Atom Dynamics

The quasielastic neutron scattering (QNS) technique based on space and time self-correlation of a single nucleus, which is supposed to move within the compound, is practically restricted to studying either the motion processes of this nucleus (e.g., hydrogen) or the fast rotation of some molecules. This becomes possible owing to a very high incoherent scattering length. For the present purposes, it can be used to analyze the living time of a proton within interstitial sites and the related energy of hopping. A typical application could be the analysis of the diffusion mode of protons, i.e., during either the hydrogen decrepitation or the HDDR (hydrogen decomposition–dehydrogenation–recombination) processes (diffusion, nucleation, wall interface mechanisms, etc.) (see *Magnets: HDDR Processed*). The analysis of the data could be somewhat difficult owing to the rather large unit cell and the multiple and different interstitial sites. However, the questions concerning the diffusion mechanisms have been partly solved, as explained below.

### 2.5 Phase Transformation Analysis from Resolved Diffraction Experiments

So far only structural and magnetic fundamental trends of the main compounds forming magnet

materials have been considered. However, magnetic properties are much improved by particularly fine-designed microstructures resulting from well-defined thermal or mechanical treatments. *In situ* neutron diffraction experiments performed with PSD instruments with high counting rates have allowed the determination and optimization of chemical and physical treatments leading to the best extrinsic properties. Some typical examples are given below.

Temperature- and time-dependent neutron diffraction experiments confirm the maximum hydrogen uptake in the $Nd_2Fe_{17}H_x$ unit cell, and its distribution onto the two accessible sites (tetrahedral and octahedral types). The preferential chemical attraction favors the larger and space repartited octahedrons (Isnard *et al*. 1990). The cell parameter expansion is determined and the behavior of a critically short Fe–Fe distance is refined. A clear correlation between the hydrogen occupation rates of the sites is established, the corresponding changes of the Fe–Fe distances and the nonlinear increase of the Curie temperature have been attributed to an increase of the exchange parameters.

Similar experiments performed with hydrides (deuterides were chosen to avoid the strong incoherent scattering of hydrogen), as well as with carbides and nitrides, allow the assertion of the existence of an extended solid solution in the 2-17 and 1-12 hydride and carbide phase diagrams and a two-phase behavior in nitrides (Fruchart *et al*. 1994).

Using a dedicated sample holder connected to a hydrogen (deuterium) cylinder and gas pressure sensors, time (kinetics), pressure level (or vacuum), and temperature (slopes and plateaus) dependent neutron diffraction experiments have been performed. For example, they permit the analysis of the structural aspects and the chemical phase transformations when the HDDR route is applied. This process is one of the most powerful ways to form a strongly coercive microstructure in micrometer-sized powders as used for bonded magnet technology (Liesert *et al*. 1997).

Neutron diffraction using PSD techniques is well suited to reproduce the high-temperature thermal and annealing treatments on real magnetic materials. *In situ* experiments permit the correlation of known dilatometric results with phase and structure transformations in bulk materials. Finally, using a high counting rate PSD, such as the D20 diffractometer at ILL, one can extract significant crystal structure and kinetic information in reasonable times even from only a tiny amount of material (a few micrometers thick), e.g., surface corrosion of material at moderate temperature, under specific atmospheres.

### 2.6 *Texture and Microstructure Analysis of Magnets*

Cradle circle equipment can be used to analyze the texture parameters (relative grain orientation of the main phase). The orientation of the grains is a critical parameter to form fully anisotropic magnets, thus providing high levels of induction, i.e., large energy products. Texturing of microcrystalline assemblies can be achieved by using different routes depending on the final state (use) of the magnet. The well-known fully dense sintered magnets are treated at a high temperature under high stress (see *Magnets: Sintered*). A preferential orientation of isotropic microcrystalline particles can be achieved by die up-setting and high-temperature fast forging (see *Textured Magnets: Deformation-induced*).

Neutron diffraction texture analysis is a good tool for examining the surfaces as well as the core of large samples (sampling size of a few cubic millimeters) after the material submitted to high stress. Different types of magnetic material can be checked using texture analysis. Using this technique, it has been shown for Nd–Fe–B materials, that fast forging at high temperature is very efficient in order to align most of the microcrystallite axes along the forging direction. These axes are initially in-plane aligned as a result of the book-mold procedure used during cooling the magnet material (Rivoirard *et al*. 2000). Moreover, the effectiveness of the metallurgical procedure is correlated to a ductile-to-brittle phase transformation and to rheological phenomena existing in the range 850–950 °C.

### 2.7 *Laue and Reflectometry Methods*

The white-beam technique of the Laue method should be mentioned. Again, owing to the excellent penetration ability of the neutron, the Laue method can be efficiently used to analyze macro- and micro-ordered materials. The first obvious use of a neutron diffraction Laue setup is to control the quality and the orientation of a single crystal within its full volume before other investigations (INS, PND, four-circle, etc.). With one exposure many details of large parts of the reciprocal space can be analyzed and evidence of, for example, twins, defects, dislocations, and strain fields can be obtained. The same method has been used to determine the temperature, magnetic field, and even pressure dependence of magnetic domains up to the limit of resolution of the camera film, i.e., a few micrometers (Tanner *et al*. 1992).

Because new materials are designed for integrated purposes and the needs of densified media for recording (e.g., using hard magnetic compounds), materials science is more and more concerned with nanoscale samples. Neutron reflectometry is a very interesting technique not only for providing information on the quality of thin-layer samples (crystalline and magnetic roughness) but also for analyzing the interface magnetic coupling, the superstructure magnetic ordering reflecting the competition between exchange forces, polarization effects via conduction

electrons, or large magnetocrystalline anisotropy of interfaces. As the scattered signals are of nuclear or magnetic origin, or both, the effectiveness of magnetic reflectometry takes advantage of polarized neutron beams and polarization analysis techniques.

## 3. Conclusion

Scattering methods using thermal neutrons are particularly well suited to deliver unique information on magnetic materials, and more particularly on those expected to show potential as high-performance magnets. Such magnetic materials are composed of transition and rare-earth metals, but often also contain further elements in rather small amounts. The large dimensional range (from electrons or orbitals to micro- and centimeter scales) can be treated using a very wide range of powerful techniques. This allows not only the characterization of static parameters, but also of dynamics and excitation phenomena, thus effectively providing typical energies. Both aspects are associated with the intrinsic quantities, such as magnetization, exchange forces, and CEF strengths.

Many extrinsic but critical quantities can also be analyzed, especially those being relevant for chemical procedures, processes, microstructure optimization, etc. The multipurpose neutron scattering techniques as such have no equivalent, especially because of their efficiency in depth penetration, contrary to x-ray techniques. Owing to the increasing neutron fluxes and to the correspondingly improved detection techniques, more and more detailed information can be obtained. Hence, either microintegrated materials or microstructured functional materials can be investigated to satisfy the interest in these materials. It can be very fruitful to combine the neutron investigation methods as described here with more conventional, laboratory-scale techniques to support the production of new, hard magnetic materials.

## Permanent Magnetic Devices in Otiatria

Inflammatory diseases of middle ear often result in partial or complete destruction of its sound conducting elements: perforation of tympanic membrane, damage to or destruction of ossicles (hammer, anvil, stirrup) (Fig. 1; Kobrak *et al*. 1963, Wullstein *et al*. 1972, Williams and Rouf 1978, Ferris *et al*. 1998, Kuvnetsov *et al*. 2001). This typically leads to significant deterioration or complete loss of hearing. Prosthesing of such miniature elements in a narrow passage, while preserving the physiological level of signal transduction and protecting the inner ear from overloading, is a challenging task for the surgeon and imposes rigorous requirements on materials for such prostheses. Application of modern magnetic materials such as $SmCo_5$ and NdFeB (see *Rare Earth Magnets: Materials* and *Magnets: Sintered*) makes it possible to manufacture miniature magnets with high magnetic energy. These magnets can produce mechanical forces, typical for middle ear, even in magnetic systems with open magnetic circuits. A human ear can hear sounds with intensities of up to 120 dB ($L = 20\ \log(P/P_0)$, where $P_0 = 2 \times 10^{-5}$ N m$^{-2}$ is the audibility threshold, $L$ is the sound intensity level). So, the maximum sound pressure $P$ on the tympanic membrane can be estimated to be 20 N m$^{-2}$, and, therefore, maximum forces in the middle ear do not exceed 0.001–0.1 N. Such forces can be achieved by permanent magnets with masses 0.01–10 g, which are close to that of ossicles (several grams). These small magnets can be produced in practically any size and shape, be covered with biologically inert materials and their magnetization can be precisely controlled. Elastic magnets can also be manufactured (see *Magnets: Bonded Permanent Magnets*). Thus, a variety of functional prostheses of middle ear elements based on such miniature magnets can be created.

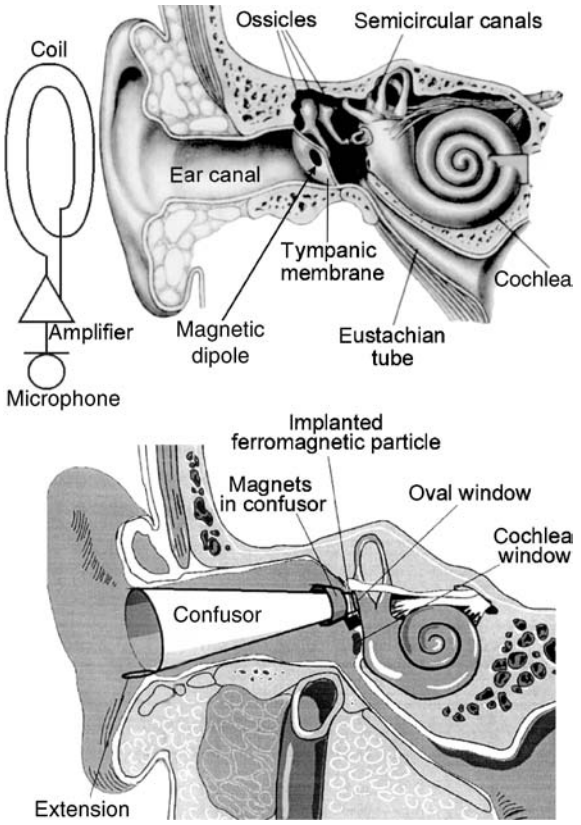

***Figure 1***
Main elements of a human ear and one of the schemes of hearing rehabilitation using an implanted miniature permanent magnet (top). The magnet is vibrated by an external alternating magnetic field of sound frequency and generates acoustic perceptions for the patient. Application of a removable confusor in patients with total absence of the middle ear sound conducting system (bottom).

### *1. Tympanic Membrane Prosthesing*

Tympanic membrane prosthesing in outpatients with dry perforative otitis media can be achieved using two thin sheets of a magnetic elastomer (rare-earth alloy particles, embedded in a biocompatible plastic, e.g., silicone). The prosthesing procedure includes insertion of one compactly rolled sheet of the magnetic elastomer through the tympanic membrane perforation into the inner ear cavity, where it is unfolded using a special tool (S) (Dmitriev and Yunin 1988). A second magnetic sheet is applied from the outer side of the tympanic membrane. The two sheets attract each other, sealing the perforation. This procedure has lead to 15–25 dB improvement in hearing of 27 patients with two-sided dry perforative otitis media and regeneration of tympanic membranes in two patients.

### *2. Magnetic Prostheses of Ossicles*

All known types of the ossicular implants form jointless junctions, which dramatically changes the middle ear acoustic impedance. Permanent magnet-based selforganizing prosthetic devices can preserve the physiological mechanism of sound conduction in the middle ear and simplify surgeons' work. For example, an anvil prosthesis consists of a horseshoe-shaped ferromagnetic element inserted under the stirrup arch and a magnet-containing stem, attached either to the hammer or to the tympanic or artificial membrane (Kuznetsov *et al*. 1983a, 1983b, 2001). The two parts attach to each other by magnetic forces, forming a slip-free magnetic junction between them,

while the anvil-stirrup joint remains physiologically flexible. Nonmagnetic elements of the prostheses are made of rigid and light weight carbon fiber-based materials. Flexibility of the construction prevents overloading of the inner ear. Hearing improvement (20–40 dB of sound conductivity) was observed in 25 of 30 patients with chronic suppurative otitis media, who were implanted with anvil prostheses, and in 24 of 30 patients with stirrup prostheses (up to 35 dB). Prostheses of ossicles with magnetic elements also allow to vibromassage the middle ear system by an external alternating magnetic field, preventing immobilization of the prosthesis due to conjunctive tissue formation.

### *3. Prosthesing of the Middle Ear Sound Conducting System after a Radical Surgery*

In patients with completely destroyed middle ear sound conducting system, but an intact inner ear, hearing rehabilitation requires both adjustment of the prosthesis impedance with the impedance of the inner ear and shielding of the round window. Magnetically soft ferromagnetic particles (steel X13) were implanted under the cicatrical tissue of oval window area in postoperative patients with chronic suppurative otitis media, impermeable auditory tube and total absence of the sound conducting system (Kuznetsov *et al.* 1982, Palchun *et al.* 1982). A removable elastic confusor, containing small permanent magnets, was attached to the cochlea window by magnetic forces (Fig. 1). This confusor focuses sound pressure on the oval window while shielding the round window. Since magnetic forces guide the confusor to the proper position during insertion into the ear canal, this procedure can be done by the patient. Confusor prosthesing provided up to 35 dB decrease in air conduction thresholds in 18 patients, which is approximately two times better, than traditional techniques such as shielding of the round window by oiled cotton tampons or by silicone-based foam "otopen" (Wullstein *et al.* 1972, Williams and Rouf 1978).

### *4. Excitation of Acoustic Vibrations in the Middle Ear Using Sound Frequency Alternating Magnetic Field Action on a Magnetic Element in the Sound Conducting System*

Implantation of miniature permanent magnets into nonmagnetic biological structures of middle ear makes it possible to transform sound frequency alternating magnetic fields into mechanical stimuli, which can be perceived by the patient as acoustic signals (Fig. 1; Kuzhetsov *et al.* 1983a, 1983b, 2001, Dmitriev *et al.* 1986, 1988).

Many coils can generate suitable alternating magnetic fields, but a flat, spiral coil, concealed under clothes on the patient's shoulder appears to be the most promising. It can generate a sound frequency alternating magnetic field from $10^{-2}$ Oe to 10 Oe in the ear cavity, providing adequate mechanical stimuli. Due to a relatively large distance from the coil to the ear, the field in the ear cavity is practically uniform: $\nabla B \approx 10^{-6}$ Oe cm$^{-1}$. The force $F$ acting on the magnetic moment m is proportional to $\nabla B$: $F = (m\nabla)B$, while the torque $M$ acting on the same magnetic moment is proportional to $H$: $M = m \times H$. Therefore, in such field a magnetic dipole will oscillate mostly tangentially. Elements of the middle ear sound conducting system (ossicles, stirrup base) normally also move predominantly tangentially. Thus, the movements of the magnet can simulate movements of the ossicles in a normal ear and provide acoustic stimuli for the patient.

Depending on the degree of the middle ear deterioration, the location of the magnet varies: it can be either glued to the remaining tympanic membrane, or attached to ossicles (or be a part of an ossicle prosthesis), or implanted into the cicatrical tissue on the oval window surface after a radical operation. The latter was the most common technique and was used in 11 patients. Biocompatible 5–50 mg $SmCo_5$ monocrystals were used. To increase the coercive force and retentivity, the monocrystals were treated by a shock wave before magnetization (Kuznetsov *et al.* 1977). Significant rehabilitation efficiency in patients with hearing thresholds of up to 70 dB was observed after such operations. The patients were monitored for several years and no negative effects of the magnets or magnetic fields on the tissues and the processes in the ear were detected.

Attaching a magnet to the tympanic membrane in patients with an intact middle ear, but a reduced sensitivity of the inner ear, and vibrating it with an external alternating magnetic field can provide additional mechanical stimulation. Extensive experimental studies were done on cadaver material to optimize the magnet size to provide a natural level of sound pressure on the tympanic membrane. Optimal magnet size was found to be 56 mg (Dmitriev and Aknesov 1992). This technique provides a significant improvement of sound perception for all tested magnet locations and solves cosmetic problems of hearing rehabilitation (no wires, earpiece).

### *5. Magnetically Controlled Implantable Devices for Restoration of Inner Ear Function in Ménière's Disease Patients*

Ménière's disease (labyrinth hydrops) is a serious inner ear disease, characterized by an increase of the hydrostatic pressure of intralabyrinth fluids, leading to irreversible destruction of hearing and vestibular functions. This ailment is treated by draining the excess endolymph from the labyrinth to normalize

the pressure using several types of implantable drainage devices, thus eliminating vertigo and preserving the remaining hearing level (Kobrak 1963).

Unfortunately, opening thresholds of these devices cannot be adjusted after implantation and the pressure in the labyrinth cannot be maintained at the level, optimum for the particular patient. Two types of implantable magnetic valves for draining endolymphatic sack were developed and tested (Kuznetsov *et al*. 1985, Yunin *et al*. 1984). Core elements of the valves are rare-earth permanent magnets and magnetic elastomers. Different compositions of magnetic particles (barium hexaferrite and/or rare-earth alloys) imbedded in silicone enable to create elastomers with a wide variety of magnetic properties. Magnetic elastomers were attracted to each other or permanent magnets and closed the endolymph outflow. The devices were grafted into the inner ear of the patients. During an attack, a postoperative patient can open the type I valve and decrease the endolymph pressure by bringing a magnet close to the implanted valve. Once the magnet is removed, the valve closes. Type II valves open automatically when the endolymph pressure exceeds a certain threshold. The valve opening threshold can be adjusted after grafting of the device by changing magnetization of the elastomer using an external impulse magnetization device. Thus, a physician can optimize the endolymph pressure for each particular patient and adjust it to a comfortable level in response to the patient's condition without surgery. Elastomers in the valves can be vibrated by external alternative magnetic field, preventing clogging of the valve due to conjunctive tissue formation and allowing active pumping of endolymph if necessary.

Six patients were implanted with type I valves, and another five received type II valves. The patients were monitored for more than seven years and demonstrated stable improvement in their condition: vertigo attacks were controlled by the valves, hearing levels were maintained. The patients were able to work and live normal lives.

### *6. Concluding Remarks*

A variety of implantable prostheses of middle ear structures based on permanent magnets and using magneto-mechanical forces for their operation were developed for treating middle ear ailments and hearing rehabilitation. Methods of surgical application of the devices were developed and in clinical trials more than 85% of 127 patients with different degrees of middle ear system degradation have shown stable improvement. This promising technology increases reliability of functional results, but needs further development and approval of regulatory authorities (FDA, etc.) for wider clinical trials and use.

## Permanent Magnets: Corrosion Properties

The rare-earth permanent magnets, particularly Nd–Fe–B magnets, possess outstanding magnetic properties and therefore have grown rapidly in production (see *Rare Earth Magnets: Materials*; *Magnets: Sintered*). However, their poor corrosion resistance (Jacobson and Kim 1987) has limited their applications. This article discusses the corrosion mechanism of Nd–Fe–B magnets and methods to improve their corrosion resistance.

### *1. Corrosion Mechanism*

Permanent magnets based on Nd–Fe–B are very sensitive to various corrosive environments. The great sensitivity to corrosion is caused by the considerable amount of rare-earth element in their composition,

since the electromotive forces of rare-earth elements are much larger than those of iron. Normally, Nd–Fe–B magnets consist of three phases: (i) the main $Nd_2Fe_{14}B$ phase; (ii) a neodymium-rich (usually $Nd_4Fe$) phase, and (iii) a boron-rich phase. From the electrical point of view, such a contact of three different metallic phases with great differences in electrochemical activity must promote rapid corrosion. Nakamura *et al*. (1989) measured the electrode potentials of the different phases in 1 N HCl solution.

Because the Nd-rich phase has a much lower electrode potential than the $Nd_2Fe_{14}B$ phase, a selective corrosion of the Nd-rich phase occurs by forming a local cell between the $Nd_2Fe_{14}B$ and Nd-rich phases. Therefore, the grain boundary phase corrosion is dominant rather than uniform corrosion for sintered Nd–Fe–B magnets, a fact made evident by microstructural observation. The corrosion rate decreases as the Nd content (or volume fraction of Nd-rich phase) decreases. On the other hand, with the increase of cathodic polarization in strong acid, the hydrogen reduction reaction produces hydrogen atoms at the cathode that can diffuse into the base metal and cause embrittlement, and therefore the rate of Nd–Fe–B magnet dissolution increases (Bala and Szymura 1991). The abnormal dissolution (mechanical degradation) rate increases linearly with the square root of the hydrogen evolution current density.

Since the Nd–Fe–B magnets are generally used in atmospheric environments, various accelerated corrosion environment tests were employed in order to predict the service life of the magnet in ambient environments. The accelerated corrosion environments include: hot–dry air, hot–humidity, high-pressure steam, and salted spray.

The kinetics of oxidation of Nd–Fe–B alloy magnets in air at elevated temperatures (80–200 °C) exhibit an exponential weight gain (Turek *et al*. 1994, LeBreton and Teillet 1990). Quick initial oxidation of the intergranular Nd-rich phases is followed by oxidation of the $Nd_2Fe_{14}B$ phase. The oxidation products are $Nd_2O_3$, $NdFeO_3$, $Fe_3O_4$, and an inhomogeneous phase close to α-Fe.

When Nd–Fe–B magnets are exposed to a hot–humid environment (50–90 °C, 50–90% relative humidity) (LeBreton and Teillet 1990), the magnet is disintegrated but the $Nd_2Fe_{14}B$ phase is generally unaffected. The oxidation occurs in the Nd-rich region, producing $Nd_2O_3$ and $Nd(OH)_3$ as is evidenced by x-ray diffraction. This disintegration increases as temperature and relative humidity increase.

A more accelerated corrosion test is carried out in a high-pressure steam vessel (McGuiness *et al*. 1994, Kim *et al*. 1996). In an autoclave (or PCT) test, grains of the $Nd_2Fe_{14}B$ phase have fallen apart from the magnet. X-ray diffraction patterns on the loose particles exhibit mainly $Nd_2Fe_{14}B$ peaks with small $Nd(OH)_3$ peaks indicating that the oxidation product is $Nd(OH)_3$ and the $Nd_2Fe_{14}B$ remains unspoiled.

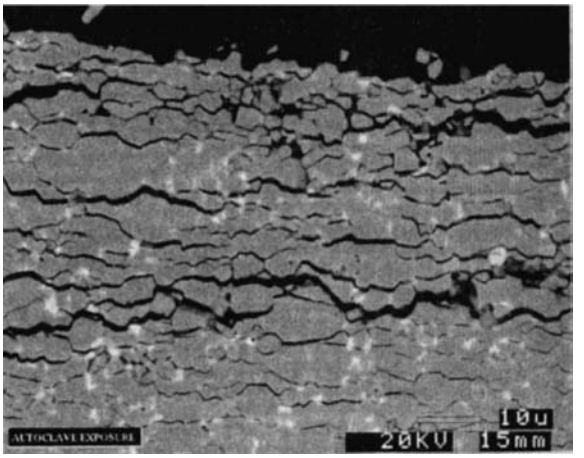

***Figure 1***
SEM micrograph of a Nd–Fe–B magnet subjected to an autoclave test (Kim *et al*. 1996).

Macroscopic disintegration was observed on both magnetic pole faces of the magnetically aligned and sintered Nd–Fe–B magnet after exposure to an autoclave environment at 115 °C and 2 bar, which is similar to the conditions of hydrogen decrepitation of the magnet. The microstructure underneath the disintegration surface shows plate-like cracking perpendicular to the magnetic orientation as shown in Fig. 1.

The microstructure of hydrogen-decrepitated samples shows similar cracking patterns. There is undoubtedly anisotropic corrosion and hydrogen decrepitation behavior in anisotropic Nd–Fe–B magnets. The similarity between these two corrosion processes infers a common corrosion mechanism. As described before, the hydrogen evolution during cathodic polarization of Nd–Fe–B in strong acid causes mechanical degradation (abnormal dissolution), and thus hydrogen decrepitation is involved and plays an important role in the corrosion mechanism. Hydrogen may be generated in the autoclave test from the decomposition of water vapor:

$$3H_2O + Nd \rightarrow Nd(OH)_3 + 3H$$

Thus, the corrosion mechanism for Nd–Fe–B magnets in the heat and humidity of the autoclave test starts with a surface reaction of water vapor with the Nd-rich grain boundary phase. The generated hydrogen atoms diffuse along the grain boundaries into the interior of the magnet. Some of the hydrogen reacts with the Nd-rich grain boundary phase, causing volume expansion of this phase ($3H + Nd \rightarrow NdH_3$) and the rest goes into the $Nd_2Fe_{14}B$ matrix ($xH + Nd_2Fe_{14}B \rightarrow Nd_2Fe_{14}BH_x$). The corrosion product of $Nd_2Fe_{14}B$ characterized by x-ray diffraction reveals that a significant expansion of the lattice has taken

place (McGuiness *et al.* 1994). Volume expansion of the Nd-rich phase and lattice expansion of the $Nd_2Fe_{14}B$ phase results in the removal of the $Nd_2Fe_{14}B$ matrix phase grains. The subsurface cracks provide the path for reacting species (water vapor) to the inside of the Nd-rich phase, which accelerates the corrosion reaction. This corrosion reaction increases as the amount of Nd-rich phase in the Nd–Fe–B magnet increases.

## 2. *Improvement of Corrosion Resistance*

As discussed in Sect. 1, the large difference in the electrochemical potential between the Nd-rich and $Nd_2Fe_{14}B$ phases promotes a rapid corrosion reaction. The grain boundary also provides the diffusion path of reacting species such as hydrogen atoms. Improvement of corrosion resistance can therefore be achieved by increasing the electrode potential of the Nd-rich phase as close as possible to that of the $Nd_2Fe_{14}B$ phase and by minimizing the Nd-rich region.

Partial substitution of iron by cobalt is reported substantially to improve the corrosion resistance by forming the $Nd_3Co$ phase in the Nd-rich grain boundary, particularly in a hot–humid environment (Tokunara and Hirosawa 1991, Kim and Camp 1996). The electrode potential of $Nd_3Co$ is higher than that of the $Nd_4Fe$ phase and is close to the $Nd_2Fe_{14}B$ phase (Nakamura *et al.* 1989). The corrosion rate of Nd–Dy–Fe–Co–B–Mo sintered magnets, as monitored by weight loss in PCT, is shown in Fig. 2. This corrosion rate decreases as the cobalt content increases to 5 at.% Co.

It is noted that a cobalt addition by itself deteriorates the coercivity although it improves the corrosion resistance and Curie temperature. Therefore, various additional elements combined with cobalt were investigated in order to compensate for the negative effect of reducing coercivity by cobalt. Elements including Al, Ga, Cu, Sn, Cr, Zr, Nb, V, Mo, or W combined with Co are found to increase the coercivity. Because of these additions, the corrosion resistance is further improved. Particularly, a combined addition of cobalt and copper substantially improves both the corrosion resistance and the coercivity without reduction of the energy product (Kim and Camp 1996).

Nickel or Ni and Co additions are also reported to improve significantly the corrosion resistance (Bala *et al.* 1990). The segregation of nickel to the intergranular Nd-rich phase would reduce the electrochemical difference among the phases yielding good corrosion resistance. It is noted, however, that a nickel addition deteriorates coercivity and reduces the Curie temperature. A further small addition of titanium in a Nd–(Fe,Co,Ni)–B alloy enhances the coercivity to a moderate level. Vanadium or molybdenum additions were also reported to improve coercivity and corrosion resistance by forming intergranular precipitates ($Fe–M_{2-}$-$B_2$), but at the expense of the energy product (Hirosawa *et al.* 1990).

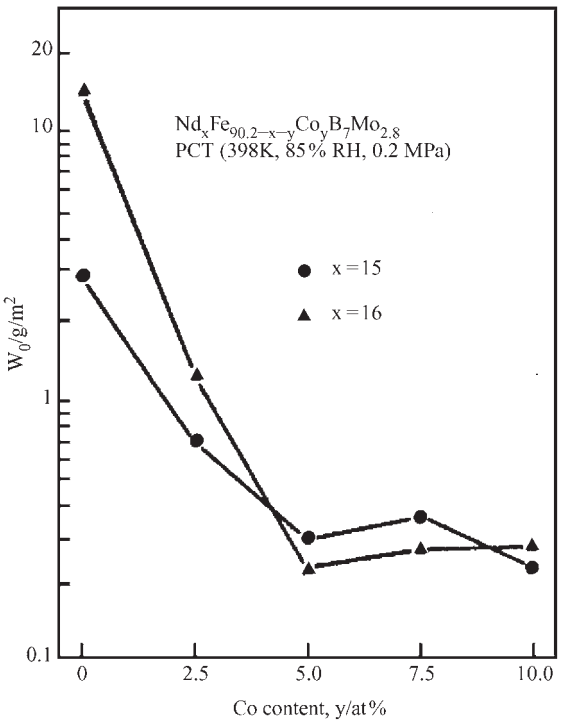

***Figure 2***
Weight loss per unit area of uncoated magnets in PCT for 130 ks as a function of cobalt content (Tokunara and Hirosawa 1991).

A partial replacement of Nd by dysprosium or terbium in Nd–Fe–B magnets also improves the corrosion resistance. The lowering of the total rare-earth amount in Nd–Fe–B magnets increases the volume fraction of the $Nd_2Fe_{14}B$ phase and thus raises the electrode potential, which improves the corrosion resistance (Tokunara and Hirosawa 1991). Chromate etching on the surface of the magnet dissolves the Nd-rich surface phase. This eliminates the reaction site, which also improves the corrosion resistance (Kim 1989).

In addition, increasing density and minimizing porosity also improves the corrosion resistance. The corrosion current reportedly increases as the porosity increases in the magnet. A vacuum impregnation of the surface porosity was reported to improve the corrosion resistance (Stevenson and Stevenson 1988). The microstructure of Nd–Fe–B magnets also affects their corrosion behavior. Nanostructured melt-spun ribbons exhibit a uniform corrosion, while the sintered magnets exhibit a localized corrosion of the

Nd-rich grain boundary phase (Nakamura *et al.* 1989). The latter has a lower electrode potential and thus a poorer corrosion resistance. Hot-worked Nd–Fe–B magnets also exhibit better corrosion resistance than the sintered magnets (Nozieres and Taylor 1990).

A postmachining heat treatment of Nd–Fe–B sintered magnets at 600–1000 °C in a vacuum or in a very low oxygen environment formed a very thin oxidation layer on the surface and thus improved the corrosion resistance in hot–humid environments (Imaizumi *et al.* 1987).

### *3. Corrosion Protection*

The corrosion resistance is further improved by applying corrosion protection layers on the surface of the magnet (Mitchell 1990). Various depositing materials can be put on the magnet surface by using various techniques. Plating can be described as the deposition of a material from a solution. There are two main types of plating: one is electrolytic or electroless plating and the second is electropainting. The most common coating is electrolytic or electroless plating of Ni, Sn, Cu, or combinations of these, because of ease of mass production, economic process, and durability.

However, an adjusted pretreatment to inhibit a reaction of nickel with the magnet is needed because Nd–Fe–B magnets may absorb hydrogen during the plating process causing cracking and, thus, failure of adherence of the layer to the magnet. Nickel plating usually exhibits a good corrosion resistance in hot–humid environments but a poor resistance in salt-spray environments. The cathodically deposited electropaint coating is also very popular because of its ease for mass production. The electropaint coating usually exhibits an excellent corrosion resistance in salt-spray environments and a moderate resistance in hot–humid environments.

Vapor deposition generally refers to the deposition of a material on to a substrate by use of the gaseous phase of the depositing material. There are several forms of vapor deposition as physical, chemical, and spray deposition. Among them the aluminum-ion vapor deposit coating is important for achieving a high corrosion resistance. It provides the highest degree of protection against hot–humid environments and exhibits a moderately good resistance to salt-spray.

## Permanent Magnets: Microstructure

The microstructure of rare earth permanent magnet materials is defined by the type, the structure and the number of phases, by the size, shape and the topological arrangement of the individual phase regions and their interfaces, and by the type, structure and geometry of lattice defects. In the following, several examples of TEM micrographs will show the differences between various types of rare earth magnets (see *Rare Earth Magnets: Materials*). The importance of newly developed permanent magnetic materials in many electro-, magnetomechanical and electronic applications can be attributed to the drastic improvement of microstructure related properties, such as the magnetic energy density product and the coercive field.

The rare earth intermetallic phases with a high uniaxial magnetocrystalline anisotropy (see *Magnetic*

*Anisotropy*), such as $SmCo_5$, $Sm_2Co_{17}$, and $Nd_2Fe_{14}B$ are the basis for high-performance rare earth magnets. Samarium–cobalt magnets exhibit the highest coercive fields ${}_JH_c$ and (Nd,Dy)–(Fe,Co)–B:(Al,Cu, Ga) magnets show the highest value of remanence $B_r$ and energy density product $(BH)_{max}$ obtained so far. Rare earth magnets are divided into the group of the so-called single phase, nucleation-controlled magnets, based on the $SmCo_5$ or $Nd_2Fe_{14}B$ hard magnetic phases, and the group of domain wall pinning controlled, multiphase magnets (see *Coercivity Mechanisms*). Two-phase magnets, which are nowadays also used in high-temperature advanced power applications consist of a continuous $Sm(Co,Cu)_{5-7}$ cellular precipitation structure within a $Sm_2(Co,Fe)_{17}$ matrix phase. Nanocrystalline rare earth magnets exhibit microstructures of single phase, two phase and multiphase character, in which the inhomogeneous magnetization behavior near the intergranular regions can create remanence enhancement (see *Magnets: Remanence-enhanced*).

High-performance rare earth permanent magnets are produced with different composition and by various processing techniques (Strnat 1988, Herbst 1991), which influence the complex, multiphase microstructure of the magnets, such as size and shape of grains, the orientation of the easy axes of the grains and the distribution of phases. The formation and distribution of the phases is determined by the composition of the magnets and the annealing treatment. The grain size of the magnets and the alignment of the grains especially strongly depend on the processing parameters:

- grain sizes in the range between 10 nm and 500 nm are obtained by melt-spinning, mechanical alloying (see *Magnets: Mechanically Alloyed*) and the HDDR (hydrogenation-disproportionation-desorption-recombination) process (see *Magnets: HDDR Processed*),
- sintered (see *Magnets: Sintered*) and hot worked magnets (see *Textured Magnets: Deformation-induced*) exhibit grain sizes above 1 μm.

The hysteresis properties of the magnets are governed by a combination of the intrinsic properties of the material, such as saturation polarization $J_s$, magnetic exchange and magnetocrystalline anisotropy of various phases, and the influence of the microstructure on the magnetization reversal process (see *Magnetic Hysteresis*). The intergranular structure between the grains plays a significant role in determining the magnetic properties, thus a detailed understanding of the microstructure and of the grain boundaries is necessary. Magnetic domain structures (see *Magnets, Soft and Hard: Domains*), which are a result of the occurrence of magnetic stray fields, are directly influenced by the microstructural features.

The direct observation of microstructure and magnetic domain structure leads to a deeper insight into the origin of the coercivity of rare earth magnets. Advanced analytical methods, such as high-resolution electron microscopy (see *Magnetic Materials: Transmission Electron Microscopy*), magnetic force microscopy (see *Magnetic Force Microscopy*), position sensitive 3D atom probe, and other techniques have been used to study rare earth magnets. Modeling of magnetic materials is performed at various levels and becomes more important as computer power is improved. Numerical 3D micromagnetic simulations of the magnetization reversal process incorporate realistic microstructures. Advanced analytical investigations and future simulations should be able to predict optimal microstructures and properties for given hard and soft magnetic materials (Fidler and Schrefl 2000).

## 1. Nucleation-controlled Magnets

The basic microstuctural feature of polycrystalline $SmCo_5$- or $Nd_2Fe_{14}B$-based magnets is the individual hard magnetic grain with its size, shape, and orientation parameters. The ideal microstructure of the so-called single phase magnets consists of aligned single-domain hard magnetic particles. Strictly speaking, these magnets show a complex, multiphase microstructure with various types of intergranular phases according to their phase diagram and phase relations. The amount of each phase and their distribution within polyphase materials are perhaps the most complex of the microstuctural parameters. The occurrence of the multiphase microstructure is one of the reasons why the coercive field of the magnets according to the magnetocrystalline anisotropy field of the hard phase, such as 30700 $kAm^{-1}$ for $SmCo_5$ and 6050 $kAm^{-1}$ for $Nd_2Fe_{14}B$, is never reached in practice.

The microstructure of single phase, anisotropic $SmCo_5$-type magnets consists of grains oriented parallel to the alignment direction. Most of the $SmCo_5$ grain interiors show a low defect density. The grain diameter exceeds the theoretical single domain size and is in the order of 5–10 μm. Besides $SmCo_5$ grains, grains with densely packed, parallel stacking faults perpendicular to the hexagonal c-axis are observed. Such basal stacking faults correspond to a transformation of the $SmCo_5$ crystal structure into the samarium-rich $Sm_2Co_7$ and $Sm_5Co_{19}$ structure types. Using high-resolution electron microscopy together with x-ray microanalysis, the different polytypes and structural modifications of these samarium-rich phases are characterized. Incoherent precipitates with diameters up to 0.5 μm were identified as $Sm_2O_3$ or CaO inclusions. The electron micrograph of Fig. 1 shows a defect-free $SmCo_5$ grain separated into magnetic domains in the demagnetized state.

In $SmCo_5$-type sintered magnets, the coercivity is determined by the nucleation field of reversed domains which is lower than the coercivity of a

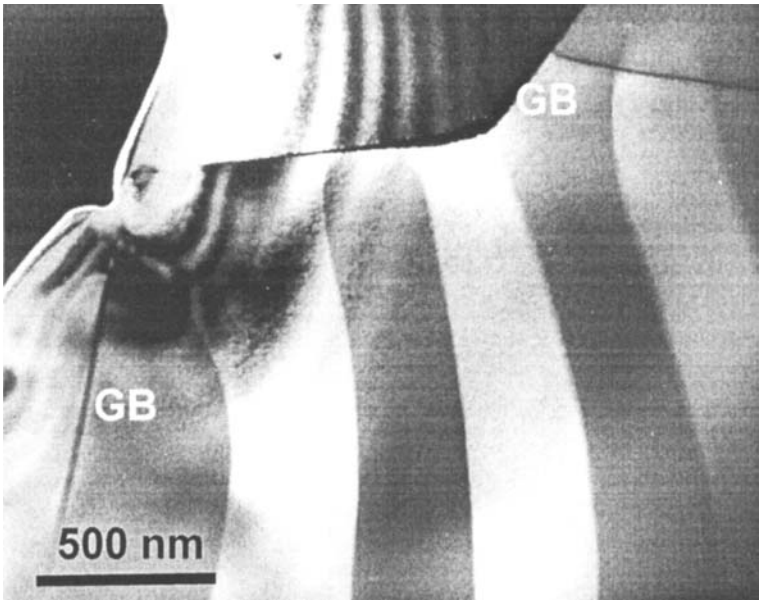

*Figure 1*
Lorentz electron micrograph showing the magnetic domain configuration in the demagnetized state of a sintered $SmCo_5$ magnet. The coercivity mechanism is controlled by nucleation and expansion of reversed domains.

magnetically saturated particle with a single domain structure and nucleation by the expansion field of the reversed domains. The nucleation of reversed domains takes place in regions with low magnetocrystalline anisotropy. Rare earth-rich precipitates mainly deteriorate the ${}_JH_c$ of the final magnet. The formation of these phases is due to the addition of a rare earth-rich sintering aid phase before the sintering process. The coercivity can be improved by adding small amounts of transition metal powders or transition metal oxides. TEM studies show that the chemical composition, the size distribution, and the impurity content (oxygen content) of the starting powder material are important factors for the magnetic properties of $SmCo_5$-type sintered magnets. For lower-cost magnets, samarium is partly substituted by a mixture of cerium–mischmetal elements or, for improved magnetic properties, by praseodymium, thus three groups of $SmCo_5$-type sintered magnets are distinguished:

- (CeMM,Sm)$Co_5$ low $J_s$, low $(BH)_{max}$,
- $SmCo_5$ high ${}_JH_c$,
- (Pr,Sm)$Co_5$ high $(BH)_{max}$.

Microstructural investigations on sintered magnets of the type (CeMM,Sm)$Co_5$ and (Pr,Sm)$Co_5$ showed similar results as in the case of $SmCo_5$ sintered magnets. The corresponding x-ray spectra of the different phases showed a mixture of rare earth elements due to their ratio of the nominal composition of the magnet.

## 2. *Doped and Substituted $Nd_2Fe_{14}B$ Magnets*

The coercive field of high-performance $Nd_2Fe_{14}B$-based magnets is determined by the uniaxial magnetocrystalline anisotropy as well as by the magnetostatic and exchange interactions between neighboring hard magnetic grains. The long-range dipolar interactions between misaligned grains are more pronounced in large-grained magnets, whereas short-range exchange coupling reduces the coercive field in small-grained magnets. Different substituent (S1, S2) and dopant (M1, M2) elements influence the microstructure, coercivity, and corrosion resistance of advanced (Nd,S1)–(Fe,S2)–B:(M1,M2) magnets. The multicomponent composition of the magnets leads to the formation of nonmagnetic and soft magnetic phases.

Generally, two types of substituent elements, which replace the rare earth element or the transition element sites in the hard magnetic phase, and two types of dopant elements were found. Selected substituent elements replace the neodymium atoms (S1 = Dy,Tb) and the iron atoms (S2 = Co,Ni,Cr), respectively, in the hard magnetic phase and considerably change intrinsic properties, such as the spontaneous polarization, the Curie temperature, and the magnetocrystalline anisotropy. The main difference between substituent and dopant elements is the solubility range within the $Nd_2Fe_{14}B$ phase. Investigations performed on sintered, melt-spun, mechanically alloyed, and hot-worked magnets have shown that two

different types of dopants can be distinguished independently of the processing route. Depending on the type, the dopant elements form additional intergranular rare earth-containing or boride phases (Fidler and Schrefl 1996):

- *Type 1 dopants* (M1 = aluminum, copper, gallium, germanium) form binary or ternary neodymium-containing phases.
- *Type 2 dopants* (M2 = titanium, zirconium; vanadium, molybdenum; niobium, tungsten) form binary or ternary boride phases.

In summary, the following phases were identified by TEM investigations:

- Primary hard magnetic phase: $Nd_2Fe_{14}B$.
- Secondary phases:

  neodymium-rich liquid sintering phase, stabilized by some amount of oxygen and iron

  $Nd_{1+\varepsilon}Fe_4B_4$

  M1-Nd ($CuNd$, $GaNd_3$, $Ga_3Nd_5$)

  M1-Fe-Nd ($M1_{1+x}Fe_{13-x}Nd_6$)

  M2-B ($TiB_2$, $ZrB_2$)

  M2-Fe-B ($V_{2-x}Fe_{1+x}B_2$, $Mo_{2-x}Fe_{1+x}B_2$, NbFeB, WFeB)

  α-Fe

  Oxide-phases ($Nd_2O_3$, …).

- Additional phases in Dy- and Co-substituted and M1- and M2-doped magnets:

  $Nd(Co,Fe)_4B$

  $Nd(Co,Fe)_2$

  $Nd_3Co$

  dysprosium-containing phases.

Intergranular phases change the coupling behavior between the hard magnetic grains. Nonmagnetic phases eliminate the direct exchange interaction and also reduce the long-range magnetostatic coupling between the hard magnetic grains; both effects lead to an increase of coercivity. The formation of intermetallic, soft magnetic Nd(Fe,S2) phases, such as the Laves type $Nd(Fe,S2)_2$-phase, deteriorate the coercivity of the magnets. If dopant elements M1 or M2 are added to NdFeB, the coercivity is generally increased and the corrosion resistance (see *Permanent Magnets: Corrosion Properties*) is improved. This is the case if the neodymium-rich intergranular phase is replaced by other phases, such as $AlFe_{13}Nd_6$ and $Nd_3Co$, especially in large-grained sintered magnets. The TEM micrograph of Fig. 2 shows the additional intergranular $Al_1Fe_{13}Nd_6$ and $Nd_3Co$ phases in a Nd(Fe,Co)B:(Al,Mo) magnet. On the other hand, the decrease of the volume fraction of the hard magnetic phase within the magnet decreases the remanence.

The processing route of the magnet strongly influences the grain size and grain size distribution. The coercive field in sintered magnets strongly depends on the sintering parameters, such as temperature and time. Nanocrystalline and submicron magnets are obtained by the melt-spinning route, by mechanical alloying, or by the HDDR process. Hot pressing and die upsetting of NdFeB ribbon materials reveals a densely packed, anisotropic magnetic material. Platelet-shaped grains with diameters less than 1 μm are

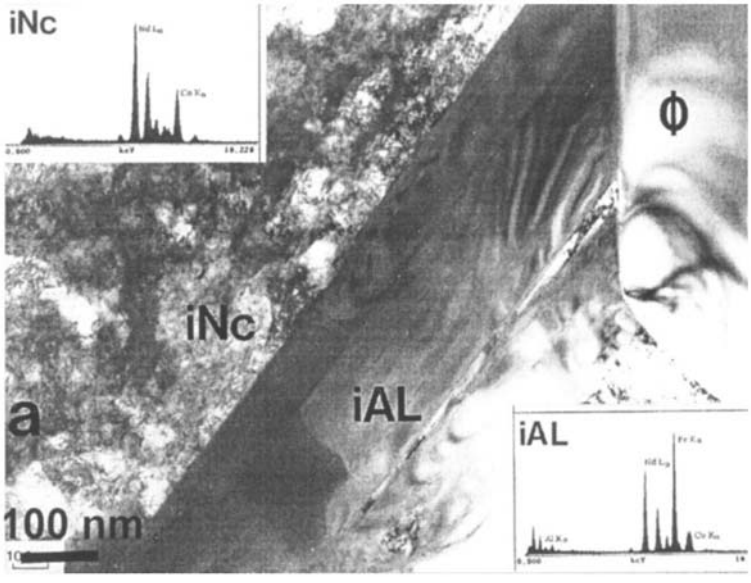

***Figure 2***
TEM micrograph showing intergranular phases, $Al_1Fe_{13}Nd_6$ (iAL) and $Nd_3Co$ (iNc), besides the $Nd_2(Fe,Co)_{14}B$ (Φ) phase in a Nd-(Fe,Co)-B:(Al,Mo) magnet.

observed by TEM investigations. The degree of orientation of the platelets, which are stacked transverse to the press direction with the easy c-axes perpendicular to the face of each grain, determines the remanence and coercive field of the magnet.

The degree of alignment, size and shape of the grains, and the intergranular regions within the ribbons control the macroscopic magnetic properties. Die-upsetting modifies the spheroidal grains (Mishra 1987) after hot pressing to platelets as shown in the TEM micrographs of Fig. 3(a). Misaligned grains, which are clearly visible, deteriorate the remanence. The c-axis for each grain runs perpendicular to the straight elongated edge. A neodymium-rich phase is found among the platelet-shaped grains as a fine layer between the straight edges or as pockets at the end of the platelets or between the misaligned and aligned grains. On the other hand, the magnets with a lower remanence show a microstructure with more equiaxed grains. In most of the melt-spun magnets, regions with abnormally grown, large grains are found. Some of these grains are fully developed, platelet-shaped grains (see *Textured Magnets: Deformation-induced*).

NdFeB sintered magnets possessing outstanding magnetic properties have succeeded in becoming a major permanent magnet material since their invention in 1983 (see *Magnets: Sintered*). The drastic increase of the energy density product of newly developed $Nd_2Fe_{14}B$-based magnets enabled the invention of many new applications of permanent magnets. Applications of highest energy density magnets ($>400\,kJm^{-3}$) are expanding (see *Magnetic Materials: Domestic Applications*; *Permanent Magnets: Sensor Applications*). These magnets are produced by a conventional powder metallurgical process which is essentially based on alloy melting, coarse milling, pulverizing, pressing in a magnetic field, sintering, heat treating and surface coating. The theoretical value of the maximum energy product of $Nd_2Fe_{14}B$-based magnets is calculated to be $512\,kJm^{-3}$ assuming 100% perfect alignment and 100% volume fraction of the hard phase. In order to densify the magnets up to the theoretical density, it is very important to control the composition of magnets thus generating a sufficient amount of liquid phase at sintering. Several authors (Kaneko 1999), have reportedly obtained NdFeB-based magnets with $400\,kJm^{-3}$ energy density product by:

- keeping the oxygen content low,
- using the powder mixing technique,
- increasing the magnetizing field and reducing the pressure during compaction,
- using the rubber isostatic pressing (RIP) technique to improve the orientation of the particles in the green compact to obtain sintered magnets with perfect orientation.

In RIP, magnet powder is subjected to such a strong pulsed field just before the compaction that the powder in the rubber mold is thoroughly oriented (Sagawa and Nagata 1993). Then the powder is compacted isostatically, while the orientation is

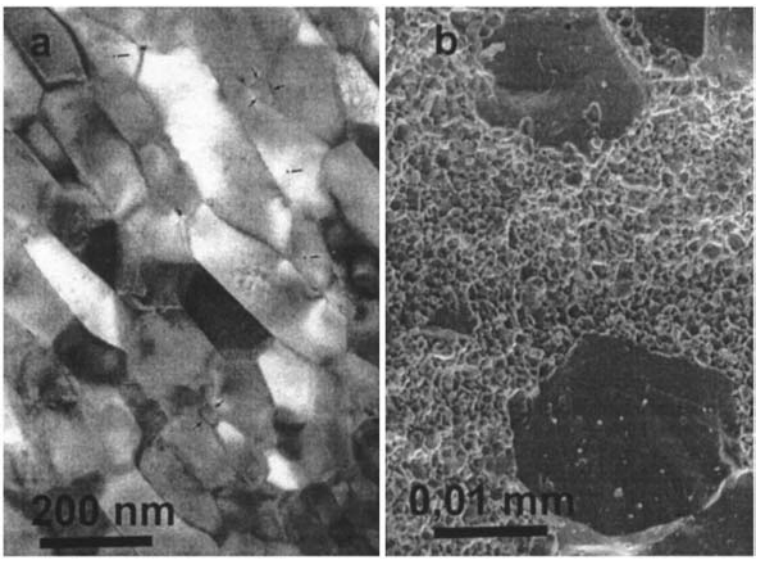

***Figure 3***

completely kept. The misalignment of the hard magnetic grains with a diameter of 2–5 μm is in the best case of the order of less than 14°. The oxygen content of the magnets has to be reduced from values of 4000–6000 ppm to a value $<1000$ ppm. A high oxygen content is one limiting factor to decreasing the neodymium content in order to improve the volume fraction of the hard magnetic phase. The squareness of the demagnetization curve and the coercive field drastically decrease as abnormal grain growth (AGG) of the $Nd_2Fe_{14}B$ grains occurs (Rodewald *et al*. 1997). The influence of oxygen on the hard magnetic properties is more complex. The oxygen content strongly affects the AGG, and the magnets with higher oxygen content have the higher critical temperature at which the AGG occurs. The SEM micrograph of Fig. 3(b) shows abnormally grown hard magnetic grains embedded within a matrix of grains with a diameter of 3–5 μm. Even the sintering process influences the degree of misalignment of the grains. Lowest misalignment is obtained by isostatic die pressing (11–14°), followed by transverse field die pressing (18–20°), and axial field die pressing (25–27°).

### *3. Pinning Controlled Sm(Co,Cu,Fe,Zr)$_{7.5–8}$ Magnets*

Copper-containing cobalt-rare earth magnets with a composition of $Sm(Co,Fe,Cu,Zr)_{6–8}$ exhibit domain wall pinning controlled magnetization curves. TEM investigations show a fine cell morphology with about $50\,nm \times 200\,nm$ in size. The rhombic cells of the type $Sm_2(Co,Fe)_{17}$ are separated by a $Sm(Co,Cu)_{5–7}$-cell boundary phase (Fig. 4(a)). The development of the continuous, cellular precipitation structure is controlled by the growth process and the chemical redistribution process and is determined by the direction of zero deformation strains due to the lattice misfit between the different phases. The cellular precipitation structure is formed during the isothermal aging procedure, whereas the chemical redistribution of the transition metals during the step aging procedure increases the coercivity of the final magnet. Growth of the cell structure occurs primarily during the isothermal aging procedure and involves the diffusion of samarium. In magnets with high coercivities ($>1000\,kAm^{-1}$), thin platelets are found perpendicular to the hexagonal c-axis.

Contrary to high-coercivity magnets which contain large crystallographic twins, a microtwinning within the cell interior phase is observed by high-resolution electron microscopy in low-coercivity magnets ($<500\,kAm^{-1}$) (Fig. 4(b)). The compositional difference between the cell boundary phase and the cell interior phase and therefore the difference in magnetocrystalline anisotropy energy of the two phases determines the coercive field. The platelet phase predominately acts as a diffusion path for the transition metals and leads to a better chemical redistribution after the isothermal aging treatment and, therefore, to a higher coercivity of the magnet. Impurities,

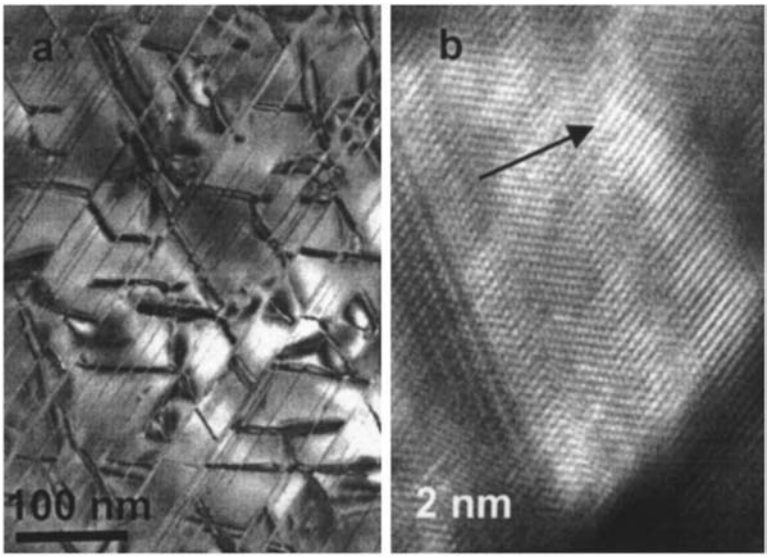

***Figure 4***

primarily oxygen or carbon, lead to the formation of macroscopic precipitates of the $Sm_2O_3$, ZrC, TiC, etc., and therefore impede the formation of the platelet phase and finally impede the chemical redistribution process.

A new series of magnets with $H_c$ up to 1050 $kAm^{-1}$ at 400 °C has been developed by Chen *et al.* (1998). These magnets have low temperature coefficients of $H_c$ and a straight line $B$ vs. $H$ (extrinsic) demagnetization curve up to 550 °C. High copper-, low iron- and a higher samarium-concentration were found to contribute to high coercivity at high temperatures (see *Magnets: High-temperature*).

## 4. Nanocrystalline, Composite $Nd_2Fe_{14}B$/($\alpha$-Fe,$Fe_3B$) Magnets

Exchange interactions between neighboring soft and hard grains lead to remanence enhancement of isotropically oriented grains in nanocrystalline composite magnets (Kneller and Hawig 1991, Coehoorn *et al.* 1989). Nanocrystalline, single-phase NdFeB magnets with isotropic alignment show an enhancement of remanence by more than 40% as compared to the remanence of noninteracting particles, if the grain size is of the order of 10–30 nm (Fig. 5(a)). Numerical micromagnetic calculations have revealed that the interplay of magnetostatic and exchange interactions between neighboring grains influence the coercive field and remanence considerably (Fidler and Schrefl 2000). Soft magnetic grains in two- or multi-phase composite permanent magnets cause a high polarization. Hard magnetic grains induce a large coercivity provided that the particles are small and strongly exchange-coupled. The coercive field shows a maximum at an average grain size of 15–20 nm. Intergrain exchange interactions override the magnetocrystalline anisotropy of the $Nd_2Fe_{14}B$ grains for smaller grains, whereas exchange hardening of the soft phases becomes less effective for larger grains.

The magnetization distribution at zero applied field for different grain sizes clearly shows that remanence enhancement increases with decreasing grain size. Owing to the competitive effects of magnetocrystalline anisotropy and intergrain exchange interactions, the magnetization of the hard magnetic grains significantly deviates from the local easy axis for a grain size $D \leqslant 20$ nm. As a consequence, coercivity drops, since intergrain exchange interactions help to overcome the energy barrier for magnetization reversal. With increasing grain size the magnetization becomes nonuniform, following either the magnetocrystalline anisotropy direction within the hard magnetic grains or forming a flux closure structure in soft magnetic regions. Neighboring $\alpha$-Fe and $Fe_3B$ grains may form large continuous areas of soft magnetic phase, where magnetostatic effects will determine the preferred direction of the magnetization. The large soft magnetic

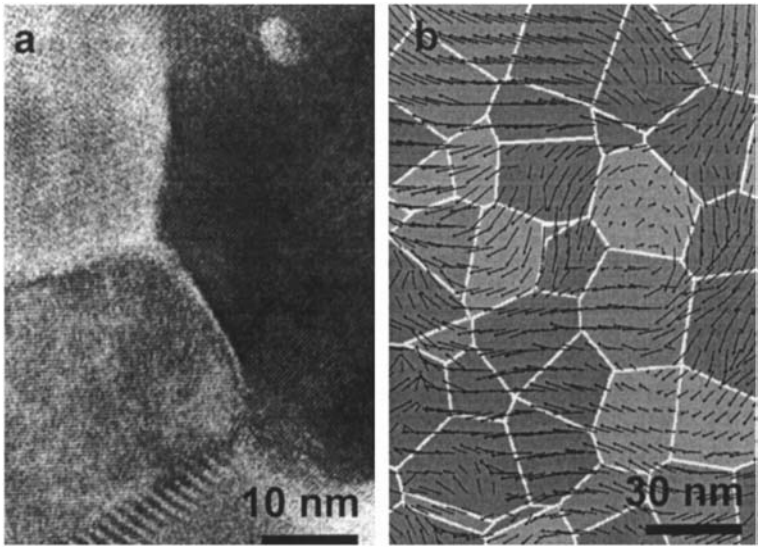

***Figure 5***
(a) High-resolution electron micrograph of a nanocrystalline, single-phase Nd-Fe-B magnet with isotropic alignment. (b) Calculated magnetization distribution with a vortex-like structure in a slice plane of a 40 vol.% $Nd_2Fe_{14}B$, 30 vol.% $\alpha$-Fe, and 30 vol.% $Fe_3B$ magnet with a mean grain size of 30 nm for zero applied field. The magnetic polarization remains parallel to the saturation direction within the soft magnetic grains, whereas it rotates towards the direction of the local anisotropy direction within the hard magnetic grains.

regions deteriorate the squareness of the demagnetization curve and cause a decrease of the coercive field for $D > 20$ nm. A vortex-like magnetic state with vanishing net magnetization will form within the soft magnetic phase if the diameter of the soft magnetic region exceeds 80 nm. Figure 5(b) presents the calculated magnetization distribution in a slice plane of a 40 vol.% $Nd_2Fe_{14}B$, 30 vol.% $\alpha$-Fe, and 30 vol.% $Fe_3B$ magnet with a mean grain size of 30 nm for zero applied field. The magnetic polarization remains parallel to the saturation direction within the soft magnetic grains, whereas it rotates towards the direction of the local anisotropy direction within the hard magnetic grains (see *Magnets: Remanence-enhanced*).

### 5. Summary

Microstructural parameters, such as grain size, shape of grains, crystal structure, crystal defects, orientation, and composition of various phases are different in $SmCo_5$-, $Sm_2Co_{17}$-, and $Nd_2Fe_{14}B$-based permanent magnet materials. The complex microstructure considerably influences the magnetic reversal process. Detailed TEM analysis revealed various additional binary and ternary phases in the intergranular region between hard magnetic grains in doped and substituted NdFeB magnets. Intergranular phases change the coupling behavior between the hard magnetic grains. Nonmagnetic phases eliminate the direct exchange interaction and also reduce the long-range magnetostatic coupling between the hard magnetic grains; both effects lead to an increase of the coercive field. The neodymium-rich intergranular phase is necessary for the liquid phase sintering process, but deteriorates the corrosion stability and reduces the remanence.

In order to improve coercivity, remanence, and energy density, it is necessary to increase the volume fraction of the hard magnetic phase by decreasing the amount of oxygen, neodymium and pores, and to improve the degree of alignment of the $Nd_2Fe_{14}B$ grains. Oxygen is partly dissolved in the neodymium-rich intergranular phase. By reducing the amount of oxygen ($< 1000$ ppm), abnormal grain growth during sintering becomes more severe. The difference in magnetic domain wall energy in precipitation-hardened $Sm(Co,Cu)_5/Sm_2(Co,Fe)_{17}$ multiphase magnets is the main factor determining coercivity. The inhomogeneous magnetization behavior near the intergranular regions of nanocrystalline rare earth magnets, which is directly responsible for remanence and coercivity, is strongly influenced by the microstructural parameters.

## Permanent Magnets: Sensor Applications

Sensors for the detection of magnetic fields in combination with a permanent magnet (actuator) are used in a variety of applications to measure the relative position/angle between mechanical parts (Roters 1941, Akoun and Yonnet 1984). Generally speaking these applications are divided into switches (e.g., end control of a linear unit) and analog or incremental continuous measurement. A common example for the latter group is all kinds of speed or position control in electrical machines (Adenot *et al.* 1996).

Magnetic switches as compared to mechanical micro-switches have no moving parts (except reed switches). Therefore, their main advantage is the theoretically infinite lifetime. In the case of continuous positioning or rotation measurement magnetic sensors are in competition with optical methods. While the latter allow a more accurate positioning measurement, the magnetic systems are less sensitive to dust and external influence. The advantages and drawbacks of competing methods have to be evaluated carefully.

This article describes the functionality of sensors, the design methods for the layout and optimization of actuating magnets in sensor applications, typical applications, as well as magnet examples with field specifications.

## *1. Magnetic Sensors*

### *1.1 Reed Switches*

The direct correspondents to mechanical microswitches are reed switches. In these devices two ferromagnetic contacts are sealed in a glass tube in an inert atmosphere. An external field serves to magnetize the contacts and they are attracted by their induced magnetic poles. Thus the contact will be closed. The external field to close the switch is commonly given in ampere turns defining the number of turns of a long solenoid per mm length multiplied by the required electric current necessary to close the switch. Typical values are 8–80 ampere-turns. The field threshold to open the switch again when the field is reduced is normally about 20–60% below the closing field.

The hysteresis between closing and opening is determined by the magnetic hardness of the contact material and by the geometry of the whole switch. Thus to reduce the switching hysteresis a very low coercive, magnetic material has to be used for the contacts and the switching distance between the two contacts has to be minimized. As an example Table 1 describes the switching behavior of a 15 ampere-turns switch driven by different AlNiCo 35/5 rods.

### *1.2 Hall Probes*

Hall effect sensors are based on a thin film of semiconducting material (typically indium arsenide) in which a voltage perpendicular to an applied current and an applied magnetic field appears (Fig. 1). This voltage is a direct measure of the magnetic field as long as the current is constant. These kinds of sensors with typical dimensions of the sensitive element of 0.6 mm × 0.2 mm are often combined with an amplifier. A following Schmitt trigger transforms the analogue signal to a digital signal if required. The switching hysteresis is normally smaller than for reed switches. For analogue sensors compensation is necessary for the temperature drift and for nonlinearity effects.

If multipole fields with a small pole pitch are to be detected by Hall probes it is necessary to keep in

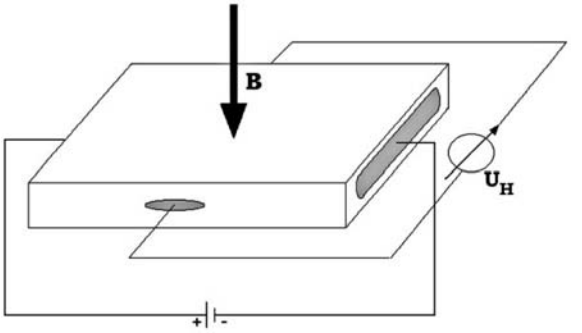

***Figure 1***

mind that the magnetic field is averaged over the size of the sensitive area in the element and thus measuring results are dependent on the sensor type. In a chip housing the Hall probe is typically 0.3–0.8 mm behind the surface of the housing.

### *1.3 XMR Sensors*

Magnetoresistance (MR) sensors use the field dependence of the electric resistance in a conducting or a semiconducting probe. While conventional MR effects are rather small in most semiconductors (about 1–3%), there has been a renaissance of these kind of sensors due to extremely large MR effects (XMR sensors), called *anisotropic* MR (AMR) (see *Magnetoresistance, Anisotropic*), *giant* MR (GMR) and, *colossal* MR (CMR) (see *Giant Magnetoresistance*). Even though the traditional MR effect has been used to measure the field strength, MR and XMR sensors are now, and in the near future will be more and more used to measure field angles by evaluating the change of resistivity in two directions. The principle of this method is shown in Fig. 2.

The in-plane magnetic field is measured in two Wheatstone bridges tilted at an angle of 45°. The measured voltages phase 1 and phase 2 correspond to the magnetic field angle $\varphi$ by phase $1 = k\cos(2\varphi)$ and phase $2 = k\sin(2\varphi)$.

The normal working range of sensors is about 10–100 $\mathrm{kAm^{-1}}$. Smaller fields can lead to deviations from the simple correlation between the field strength and the measured voltage while higher fields can irreversibly destroy some sensors.

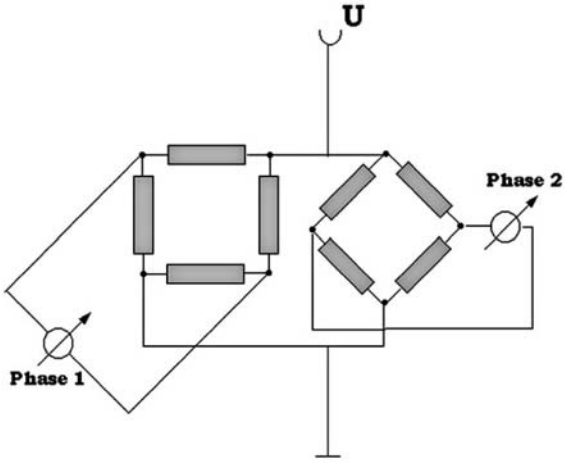

***Figure 2***
Schematic view of angular measurement with MR sensors.

### *1.4 Proximity Sensors*

These kinds of sensors are used in many kinds of automation. The approach of a ferromagnetic or conducting part to a coil is detected by the changed inductance of the coil. The coil forms a part of an LC circuit of which the frequency is measured with a high accuracy.

### *1.5 Induction Coils*

In dynamical devices rotating with a constant speed the induced voltage in a coil can be evaluated to determine the angular position of a spindle. Typically multipole magnets are fixed to a spindle and the rotation speed can be detected by either the amplitude of the induced a.c. voltage or by counting the periods of this voltage. This method is used for speed control in tool machines and in washing machines.

### *1.6 Impulse Wire Sensors*

In these, also called *Wiegand* sensors, a wire with a single magnetic domain is magnetically reversed and one corresponding large Barkhausen jump is detected by a coil (Rauscher and Radeloff 1991).

### *1.7 Permanent Magnetic Linear Contactless Displacement*

Permanent magnetic linear contactless displacement (PLCD) sensors use the change of induction of a locally saturated soft magnetic core. Even though it was introduced in the 1980s this principle is restricted to a few applications.

## *2. Field Design for Sensor Applications*

Most of the traditional methods (e.g., finite element method, FEM; finite difference method, FDM; and boundary integral method, BIM) to calculate magnetic fields are not appropriate for the design of configurations in sensor applications. On the one hand the open magnetic circuit of a singular permanent magnet does not require complicated numeric calculations for simply shaped magnets like rods or bar magnets. The field of these magnets can be calculated analytically. On the other hand most applications work with multipole magnets for which the calculated field depends greatly on the magnetic model of the magnet. In these cases it is necessary to take into account that a multipole magnetized magnet or, even more complicated, a multipole oriented anisotropic magnet has different magnetic material properties and direction of magnetization in each point within a magnet.

Traditional models in which the magnet is homogeneously magnetized in one direction are no longer

applicable. It is thus necessary to calculate the magnetic properties and the magnetization direction within each element of the permanent magnet from the circumstances during production or magnetization. The melt flow orientation simulation (MFOS) used to calculate the resulting magnetic field, therefore, consists of two analyzing steps. In a first step the magnetic field of the production tools are evaluated using conventional numerical methods. From the resulting field the distribution of magnetic material properties and the state of magnetization can be deduced for each point within the permanent magnet. In a second analysis these values are used to calculate the magnetic field that is produced by the final permanent magnet.

With this method crucial magnetic properties like the steepness of the transition between a north and a south pole or the irregular switching patterns or special magnetic shapes can be designed on the computer and can be compared to the required values without changing any dimension of the magnet. This method is demonstrated in Fig. 3.

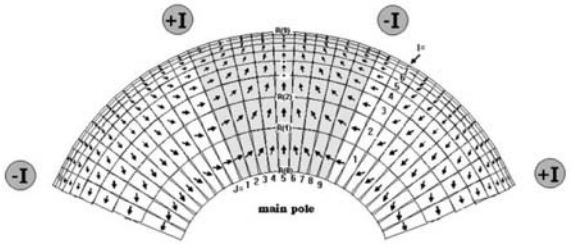

***Figure 3***
Principle of MFOS. The orienting field (from coil +I, −I) is calculated and the actual magnetization state in each element of the oriented magnet is simulated to calculate the resulting field.

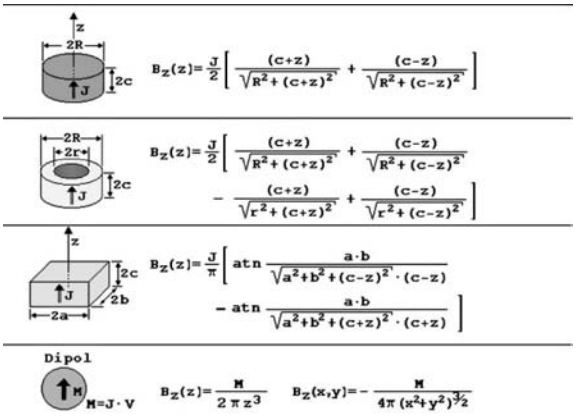

***Figure 4***
Analytical field of simply shaped permanent magnets.

### *2.1 Axially Magnetized Permanent Magnets for Sensors*

For the easy case of simply shaped magnets magnetized in one direction the field of bar-shaped, disc-shaped, or ring-shaped magnets can be calculated analytically by the formulas shown in Fig. 4. All these fields approach the dipole characteristic at larger distances as shown in Fig. 5.

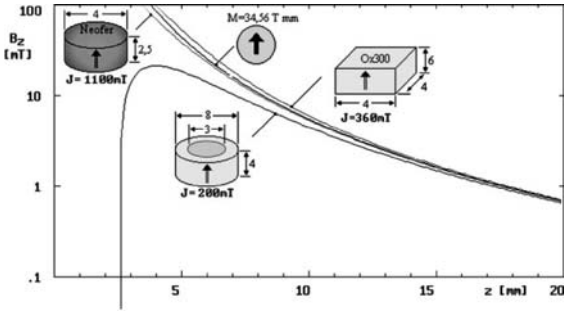

***Figure 5***
Field profile of the magnets in Fig. 4.

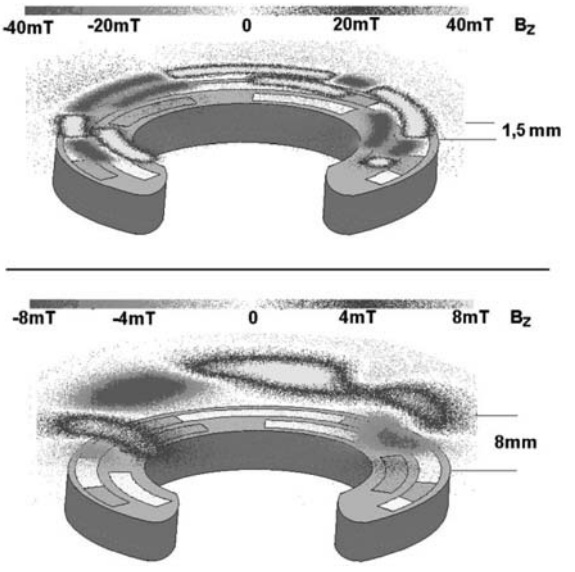

***Figure 6***
Field 1.5 mm and 4 mm above an irregularly magnetized permanent magnet.

### *2.2 Multipole Magnets and Irregularly Magnetized Permanent Magnets for Sensors*

Traditionally an isotropic permanent magnet material can be magnetized in a multipole pattern. In most cases isotropic ferrite rings are magnetized in an $n$ pole pattern on the circumference with a multipole coil supplied with a high current pulse of some microseconds. A large number of these magnets have been substituted by polymer-bonded anisotropic magnets. By injection molding of permanent magnet powder in a polymer matrix it is possible to orientate the powder particles during the injection process and thus to form a magnet with multipole anisotropy. These magnets are often magnetized due to the orientating field during the injection process. However, a final pulsed magnetic field can improve the magnetization by about 5–10%.

As an example Fig. 6 shows a permanent magnet magnetized on two radii in an irregular pattern for switching two sensors. By numerical simulation it is shown that the distance from the magnet to the sensitive Hall element has to be $<1.5$ mm. This is not due to the too low field at a distance $>1.5$ mm but due to the diffuse reflection of the magnetization pattern at a larger distance.

## Perovskites: Resistivity Behavior

Many compounds with perovskite structure are dielectrics and the temperature dependence of the resistivity $\rho(T)$ is of no interest. However, there is a large class of perovskite compounds in which a metal–insulator transition (MIT) takes place. Such perovskite compounds have the chemical formula $Ln_{1-x}A_xBO_3$, where Ln is a rare-earth atom and A is a bivalent atom and B may be manganese, nickel, cobalt, titanium, or vanadium. The MIT can occur as a consequence of a change in the concentration of A (especially for manganites $Ln_{1-x}A_xMnO_3$). In addition changes in temperature or an external magnetic field may also induce a metal–insulator transition. In spite of the apparent similarity of the $\rho(T)$ dependencies at the MIT, the underlying physical mechanisms that cause these transitions for different compounds are different. Following Imada *et al.* (1998), we will divide these compounds into three classes which exhibit a MIT controlled by:

(i) double exchange
(ii) bandwidth, and
(iii) band filling.

The crystal structure for all these compounds is a distorted cubic one. However, the distortions can be of various types and, therefore, they have a different effect on the band structure. The usual distortions have orthorhombic Pbnm or rhombohedral $R\bar{3}C$ lattice symmetry for the compounds in question, and the unit cell of the perovskite lattice is shown at Fig. 1.

The substitution of a bivalent element A for Ln in the compounds $LnBO_3$ leads to an increase in current carriers (holes) and this has a direct effect on the resistivity. Similarly, a deficiency ($x$) of Ln in $Ln_{1-x}BO_3$ affects the resistivity; these compounds being

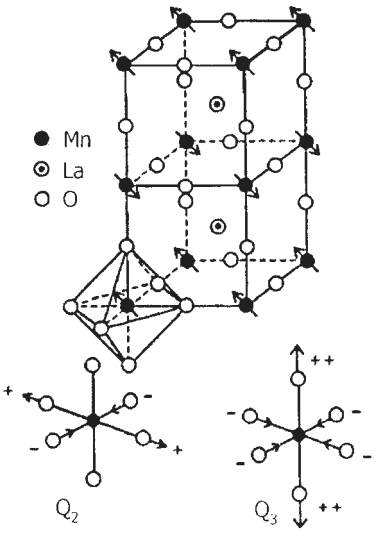

***Figure 1***
The ideal cubic perovskite structure, showing the AF type A order for $LaMnO_3$. In the actual structure the oxygen octahedron is distorted by a combination of the breathing mode ($Q_1$), the basal-plane distortion mode ($Q_2$), and the octahedral stretching mode ($Q_3$) in addition to a small rotation of the octahedron.

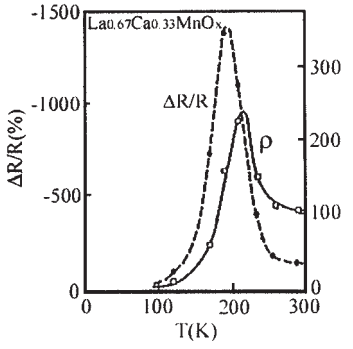

***Figure 2***

related to ionic conductors and their ionic mobility is high at high temperatures. These deficiency compounds can exist in a rather broad range of chemical composition. In both cases a lattice distortion takes place due to difference in size between Ln and A (or vacancy) atoms.

The application of a magnetic field can induce a MIT or shift the temperature at which it occurs; such changes can cause the resistivity of some manganite compounds to decrease by several orders of magnitude. This effect was discovered in 1993 (von Helmot *et al.* 1993, Jin *et al.* 1994) and was named the colossal magnetoresistive effect (CMR). Figure 2 shows the temperature dependence of the resistivity, $\rho(T)$, and magnetoresistance $\Delta R/R$ for a thin film sample of $La_{0.67}Ca_{0.33}MnO_3$. The decrease in the resistance can be as high as a field of 1000 in a field of 6 T at 200 K. The physical properties of all compounds with perovskite structure are very sensitive to the method of preparation and the occurrence of defects.

The interest in these materials arises from the prospect of their use in various electronic devices controlled by magnetic field, examples of which are magnetic field sensors and more specifically spin transistors. These CMR materials have also been found to have a large magneto-optical Faraday effect, and some new effects have been observed for these materials in experiments with spin polarized tunneling in superconductors.

## 1. Double Exchange System

### 1.1 Doped Rare-earth Manganites

The compounds $Ln_{1-x}A_xMnO_3$ have rather complex phase diagrams, and consequently different properties for different compositions. In compounds such as $La_{1-x}A_xMnO_3$ (A = Ca, Sr, Ba, Pb; $0.2 < x < 0.4$) at some temperature, $T_m$, the MIT takes place even

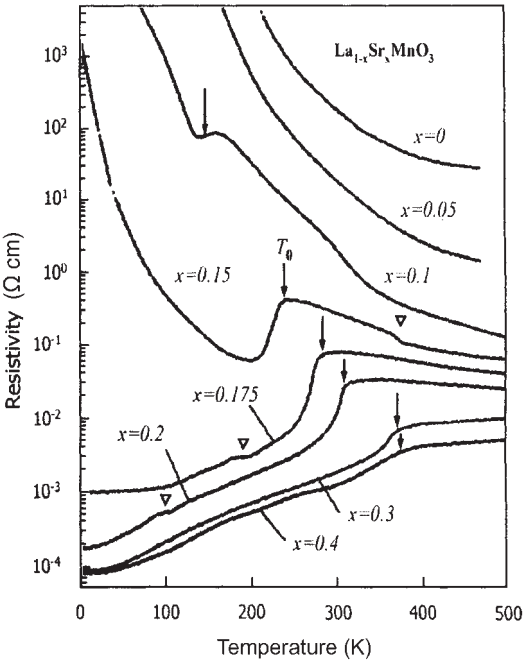

***Figure 3***
Temperature dependence of resistivity for $La_{1-x}Sr_xMnO_3$ crystals. Arrows indicate the critical temperature for the ferromagnetic phase transition. Anomalies indicated by open triangles are due to the structural transition (after Urushibara *et al.* 1995).

without an external magnetic field (Fig. 2 and 3). In other compounds, such as $Pr_{0.7}Ca_{0.3}MnO_3$ the MIT is induced by a magnetic field (Fig. 4). In this instance the change of $\rho(T)$ is closely connected with a change in the magnetic structure.

The maximum in $\rho(T)$ is situated near the Curie temperature, $T_C$. In addition, $\rho(T)$ and $\Delta R/R$ are also sensitive to changes in the lattice parameter. Values of $\Delta R/R$ for thin films and ceramic polycrystalline samples are found to be much larger than those observed for the corresponding single crystal samples with high sample quality. This is especially so in low magnetic fields. It has been shown that in polycrystals and thin films, the main contribution to the magnetoresistance in low magnetic fields derives from the grain boundaries. A change in magnetic order often results in a change of crystal structure in a compound. A deformation of the crystal lattice in the manganites can also be due to the Jahn-Teller (JT) effect of $Mn^{3+}$.

Due to the complexity of these compounds there can be no exhaustive explanation of the CMR effects in the manganites. These compounds belong to the class of strongly correlated systems in which electronic, magnetic, and lattice subsystems are intimately

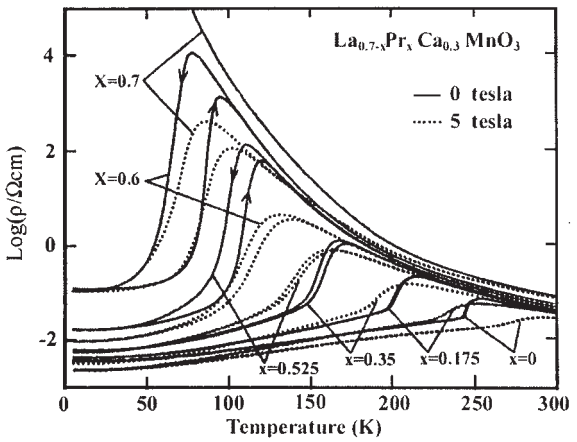

***Figure 4***
Temperature dependence of resistivity $\rho$ for $La_{0.7-x}Pr_xCa_{0.3}MnO_3$ compound without and in magnetic field of 5 T (after Hwang *et al.* 1995).

linked. The presence of a strong isotopic effect can be taken as evidence for the important role played by the electron–phonon interaction. The main theories adopted to explain the MIT and CMR effects in manganites are based on the concept of double exchange and take account of the Jahn-Teller effect.

### *1.2 Double Exchange Model*

The properties of the doped rare-earth manganites were first discussed by Zener (1951) using a model based on double exchange. A more detailed consideration of the model was made by Anderson and Hasegawa (1955). The double exchange represents a kind of indirect exchange between cations with their charge states differing by one and linked through an anion. In the case of the manganites the manganese ions, $Mn^{3+}$ and $Mn^{4+}$, interact through an $O^{2-}$ (Fig. 5). The extra electron has an equal probability of being at the first or second Mn site.

That is, the configurations, $Mn^{3+}$–$O^{2-}$–$Mn^{4+}$ and $Mn^{4+}$–$O^{2-}$–$Mn^{3+}$, are equivalent and the ground state of the system is degenerate. So between $Mn^{3+}$ and $Mn^{4+}$ ions a resonance bond exists resulting from electron transfer. This in turn leads to an energy lowering that depends on the mutual orientation of the cation spins **S1** and **S2**. As a consequence of this degeneracy the spin of the transferred electron in the lowest energy state must have the same orientation as **S1** and **S2,** and thus this indirect exchange is ferromagnetic. As was shown by Anderson and Hasegawa (1955), the energy gain is $2b\cos(\Theta/2)$, where $\Theta$ is the angle between **S1** and **S2** spins (Fig. 5), and $b$ is expressed through the transfer integral from the first to the second manganese ion.

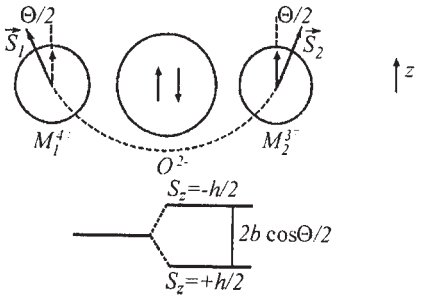

***Figure 5***
Diagram of the double exchange model.

From the discussion above, it follows that if there is a distribution of $Mn^{3+}$ and $Mn^{4+}$ ions within the crystal, there can be electron transfer between these ions and a tendency to orient their spins in a ferromagnetic (FM) manner; there will be a feedback between these processes. The FM ordering of the compound leads to an increase in the conductivity, and the application of an external magnetic field leads to an enhancement of FM ordering resulting in an increase of the conductivity. In the case of $Pr_{0.7}Ca_{0.3}MnO_3$ (Fig. 4), an antiferromagnetic compound, an external magnetic field results in a FM state and produces a metal–insulator transition.

A detailed consideration (Millis *et al.* 1995) of the role of double exchange in the manganites exhibiting CMR has revealed that this model does not adequately explain the behavior of the resistivity. Other models have been proposed that take into account a strong electron–phonon interaction that results in polaron formation. In the report of Millis *et al.* (1995) it was suggested that the cause for such polaron formation is splitting of outer level $e_g$ of $Mn^{3+}$ ion when static or dynamic Jahn-Teller lattice distortion takes place.

### *1.3 The Jahn-Teller Effect*

The Jahn-Teller (JT) effect involves the partial removal of the *d*-electron degeneracy for atoms in a crystal field, and results in reduction of symmetry of the lattice. Since the ground state of the system has an unstable orbital degeneracy, this degeneracy can be removed by lowering of the self-symmetry when a deformation of the surrounding of the ions occurs, which in turn leads to a reduction in the crystal field energy and removal of the degeneracy.

In the case of the rare-earth manganites with perovskite structure, manganese ions are surrounded by an octahedron consisting of six oxygen ions (Fig. 1). The $Mn^{3+}$ ion with electronic configuration $d^4$ in a field with octahedral symmetry has a half-filled low-lying threefold level $t_{2g}$ ($d^3$) and a higher-lying

twofold level $e_g$ containing one electron. Such a configuration is the effect of strong exchange coupling where, according to the Hund's rule, all spins are oriented parallel. As a result of this, there is an effective hole in one of the orbitals of the cation which results in stronger screening from both anions along this orbital axis. Consequently, if the state $d_{x^2-y^2}$ is unfilled, there is an elongation of the octahedron along its axis ($c > a$). If, however, the state $d_{z^2}$ is unfilled there is a distortion in the perpendicular direction (Fig. 1) and in this case $c < a$. These distortions involve the removal of the *d*-level degeneracy and a reduction in the energy.

If a crystal contains a sufficient number of JT ions, then a co-operative ordering of the distorted polyhedrons may arise such that the crystal symmetry and the energy is lowered. Such crystal distortions can only take place at sufficiently low temperatures. As the temperature increases the crystal undergoes a phase transition at which the lattice symmetry makes increase. For low concentration of JT ions and at elevated temperatures a dynamical JT effect may occur. This consists of an interaction between the local electron configuration distortions and the lattice vibrations (phonons). As a result of this interaction the local distortion can be removed, and the symmetry surrounding the cation becomes cubic when averaged over time. In the doped rare-earth manganites the dynamical JT effect can occur due to the charge transfer between $Mn^{3+}$ and $Mn^{4+}$ ions.

### 1.4 Bond Directions

The change of conductivity and MIT in the manganites is also connected with orbital overlap. In the interaction between two cations through the anion (C-A-C), there is a weak overlap of cation orbitals, and the anion fulfils a connecting function. This interaction depends on the nature of the interacting atoms, and is displayed in an anisotropy of the 3*d* cation orbitals, the interaction depending on the distance between atoms and on the bond angle of C-A-C. A correlation between the C-A-C bond angle and the nature of the magnetic ordering has been observed, and found to determine the metal–insulator transition. For ferromagnetic compounds the C-A-C angle is approximately 180°. Doping of a basic compound by atoms with different size results in a change of the C-A-C bond angle. They may have consequences for the MIT.

### 1.5 The Role of Inhomogeneity

Also, it has also been demonstrated that structural and chemical inhomogeneities play an important role, and this becomes very important when the concentration, $x$, of a doped element A is small.

It was suggested by Gor'kov (1998) that Coulombic forces result in holes becoming localized near dopants, which makes the formation of conducting clusters along these charged centers a major factor in resistivity behavior of manganites. A charge transfer in the cluster is possible due to the double exchange and the localization is due to the JT effect. This is demonstrated in the data for $La_{1-x}Sr_xMnO_3$ (Fig. 3), where the transition between two kinds of $\rho(T)$ dependence occurs at $x \sim 0.16$. This corresponds to a percolation threshold for a three-dimensional system of random conducting links. Thus the FM phase and metallic-like conductivity arise in percolating clusters which develop when the dopant concentration increases.

### 1.6 Resistivity Behavior in the Metallic Region

For manganites compounds that undergo the MIT in a particular concentration range, for example for $0.2 < x < 0.4$ in the $La_{1-x}Sr_xMnO_3$ system (Urushibara *et al.* 1995) or for $La_{0.67}(Pb,Ca)_{0.33}MnO_3$ compound (Jaime *et al.* 1998), the resistivity can be described by $\rho(T) = \rho_o + AT^2$ in a fairly wide temperature range (from 10 K to 200 K, Fig. 6). The nature of such resistivity behavior remains unclear, due mainly to the lack of detailed experiments performed on good quality, single crystal samples. Several mechanisms may be held responsible for the $T^2$-dependence.

Amongst these are electron–electron scattering, electron–magnon scattering, and a peculiar electron–

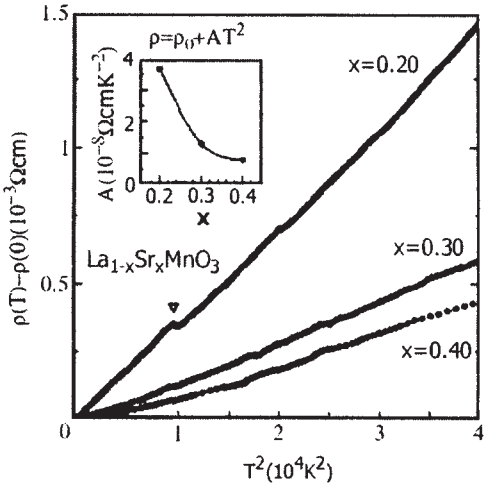

***Figure 6***
Temperature dependence of resistivity in the low-temperature region ($T < 200$ K) for $La_{1-x}Sr_xCoO_3$ crystals. The $T^2$ dependence of resistivity was observed. Inset: shows the coefficient A against the nominal hole concentration $x$. (after Urushibara *et al.* 1995).

phonon interaction due to specific features of the Fermi surface. It has been shown (Jaime *et al.* 1998) that the Kadowaki–Woods relation, $A = C\gamma^2$, where $\gamma$ is the coefficient of the electronic specific heat and $C$ a universal constant, $C = 10^{-5}\,\mu\Omega\,\mathrm{cm}\,(\mathrm{molK\,mJ^{-1}})^2$, is not fulfilled in these compounds. This relation provides an anomalously large value that rules out the electron–electron scattering mechanism. In addition the $AT^2$ value for 200 K is more than ten times greater than the $\rho_o$ value, being as high as $\sim 5\,\mu\Omega\,\mathrm{cm}$ for the best samples. Therefore any reliable method determining the scattering mechanisms remains absent at the present time.

## 2. *Bandwidth-controlled MIT Systems*

### 2.1 $Ln_{1-x}A_xNiO_3$

The compounds, $LnNiO_3$, exist for all lanthanide elements and have pseudocubic perovskite structure, which is rhombohedral $R\bar{3}C$ for $LaNiO_3$ and orthorhombic Pbnm for the other rare earths (Medarde 1997). The temperature dependence of $\rho(T)$ for $LaNiO_3$ may be described as metallic ($d\rho/dT > 0$) in the temperature range $T = 0.4$–$300\,\mathrm{K}$ (Gayathri *et al.* 1999), but other compounds experience a MIT at a certain $T_{M\text{-}I}$ and $\rho(T)$ exhibits semiconductor behaviour ($d\rho/dT < 0$) (Fig. 7). The evolution of $T_{M\text{-}I}$ along the compound series can be correlated with the degree of deviation of each compound from the ideal perovskite structure, which increases as lanthanum is replaced by the smaller-size rare earth ions.

The metal–insulator transition occurs close to an antiferromagnetic transition, and the formation of ordered spin structures is attributed to the formation of an orbital superlattice. However, in spite of there being nominally one electron in the $e_g$ orbital, as in $LaMnO_3$, no evidence for Jahn-Teller distortion has been found. The 3-D magnetic ordering consists of alternating converted bilayers AA(AA)AA(AA) … along the [001] direction, with AA and (AA) representing the magnetic arrangement of nickel moments in adjacent (001) planes. The coexistence of F and AF interactions, which is revealed in the ordered spin structure, suggests the existence of an orbital superlattice such as the regular occupation of either $d_{x^2-y^2}$ or $d_{3z^2-r^2}$ type orbitals.

The relevant parameter controlling the transition at $T_{M\text{-}I}$ and the Néel temperature, $T_N$, as well as the stability of different crystallographic structures found along the compound series is the Ni-O-Ni superexchange bond angle $\Theta$. The insulating state of $LnNiO_3$ should be classified as a charge-transfer insulator, i.e., the MIT takes place due to the opening of a charge-transfer type gap below $T_{M\text{-}I}$. The high valency of the $Ni^{3+}$ ions in $LnNiO_3$ makes its charge transfer energy $\Delta$ as small as $\sim 1\,\mathrm{eV}$ and stabilizes its low-spin configuration $t_{2g\uparrow}t_{2g\downarrow}e_{g\uparrow}$. In this system the ground state has a strong mixture of $d^7$, $d^8L$, and $d^9L^2$ configurations, resulting in a net $d$-electron number as large as $n_d = 7.8$. The nickel magnetic moment is found to be $\sim 0.91\,\mu_B$, close to the ionic value of 1 $\mu_B$, and this is a result of the charge transfer which occurs from O $2p$ orbitals to $e_{g\uparrow}$ and $e_{g\downarrow}$ orbitals in $Ni^{3+}$. One electron is involved in the hybridization between the $t_{2g}$ and $e_g$ orbitals on the mean field level, so there is no pair-transfer contribution in the high-spin $Ni^{3+}$ ion because the spin is fully polarized (Imada *et al.* 1998).

For $LaNiO_{3-x}$ compounds the $\rho(T)$ behavior changes with $x$ increasing, and as the number of vacancies increases $\rho(T)$ may be approximated by $\exp(-T_o/T^{1/4})$. This is in accord with the Mott dependence for disordered systems with random thermally activated hopping, and $\sim\exp(-Q/T)$ for the ordered vacancies state ($x = 0.5$) (Sanchesz *et al.* 1996).

For a small oxygen deficiency, x, the resistivity $\rho(T)$ shows a power-law dependence $\rho(T) = \rho_o + \alpha T^{1.5} + \beta f(T)$, where $f(T)$ is a function leading to a linear temperature dependence at high temperature ($T > 200\,\mathrm{K}$) and to a $T^n$-dependence ($n > 2$) at low temperatures. $\rho_o$ is the residual resistivity and $\alpha$ and $\beta$ are constants (Gayathri *et al.* 1999). The $T^{1.5}$ term implies that the power-law exponent is greater than unity even at the highest temperatures. Such a strong dependence can arise from scattering involving optical phonons in the system. The most metallic sample has a clear positive magnetoresistance (MR) which progressively becomes negative as the oxygen deficiency increases. The positive MR may arise from a band-like contribution, whilst the negative MR, observed for the oxygen-deficient samples, arises from the weak-localization contribution and is not due to any magnetic interactions.

## 3. *Filling-controlled MIT Systems*

### 3.1 $Ln_{1-x}A_xTiO_3$

The compound $LnTiO_3$ is a typical Mott–Hubbard insulator with $Ti^{3+}$ in a $d^1$ configuration, and the A content, $x$, represents the nominal "hole" concentration per titanium site or equivalently the 3*d* band filling ($n$) is given by $n = 1-x$. The crystalline structure is an orthorhombically distorted perovskite. The Ti-O-Ti bond angle distortion, which affects the transfer energy ($t$) of the 3*d* electron or the one electron bandwidth ($W$), depends critically on the ionic radii (Ln, A) or on the tolerance factor. With decreasing size of the Ln ion, $LnTiO_3$ changes from an antiferromagnetic (AFM) insulator ($LaTiO_3$) to a ferromagnetic (FM) insulator ($YTiO_3$). The $t_{2g}$ configuration in the nearly cubic $LaTiO_3$ is in the quadruply degenerate spin-orbit ground state.

This develops into two states with have antiparallel orbital and spin moments (both directed in the [111] direction) and alternating between nearest neighbors, which results in this G-type AFM state. An increase in the distortion induces greater hybridization between neighboring *xy*, *yz*, and *zx* orbitals, leading to an enhancement of the AFM orbital exchange as well as the FM exchange. This enhancement derives from Hund's rule coupling (Imada *et al.* 1998). The magnetic ordering favors the Jahn-Teller distortion, and the $t_{2g}$ level is split into two low-lying levels and one higher level. At each site one of the two lower orbitals is occupied so that the neighboring orbitals are approximately orthogonal to each other with their spins FM aligned.

Filling control in the 3*d* band can be achieved by partially replacing the trivalent ions with divalent calcium or strontium ions. In Fig. 8 the temperature dependencies of the resistivity $\rho(T)$ for $CeTiO_{3+y/2}$ and $Ce_{1-x}A_xTiO_3$ are shown. For $CeTiO_{3+y/2}$, which has a relatively weak electron correlation, only a small amount of hole doping is sufficient to destroy the AFM state and cause the MIT. The compound $Ce_{1-x}Sr_xTiO_3$ ($0.04 < x < 0.4$) is similar to $La_{1-x}Sr_xTiO_3$, and $\rho(T)$ manifests metallic behavior which can be modeled over a wide temperature interval by $\rho(T) = \rho_0 + AT^2$ ($\rho_0$ is a residual resistivity and A is a constant) (Fig. 9). This $T^2$ dependence of the resistivity is reminiscent of the dominant electron–electron scattering process, and the Kadowaki–Woods relation $A = C\gamma^2$ is fulfilled for these compounds. It must be noted that the model holds for rather high temperatures (up to 300 K). The coefficient A becomes enhanced as the Mott–Hubbard insulator state is approached from the metallic side.

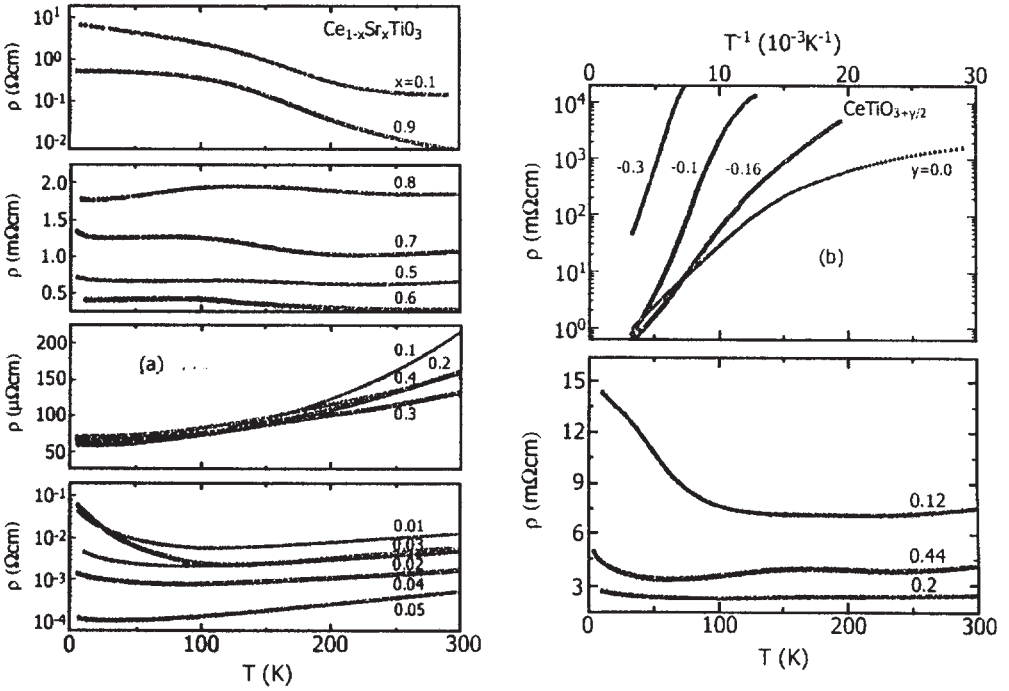

***Figure 8***

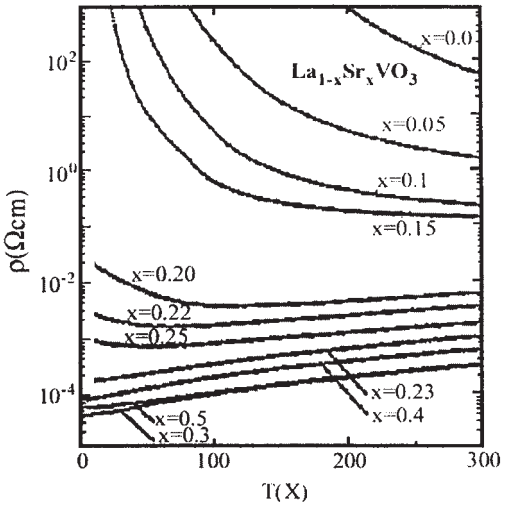

***Figure 10***
Temperature dependence of resistivity, $\rho$ in $La_{1-x}Sr_xVO_3$ (after Inaba *et al.* 1995).

### 3.2 $Ln_{1-x}A_xVO_3$

The parent compound $LnVO_3$ has a tetragonal structure for Ln = La, Ce and perovskite structure, with an orthorhombic distortion for the other lanthanides. $LnVO_3$ is a typical Mott–Hubbard insulator and undergoes an AFM transition at temperatures between 120 K and 150 K. The AFM phase is accompanied by a spin canting, giving rise to a weak ferromagnetic component.

With hole doping by partial substitution of divalent ions for rare earth ions, the insulating AFM phase is suppressed. In Fig. 10 one can see that $\rho(T)$ changes from activation type to metallic-like behavior for $x>0.2$. With hole doping, the charge-transfer gap shifts to a lower energy mainly due to the shift in the 2*p* band, and the Mott–Hubbard gap is closed. In the metallic region $\rho(T)$ (Fig. 11) can be well expressed by the relation $\rho(T)=\rho_0+AT^{1.5}$. The $T^{1.5}$ dependence of the resistivity can be interpreted in terms of the strong Curie-like enhancement of the spin susceptibility due to strong antiferromagnetic spin fluctuations (Inaba *et al.* 1995).

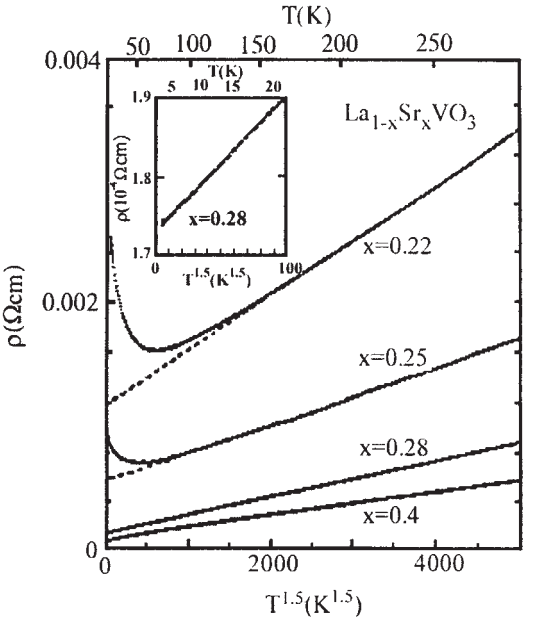

***Figure 11***
Temperature dependence of resistivity, $\rho$, of samples of $La_{1-x}Sr_xVO_3$ near the metal–insulator phase boundary; $\rho$ is plotted vs. $T^{1.5}$. (after Inaba *et al.* 1995).

### 3.3 $Ln_{1-x}A_xCoO_3$

The ground state of $LaCoO_3$ is a nonmagnetic insulator and the predominant configuration of the *d*-electrons is $3d^6$ for $Co^{3+}$ which fully occupy the $t_{2g}$ level resulting from crystal field splitting (10 Dq); this slightly exceeds the Hund's rule coupling energy. With an increase of the temperature the compounds undergo a spin-state transition from a nonmagnetic ($t_{2g}^6$, $S=0$) to a paramagnetic state ($t_{2g}^5$ $e_{2g}^1$, $S=1$ or $t_{2g}^4$ $e_{2g}^2$, $S=2$). A small amount of hole doping gives rise not only to a decrease in resistivity but also to a large change of magnetic susceptibility (Imada *et al.* 1998). A hole, with O 2*p*-state character, causes a

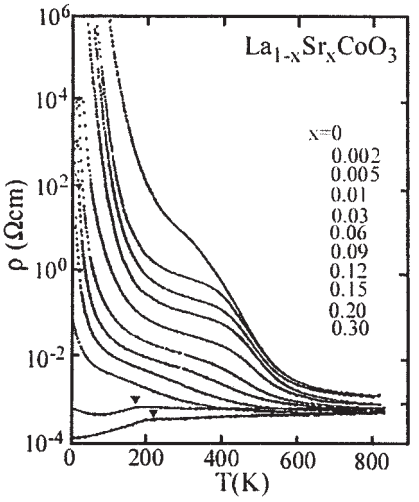

***Figure 12***
Temperature dependence of resistivity, $\rho$, in $La_{1-x}Sr_xCoO_3$ with various doping levels. Triangles represent the FM transition temperature (after Imada *et al.* 1998).

local spin-state transition (low spin to intermediate spin) over 10–16 cobalt sites around deriving from strong $2p\sigma-3de_g$ hybridization. Such a large spin polaron is a precursor state for the FM metallic state in $La_{1-x}$ $Sr_xCoO_3$ ($x>0.2$).

The resistivity $\rho(T)$ decreases with increasing x and the behavior of $\rho(T)$ changes abruptly around the composition $x=0.2$ (Fig. 12). The resistivity for $x<0.2$ follows the dependence $\rho(T)=\rho_0\exp[(T_0/T)^n]$, where $n=S$. This is the signature of variable range hopping in the presence of a Coulomb gap within the density of states, and it seems to be a consequence of the cluster nature of the magnetic spins. In compounds with $x>0.2$, the FM as well as the metallic behavior is related to the formation of $Co^{4+}$ ions following from $Sr^{2+}$ substitution. The macroscopic metallic state is formed through percolation. As the temperature is reduced to below approximately 100 K, the spin-state transition will drive most of the $Co^{3+}$ ions into the low-spin state, thus gradually localizing the carriers in the FM clusters (Fig. 13).

Metallic cobaltite compounds show negative magnetoresistance (MR), the highest value of MR is observed close to $T_c$. The value of the MR is much

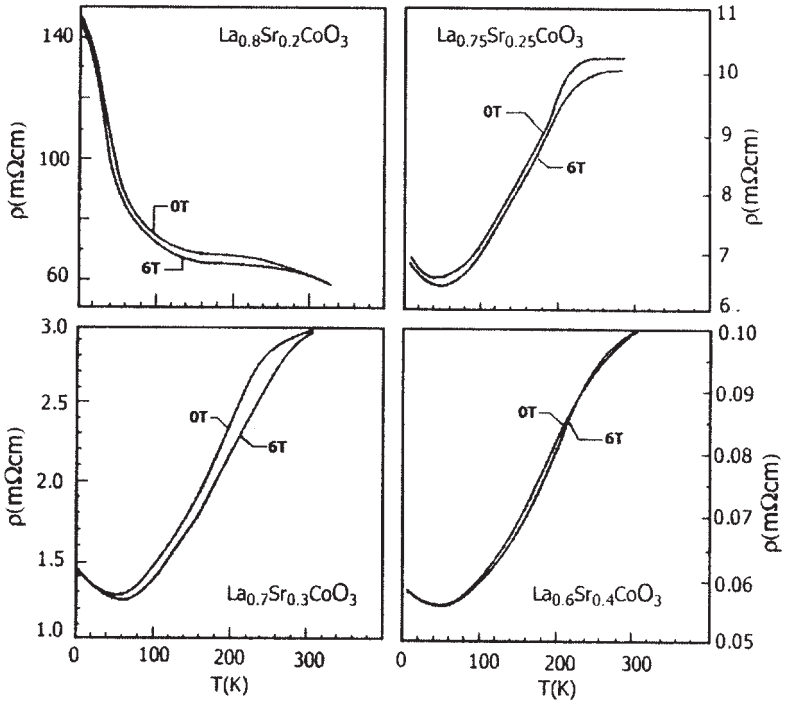

***Figure 13***
Temperature dependence of resistivity, $\rho$, in zero field (0 T) and in the field of 6 teslas (6 T) for $La_{1-x}$ $Sr_xCoO_3$ compounds (after Mahendiran and Raychaudhuri 1996).

smaller than that observed for the manganites. The negative MR derives from suppression of spin-disorder scattering due to the application of an external magnetic field. The spin-fluctuation scattering is strongest near $T_c$ and the negative MR also is at a maximum. In conclusion $La_{1-x}Sr_xCoO_3$ is described as a filling-controlled system since the doped holes not only act as metallic carriers but also induce a ferromagnetic moment.

### *4. Summary*

The resistivity behavior of the compounds with perovskite structure show similar features in spite of different mechanisms. The presence of Jahn-Teller ions involves a structural distortion that leads to band splitting. Magnetic interactions also play a very important role, and these compounds are strongly-correlated systems in which electron, lattice, and magnetic degrees of freedom act together to determine their physical properties including resistivity. The peculiarities of the resistivity behavior depend not only on a specific physical mechanism but also on the sample quality. A detailed study of these compounds demands fabrication of samples with perfect structure in order to separate properties intrinsic to the compound from properties associated with the preparation conditions and various defects.

## Perturbed Angular Correlations (PAC)

Among the numerous experimental techniques available for studying solids, techniques focused on hyperfine interactions form a subclass that probes a material at the smallest possible length scale. After an outline of the basic principles of hyperfine interactions, the perturbed angular correlation (PAC) method is described and compared with the widely used Mössbauer technique (Cahn and Lifshin 1993). Particular attention is paid to information that can be obtained from PAC experiments. The extended applicability of the method enabled by employing advanced *ab initio* theories is also discussed. Finally, a PAC study of Fe/Cr multilayers is given as an example.

### *1. Hyperfine Interactions*

The simplest nonrelativistic quantum mechanical interpretation of an atom is based on an infinitely massive and point-like nucleus, and ignoring interactions between electrons. This leads to the well-known hydrogen-like electron energy levels, with a

characteristic separation of a few electron volts. Including electron–electron interactions and relativistic effects produce both a shift and degeneracy lifting of these levels on a millielectron volt scale. The resulting energy level scheme is called the fine structure. An even more subtle correction to these levels—the hyperfine structure—stems from the nucleus not being point-like. Deviation from a point can occur both in real space and in spin space.

In the former case, the simplest nontrivial example is a description of the charge density within the nucleus as a deformed sphere (prolate or oblate), which can be characterized by the nuclear quadrupole moment, $Q$. In spin space, the smallest deviation from a point is described by the nuclear magnetic dipole moment, $\mu$. The interaction of both nuclear moments $Q$ and $\mu$ with the surrounding electrons leads to a hyperfine structure in the electron energy levels, on a scale of $10^{-12}$eV. As we are dealing here with an interaction, exactly the same hyperfine structure will occur both in the *electronic* and in the *nuclear* energy levels. The PAC technique is based on the hyperfine structure of nuclear energy levels.

The hyperfine interaction operates over a very short range. It is determined by the nuclear wave functions—which are only nonzero inside and close to the nucleus—and the tails of the (valence) electron wave functions that reach the nucleus. As a consequence, bonding effects on the valence electrons caused by the atom being contained in a molecule, liquid, or solid are transferred to the nuclear hyperfine structure. Hence, measurements of a hyperfine structure provide information on the chemical environment of a particular atom. For research in magnetism, the interaction of the nuclear magnetic moment with the magnetic field due to surrounding electron spins is important.

This interaction is mainly given by the Fermi contact term, which describes a nucleus embedded in a homogeneous magnetic medium due to the net $s$ electron spin density, $m(0)$, at the nucleus (in a relativistic approach $p$ electrons can also penetrate the nucleus). The magnetic field generated this way at a nucleus is called the magnetic hyperfine field, $B_{\mathrm{hf}}$, and is given by:

$$B_{\mathrm{hf}} = \frac{8\pi}{3}\mu_0\mu_{\mathrm{B}}m(0) \tag{1}$$

where $\mu_0$ is the permeability of vacuum and $\mu_{\mathrm{B}}$ the Bohr magneton. The splitting of nuclear energy levels is related to $B_{\mathrm{hf}}$ by:

$$\Delta E_{\mathrm{hf}} = \frac{\mu}{I}B_{\mathrm{hf}} \tag{2}$$

where $\mu$ is the magnetic dipole moment of the nucleus and $I$ its spin quantum number. Apart from the Fermi contact term, other (and usually smaller) contributions to the hyperfine field originate in orbital and spin motion of electrons.

## 2. *Measuring Hyperfine Interactions by PAC*

Several experimental techniques based on different principles are available to measure the magnetic hyperfine interaction. In Mössbauer spectroscopy (MS) recoilless emission and absorption of a Doppler-shifted $\gamma$-ray by a radioactive nucleus is exploited. Time differential perturbed angular correlation (TDPAC or PAC) spectroscopy uses the reorientation of an oriented ensemble of nuclei under the influence of a hyperfine field (Schatz and Weidinger 1996, Catchen 1995). It needs a radioactive nucleus with a subsequent emission of two $\gamma$-rays in its decay scheme. Nuclei emit $\gamma$-rays preferentially along their spin direction. Hence, detecting the first of the two $\gamma$-rays by a fixed detector selects an ensemble of nuclei with their spin oriented preferentially along this detector axis.

If a hyperfine field is present, the hyperfine-split nuclear Zeeman levels are repopulated by the hyperfine interaction. This repopulation is equivalent to a reorientation of the nuclear spin, an effect which in a semiclassical picture is called the Larmor precession of the nuclear spin around the direction of the hyperfine field. Hence, the frequency of this rotation can be monitored by detection of the second $\gamma$-ray by a second detector, making a fixed angle with the first one. After data reduction, the resulting function, called $R(t)$, is proportional to the time evolution of the emission probability of the second $\gamma$-ray in a given direction and clearly shows the spin precession (Fig. 1). The relation between the observed precession frequency, $\nu$, and the hyperfine field is:

$$\nu = \frac{\mu}{hI}B_{\mathrm{hf}} \tag{3}$$

where $h$ is Planck's constant. Information which can be obtained by analyzing $R(t)$ is discussed in Sect. 4.

## 3. *A Comparison Between PAC and MS*

Owing to the fast electronics needed to perform a PAC measurement (note that the time scale in Fig. 1 is in the nanosecond range) this method is less used than its ''sister'' technique MS. Nevertheless, PAC has some advantages over MS. It is insensitive to temperature, in contrast to MS where the recoilless fraction is strongly temperature dependent and prevents the use of MS at too high a temperature. Therefore, PAC is better suited to follow phenomena as a function of temperature. The number of radioactive nuclei which are needed is orders of magnitude lower than for MS. An absolute amount of $10^{11}$–$10^{12}$ PAC probes is sufficient. Hence, if the studied nucleus represents an impurity in a material, it has a

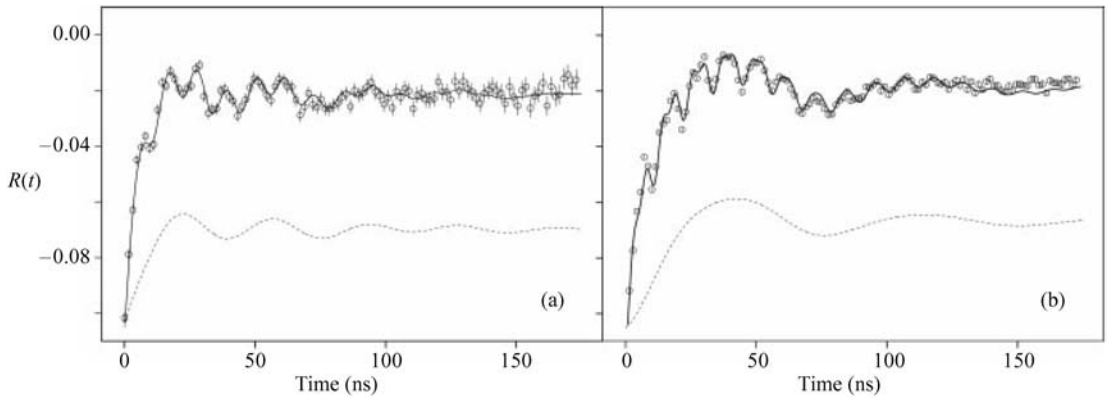

***Figure 1***
PAC measurements at 289 K for two different orientations (with respect to the detectors) of a Fe/Cr multilayer with an iron thickness of 2 nm and a chromium thickness of 7.5 nm.

negligible effect on the matrix. However, there are some disadvantages.

If interactions become too strong, the oscillations in $R(t)$ become too fast to detect. Therefore, there is an upper limit to the interaction strength detectable by PAC. If the interaction is too weak, a single oscillation takes longer than the time interval where enough data can be gathered. This determines the lower limit of the detectable interaction strengths. In MS only such a lower limit is present. Another advantage of MS is that it can measure the *s* electron density in the nucleus by the isomer shift, a quantity not probed by PAC. Finally, PAC is suited for some nuclei which are inaccessible by MS and vice versa (the most common PAC nuclei are $^{111}$Cd (parent $^{111}$In), $^{181}$Ta (parent $^{181}$Hf), and $^{100}$Pd (parent $^{100}$Rh)). The above aspects of PAC and MS indicate that the two methods are complementary.

## 4. Information Obtained in a PAC Experiment

### 4.1 Site Occupation

The $R(t)$ function is characteristic for a specific environment felt by the probe nucleus. If two or more distinct environments are present, the measured $R(t)$ is a sum of the $R(t)$ functions due to each environment. The distinct sites can, for example, be nonequivalent lattice positions, a substitutional and an interstitial position, or a surface and a bulk position. Unraveling a measured $R(t)$ function into the partial $R(t)$ functions from which it is built, and assigning these to a specific position in the sample makes it possible to track their occupation by probe atoms. This enables, for example, a study of the formation and migration of defect complexes as a function of temperature.

### 4.2 Magnitude of the Magnetic Hyperfine Field

The frequencies of an $R(t)$ function are proportional to the Larmor precession frequency, and hence to the strength of the magnetic hyperfine field. Quantitative information on the hyperfine field is useful for, e.g., position assignment (see Sect. 4.1). Also, it can help to determine the type of magnetic order, or at least to exclude some possibilities. For example, a probe nucleus symmetrically surrounded by neighbors with antiferromagnetically coupled magnetic moments will probably feel a zero or tiny hyperfine field, whereas this field should be considerably higher if all neighbors have their magnetic moments coupled ferromagnetically. Since the hyperfine field is very sensitive to electronic structure, PAC experiments also provide the possibility of testing *ab initio* electronic theories.

### 4.3 Orientation of the Magnetic Hyperfine Field

The general formalism of PAC shows that a probe nucleus with nuclear spin $I = 5/2$ ($^{111}$Cd) at a unique position and feeling a single magnetic hyperfine field generates two frequencies in $R(t)$, i.e., $\nu$ and $2\nu$. Their amplitude in a Fourier analysis of $R(t)$ is related to the absolute direction of the hyperfine field with respect to the detector setup. If the hyperfine field is perpendicular to the detector plane, only $2\nu$ is present. If $B_{\mathrm{hf}}$ makes an angle of 30° with the detector plane and of 45° with the first $\gamma$-ray detector, then the ratio $\nu/2\nu$ is 3/1.

### 4.4 Distributions

The measured $R(t)$ function usually shows an amplitude vanishing for $t > 500$ ns. The reason is that the hyperfine field—and hence the frequencies making up

$R(t)$—is not an infinitely sharply determined quantity. Small intrinsic effects, such as vibrational motion of the probe atom, can cause slight changes in the environments, which will show up as a damping of $R(t)$ described by mainly Lorentzian or Gaussian distributions on the frequencies in its Fourier spectrum. For such intrinsic effects, the damping is generally very weak. If, however, severe perturbations of the environments are present, e.g., lattice defects, vacancies, impurities, $R(t)$ will die out much faster. Determining the amount of distribution can therefore tell how pure the environment of the probe is on the atomic scale. Another use of the distribution is discussed in Sect. 6.

## 5. *Theoretical Understanding of Hyperfine Fields*

A very important problem when using any nuclear technique is to relate a measured hyperfine field (which is a very local quantity) to particular chemical and physical properties of the neighborhood of the probe nucleus, and even of the material as a whole. This problem was for long dealt with in a rather crude, phenomenological way. It took until the early 1990s to be solved, when *ab initio* methods with quantitative predicting power were developed. Major work was carried out by Blaha *et al.* (1999) within the framework of density functional theory (DFT, see *Density Functional Theory: Magnetism*). By using the full potential felt by the electrons and solving the resulting Kohn–Sham equation by the linearized augmented plane wave (LAPW) method, the tails of the electron wave functions near the nucleus can be calculated with a sufficient accuracy to obtain the hyperfine field. The method has been implemented in the computer code WIEN, which is a standard tool for calculating hyperfine fields in a variety of materials.

## 6. *Example*

To illustrate PAC measurements, thin Fe/Cr multilayers are discussed as a case study (Meersschaut *et al.* 1995).

Bulk b.c.c. chromium is known to have an exotic type of antiferromagnetic order: a spin density wave (SDW). The moments are oriented along the 100 direction and moments at neighboring atoms are antiparallel. But instead of displaying the same magnitude of moment everywhere in the crystal, as is usual in an antiferromagnet, in chromium the moment magnitude is sinusoidally modulated with a period of approximately 20 lattice units. Between 311K and 123K the moments are perpendicular to the propagation direction of the wave (transverse SDW). Below 123K the moments are parallel to the propagation direction (longitudinal SDW).

An interesting question as to the magnetic order and the character of the SDW arises when thin chromium layers are considered with a thickness approaching the period of the SDW. Will the SDW survive or not? If so, will it be transverse or longitudinal? Will the chromium moments keep their original 100 direction? To examine this, $^{111}$In nuclei were implanted into a multilayer containing several Fe/Cr bilayers, grown with the 100 direction perpendicular to the layer. The $^{111}$In probe atom is known to take substitutional lattice sites in both the chromium and iron layers, where they decay with a lifetime of 2.81 days into the PAC nucleus $^{111}$Cd. The latter nucleus interacts with a hyperfine field generated by the surrounding cadmium electrons, which is directed along the cadmium moment (the moment of the diamagnetic cadmium atom is induced by, and hence is parallel to, the surrounding chromium moments).

The $R(t)$ function of two PAC measurements is shown in Fig. 1. In Fig. 1(a) the multilayer is parallel to the detector plane and in Fig. 1(b) it is perpendicular to it. In both $R(t)$ functions contributions from a slow and a fast frequency are visible. The slow frequency belongs to $^{111}$Cd nuclei in a chromium environment and the fast one to an iron environment. The line through the data points is a best fit, with the chromium contribution to it shown in the lower curves. From the change in frequencies when the multilayer is tilted from Figs. 1(a) to (b), it can be deduced that the hyperfine field on cadmium in chromium—and therefore the chromium magnetization—is oriented perpendicular to the plane of the multilayer, and hence along the 100 direction. Moreover, the $R(t)$ function belonging to chromium positions is not a pure sine wave but a Bessel function. Theory shows that this typical shape appears when the nuclei each experience a different hyperfine field corresponding to an Overhauser distribution in frequency space and a sine wave in real space: solid proof that the SDW is present in this type of Fe/Cr multilayer. Furthermore it has been shown—first by PAC and later by neutron scattering and transport methods—that the SDW is longitudinal and disappears below a critical chromium thickness.

# Photoemission: Spin-polarized and Angle-resolved

Magnetism arises from the spins of electrons in partially filled outer shells of atoms in a solid which interact with each other via the exchange interaction. In a paramagnetic material all electronic states are degenerate with respect to spin, and consequently are occupied by two electrons, one with spin up and one with spin down. The exchange interaction lifts this degeneracy, lowering the energies of spin up, and raising those of spin down states. The energy difference between these states is the exchange splitting. Therefore, the spin-polarized electronic (band) structure is the key ingredient for understanding magnetism (see *Density Functional Theory: Magnetism*). Photoemission is commonly used to probe the electronic structure of solids. By also analyzing the spin polarization of the photoelectrons, information on the spin-polarized band structure is obtained. One speaks of electron spin polarization if one can find a direction in space with respect to which the two possible spin states are not equally populated. For ferromagnetically ordered materials, this direction is naturally the magnetization direction. The exchange splitting between majority and minority states of the same symmetry can be measured directly by spin-polarized photoemission.

From temperature-dependent measurements, the change of the band structure on approaching the Curie temperature can be compared with various models of the ferro- to paramagnetic phase transition. The exchange coupling of ultrathin layers adsorbed on ferromagnetic surfaces can be studied. The origin of oscillating interlayer exchange coupling between ferromagnetic layers via a nonferromagnetic interlayer was clarified by spin-resolved photoemission. The degree of spin polarization at the Fermi level is important for devices utilizing spin-dependent transport phenomena. Core-level photoelectron spectra also show spin polarization which can be used as an *element-specific* indicator for magnetic order. While such spectra involving inner shell excitations do not give direct evidence on the spin-polarized electronic structure of the partially filled outer (valence) states, which are the source of magnetism, indirect information is contained in the line shape, the degree of spin polarization, and the presence of satellites. An important aspect of spin-polarized core level spectroscopy is the possibility of characterizing the relative spin orientation of different species in a multicomponent sample because core-level spectra occur with different excitation energies.

Spin-dependent mean free paths and photoelectron diffraction effects may have an influence on the measured spin-resolved photoemission spectra. Apart from a magnetic ground state, spin–orbit interaction gives rise to spin polarization in photoelectron spectra. While for valence states this is, in most cases, a relatively small effect, the large spin orbit interaction encountered for ionized inner shells with nonzero orbital momentum will in general give rise to significant spin polarization, both for magnetic and nonmagnetic systems. By choosing a suitable geometry this effect may be avoided, so that only the exchange-related effect remains. Alternatively, for magnetic systems the combined influence of the exchange and spin orbit interactions leads to magnetic dichroism. The continuous background of secondary electrons also is spin-polarized, and the degree of polarization at low energies can be related to the ground state magnetic moment.

## 1. Angle-resolved Photoemission

In a photoemission (PE) experiment, UV or soft x-rays are used to excite electrons from a sample. In the excitation process the photon is annihilated, and energy conservation requires that the total energy is unchanged,

$$E_{\mathrm{i}} + h\nu = E_{\mathrm{f}} + E_{\mathrm{kin}} \tag{1}$$

where $E_{\mathrm{i}}$ and $E_{\mathrm{f}}$ are the energies of the initial and final state of the sample, $E_{\mathrm{kin}}$ is the energy of the photoelectron, and $h\nu$ is energy of the photon (Kevan 1992, Hüfner 1995). The difference between $E_{\mathrm{i}}$ and $E_{\mathrm{f}}$ is conventionally termed binding energy $E_{\mathrm{B}}$. It is determined from the photon energy chosen for the experiment and the measured kinetic energy of the photoelectron,

$$E_{\mathrm{B}} = h\nu - E_{\mathrm{kin}} - \phi_{\mathrm{A}} \tag{2}$$

where $\phi_{\mathrm{A}}$ is the work function of the sample. The kinetic energies are usually measured by electrostatic analyzers. For solid metallic samples, the most weakly bound electrons are those at the Fermi level. Therefore, the highest kinetic energy photoelectrons are generated by ejecting electrons from states at the Fermi level $E_{\mathrm{F}}$, and this cut-off is used as reference (zero) for binding energies such that

$$E_{\mathrm{B}} = E_{\mathrm{kin}} - E_{\mathrm{kin}}(E_{\mathrm{F}}) \tag{3}$$

In addition to energy conservation, momentum also has to be conserved. The relationship between electron energy and momentum, i.e., the band structure, leads to pronounced angular dependencies. In angle-resolved photoemission, the energy distribution of the photoelectrons is measured as a function of emission angle in order to obtain information on the band structure. For making the connection between measured angle-resolved PE spectra and the band structure, the sample has to be a single crystal. Maxima in photoelectron spectra arise whenever the photon energy matches the energy difference between an occupied state and an unoccupied state in the band structure. The components of the photoelectron wave vector parallel ($k_{\parallel}$) and perpendicular ($k_{\perp}$) to the surface are

$$k_{\parallel}[k_{\perp}] = (2mE_{\mathrm{kin}}/h^2)^{1/2} \times \sin\theta[\times\cos\theta]$$
$$= 0.5123 \times (E_{\mathrm{kin}}/1\mathrm{eV})^{1/2}\mathrm{\AA}^{-1} \times \sin\theta[\times\cos\theta] \quad (4)$$

where $m$ is the electron mass, and $\theta$ the emission angle measured to the surface normal. The parallel component is conserved (to within a reciprocal lattice vector) for photoelectrons crossing the surface, so that $k_{\parallel}$ measured in vacuum is identical to that in the solid.

To interpret the perpendicular photoelectron wave vector component $k_{\perp}$ measured in vacuum, the relationship between $E$ and $k$ in the solid and the way in which the wave functions in the solid and in vacuum are matched have to be known. Structures in PE spectra are interpreted assuming that the momentum is retained within the excitation (''vertical'' or ''direct transitions''). With increasing final state energy, the allowed final states become more dense, and the finite angular acceptance of photoelectron spectrometers integrates over an electron momentum range comparable to the Brillouin zone. Spectra taken under such conditions may be interpreted in terms of density of states, which can be obtained from the momentum-resolved band structure by integration in $k$-space. Angular variations may then still arise from diffraction effects, because the photoelectrons are scattered by the regular array of atoms in the crystal lattice.

## 2. Electron Spin Analysis

Electron spin polarization $P$ is defined as

$$P = (N_{\mathrm{up}} - N_{\mathrm{down}})/(N_{\mathrm{up}} + N_{\mathrm{down}}) \quad (5)$$

where $N_{\mathrm{up}}$ and $N_{\mathrm{down}}$ are the numbers of electrons with spin parallel and antiparallel to a chosen quantization axis. For magnetic materials the quantization axis is the direction of sample magnetization. To measure photoelectron spin polarization, the energy-analyzed photoelectrons are subjected to a spin-dependent scattering process (Kessler 1985, Feder 1985). The majority of spin polarimeters derive their spin dependence from spin–orbit interaction. The spin of the free electron may couple to the angular momentum in the scattering process, which gives rise to a spin-dependent contribution to the scattering potential. This spin-dependent contribution is generally small. A sizable magnitude of this effect is usually only found for conditions where the mean scattering cross section is small, so that the spin-dependent part becomes significant. In general a compromise has to be found between the requirements of a large analyzing power and a large mean scattering cross section. For spin–orbit based detectors it is possible in principle to measure both transverse spin components simultaneously.

The optimum scattering energy for so-called Mott detectors is around 100 kV, and this provides scattering asymmetries between 0.2 and 0.3. Mott detectors have been designed and are commercially available with scattering energies of around 30 kV. The lower scattering energy reduces the size, complexity, and cost of such a detector at the expense of lower asymmetries and scattering efficiency. Low energy scattering is employed either in a LEED type arrangement where spin–orbit interaction influences the scattering efficiency for higher-order LEED beams scattered from the surface of a heavy material, or in diffuse scattering off a polycrystalline target composed of a heavy element. Finally, scattering off the surface of a magnetized single crystal of iron has been exploited for spin analysis (Hillebrecht *et al.* 1992). This technique offers a superior performance in comparison to Mott detectors. However, it is much more complicated as it requires careful preparation of the scattering target. Details are summarized in Table 1, and can be drawn from the literature.

## 3. Technical Aspects

The elastic mean free path for electrons in solids is of the order of 0.5 to 5 nm. Therefore, photoemission is a highly surface-sensitive technique. Clean surfaces are prepared in ultrahigh vacuum, e.g., by sputtering and annealing, cleaving, or deposition. In order to correlate the angular dependencies of photoemission with the band structure, single crystalline samples are required. To exploit fully the potential of the technique, tunable, monochromatic, and polarized light is needed, which is readily available at synchrotron radiation sources. Because of the limited elastic mean free path, photoelectrons undergo numerous inelastic scattering processes, generating secondary electrons with reduced energy. This leads to a continuous background of secondary electrons. For ferromagnetic materials, this background is also spin-polarized (Kisker *et al.* 1982). Photoemission experiments have to be carried out on remanently magnetized samples, and the influence of stray fields on the electron

***Table 1***
Characteristic parameters of spin polarimeters. If no orientation for the scattering target is given, a polycrystalline one is used. The spin asymmetry is given by the difference of differential scattering cross sections for the two channels corresponding to up and down spin electrons, normalized to the sum. The figure of merit, given by the square of the spin asymmetry times the average scattering cross section, is a measure for the performance of a spin detector; to reach a certain statistical uncertainty, the data acqusition time varies as the reciprocal of the figure of merit. For the LEED polarimeters, the performance depends on the crystalline quality of the surface. For VLEED, the polarization is determined by sequential measurements with reversed target magnetization, which halves the figure of merit (included).

| Type of spin polarimeter | Operating energy (eV) | Scattering target | Spin asymmetry | Figure of merit $\times 10^{-4}$ |
|---|---|---|---|---|
| Mott detector | $10^5$ | Au | 0.25 | 1 |
| Medim energy Mott detector | $2–4 \times 10^{-4}$ | Au | 0.2 | 0.2 |
| Diffuse scattering | 150–300 | Au | 0.07–0.11 | 1 |
| LEED | 105 | W(100) | 0.27 | 1.6 |
| VLEED | 12 | Fe(100) | 0.2–0.4 | 5–10 |

trajectories has to be excluded. Ultrathin films grown *in situ* are easy to magnetize within the film plane, and have negligible stray fields.

## *4. 3d Ferromagnets*

Figure 1 shows spin-resolved photoemission spectra for iron, cobalt, and nickel taken in normal emission with 20 eV photons (21.2 eV for cobalt) from single crystal surfaces. With calculated band structures available, the features in the spectra can be attributed to transitions from specific occupied bands, allowing determination of the exchange splitting. In general, a large number of spectra is taken with different photon energies or for different emission geometries. The shifts of the peaks observed in such data sets allow determination of the dispersion of the electronic bands.

The spectrum for iron (Kisker *et al.* 1985) shows a majority peak at 2.6 eV, which is present with small shifts in binding energy (BE) for all photon energies. The minority spectrum shows only a weak structure at the Fermi level, which is attributed to indirect transitions. The dispersion of the bands close to $E_F$ causes a majority spin polarization for photon energies below 33 eV, switching to minority for higher photon energies.

For the spectrum of h.c.p.-cobalt (Getzlaff *et al.* 1996), the minority peak is caused by transitions from bands of $\Delta_9$ and $\Delta_7$ symmetry, which cross the Fermi level and consequently have a high density of states at $E_F$. The peak in the majority spectrum appears at slightly higher BE. By analyzing the energy and angle dependence of these structures, an exchange splitting of 1.6 eV is found, in agreement with calculations.

The spectrum of Ni(110) shows only a sharp structure at the Fermi level (Ono *et al.* 1998). At different photon energies, features up to about 3 eV BE are observed. This suggests that the bandwidth is smaller by 30% than the calculated bandwidth. This is ascribed to correlation (self energy) effects, which tend to narrow the bands. The majority and minority peaks have different binding energies. This reflects directly the exchange splitting, 0.12 eV in this case. Furthermore, the exchange splitting varies between 0.1 and 0.4 eV for different points in the Brillouin zone.

For some applications of ultrathin magnetic films, a large spin polarization at the Fermi level is desired. For this purpose, the stabilization of magnetic materials in different phases is of interest as it permits the tailoring of magnetic properties at surfaces or interfaces for specific applications. Electronic structure calculations suggest that f.c.c.-Fe may show widely different magnetic properties for small variations of lattice constant, ranging from nonmagnetic to antiferro- and ferromagnetic states. The ferromagnetic f.c.c. phase is expected to have a higher magnetic moment than the b.c.c. phase, and may possibly be a strong ferromagnet, i.e., show complete (100%) spin polarization at the Fermi level. Figure 2 shows the evolution of the spin-polarized electronic structure of iron with different crystal structures (Kläsges *et al.* 1998); f.c.c.-iron is grown on f.c.c.-cobalt, which can be grown in f.c.c.-structure f.c.c.-Cu(100) up to several hundred monolayers (ML). The initial spectrum shows the spin-resolved spectrum of cobalt in the f.c.c. phase. Close to $E_F$, one finds a minority polarization, and at higher BEs the spin polarization changes to majority. The spectrum for f.c.c.-Fe (3 monolayer film) shows a majority peak at 2.9 eV and a minority peak at 0.4 eV. This 2.5 eV splitting can be interpreted as an exchange splitting. The increased magnitude of this splitting shows that the magnetic moment is indeed increased compared with the bulk b.c.c. value.

The reduced spin polarization for the 6 ML film shows that the major part of the film is ferromagnetically aligned to the substrate. Nevertheless, the

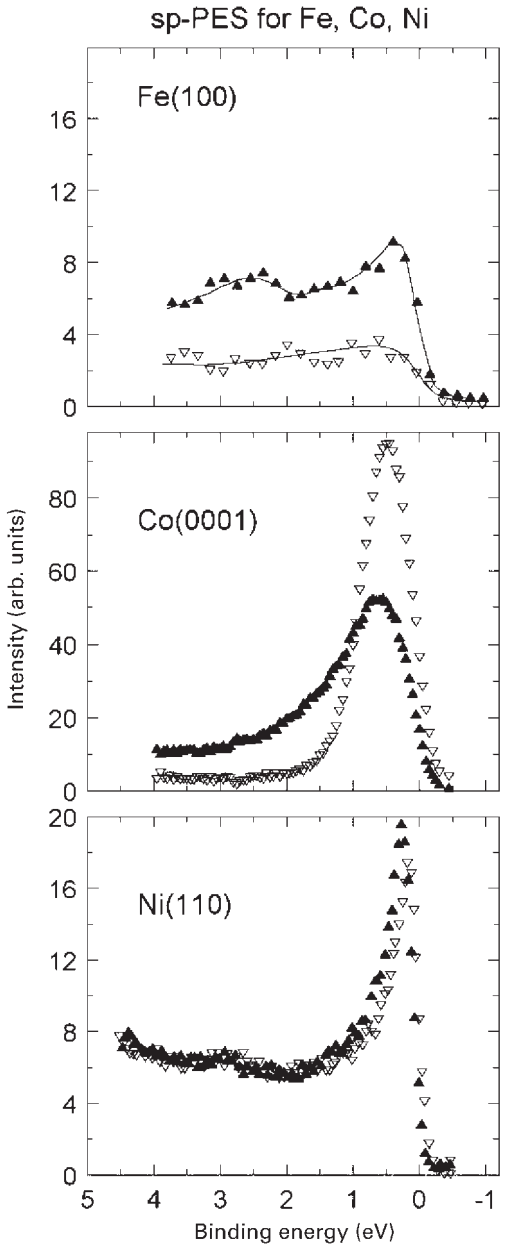

*Figure 1*
Spin-resolved photoemission spectra for the 3d ferromagnets, taken with 20 eV photons (21.2 eV for cobalt) in normal emission: data for Fe(100) with normal light incidence (from Kisker *et al*. 1985); for Co(0001) light incidence under 30° to surface normal, magnetization in the surface plane (Getzlaff *et al*. 1996); for Ni(110) light incidence 20° to surface normal (Ono *et al*. 1998). For all examples filled triangles pointing up represent majority spin electrons, empty triangles pointing down are for minority spin electrons.

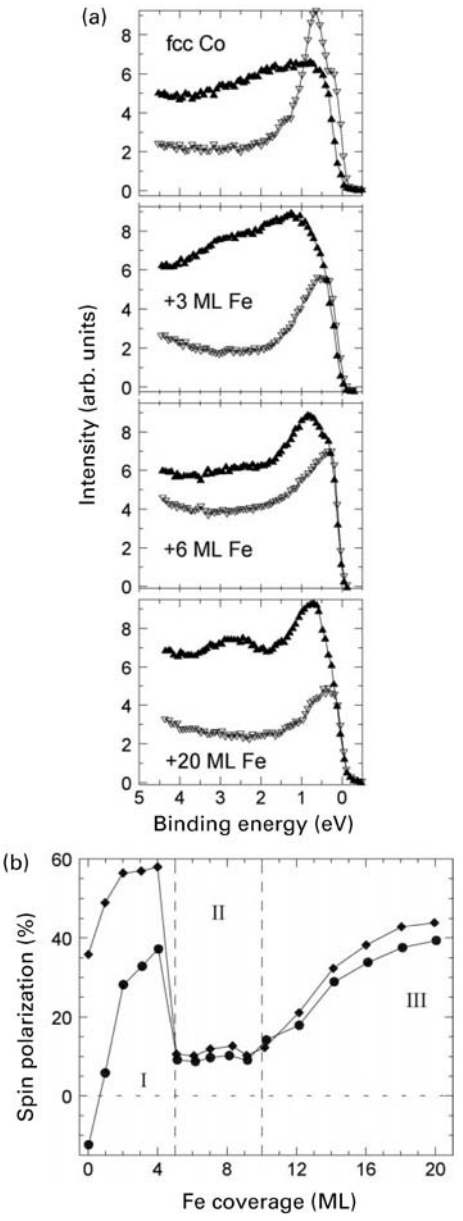

*Figure 2*
(a) Evolution of spin-resolved photoemission spectra for Fe films grown on f.c.c. Co(100); photon energy 34 eV, normal emission, plane-polarized light under 45° incidence; (b) spin polarization data for Fe films grown on f.c.c.-cobalt, derived from the spectra in Fig. 2(a). The polarization shows three thickness regimes, which are associated with f.c.c.-Fe (area I), a distorted Fe phase with low moment (area II), and finally a transition to b.c.c.-Fe (area III); circles for spin polarization at 0.8 eV binding energy, diamonds for 1.8 eV (from Kläsges *et al*. 1998).

finite spin polarization demonstrates that the surface layer is still ferromagnetically aligned to the cobalt magnetization. A fraction of the surface layer is still in the high moment state, as can be seen from the weak structure between 2 and 3 eV. For coverages above 10 ML, the whole film reverts to the thermodynamically stable b.c.c. structure. The polarization increases, as the whole film orders ferromagnetically; however, the exchange splitting of about 2.2 eV is typical for the b.c.c. moment. Figure 2(b) shows the polarization measured at different points in the spectrum, which tracks very well the magnetic moments derived from other experiments.

## 5. *Ferro- to Paramagnetic Transition*

Figure 3 shows the change of the spin-resolved PE spectrum of b.c.c.-Fe with temperature (Kisker *et al.* 1984). The key issue for such studies is to gain an insight into the underlying physics of the transition from the para- to the ferromagnetic state. While the spin-averaged spectra do not change significantly on heating to $0.85\,T_C$, the spin-resolved data show significant changes: the minority peak at 0.4 eV BE loses intensity and becomes broader, and the majority spin peak at 2.6 eV also loses intensity, with nearly unchanged width and BE. The results show that the exchange splitting is of the order of 2 eV, and does not change significantly on approaching the Curie temperature.

Figure 4 shows similar temperature-dependent data for Ni(110) (Hopster *et al.* 1983). The data clearly show a scaling of the exchange splitting proportional to the macroscopic magnetization with increasing temperature, in agreement with the Stoner model. In contrast, these results are inconsistent with a so-called local band model, where the decrease of the magnetization is caused by transverse fluctuations of microscopic regions which still have the full temperature-independent exchange splitting. By choosing different excitation conditions, Fujii *et al.* (1995) probed a different region of the Brillouin zone. The results showed aspects of both types of behavior: an exchange-splitting decreasing with temperature, and a contribution of the local band model with temperature-independent exchange splitting.

Spin- and angle-resolved photoemission of elemental 3d ferromagnets has shown that, depending on the material, different mechanisms are responsible for the ferro- to paramagnetic transition. The small changes of the exchange splitting observed for iron can apparently be understood within a local band model, while the temperature-dependent exchange splitting found for nickel can be explained within the Stoner model (see *Itinerant Electron Systems: Magnetism (Ferromagnetism)*). This does not rule out that in each case the nondominant mechanism is to some extent in operation (Kisker 1984, Fujii *et al.* 1995).

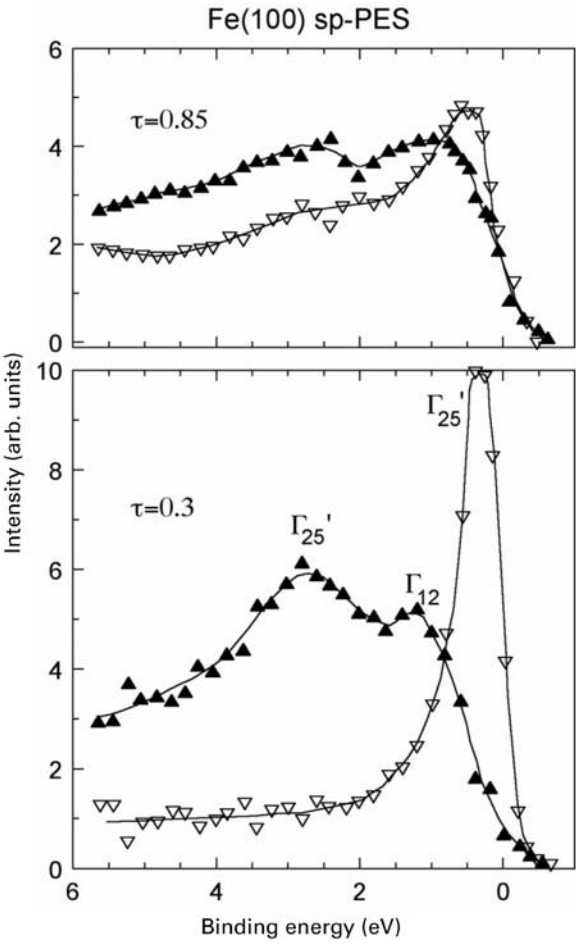

***Figure 3***
Evolution of the spin-polarized photoemission spectrum of Fe(100) on approaching the Curie temperature $T_C = 1043$ K (Kisker *et al.* 1984). Photon energy 60 eV, normal emission, s-polarized light; lower panel for temperatures $\tau = T/T_C = 0.3$, upper for $\tau = T/T_C = 0.85$; triangles pointing up for majority states.

## 6. *Quantum Well States*

The magnetization between two ultrathin films, forming a sandwich with a nonmagnetic layer in-between, may be coupled by exchange interaction via the nonmagnetic interlayer (Grünberg *et al.* 1986). The coupling strength oscillates periodically with interlayer thickness between ferro- and antiferromagnetic coupling, and furthermore decays with interlayer thickness. The most widely used material combinations are Fe–Cr and f.c.c.-Co–Cu (Parkin 1994). The thickness of the interlayer is up to about 20 monolayers. The coupling can be understood in terms of a modified RKKY theory (see *Magnetism in Solids: General*

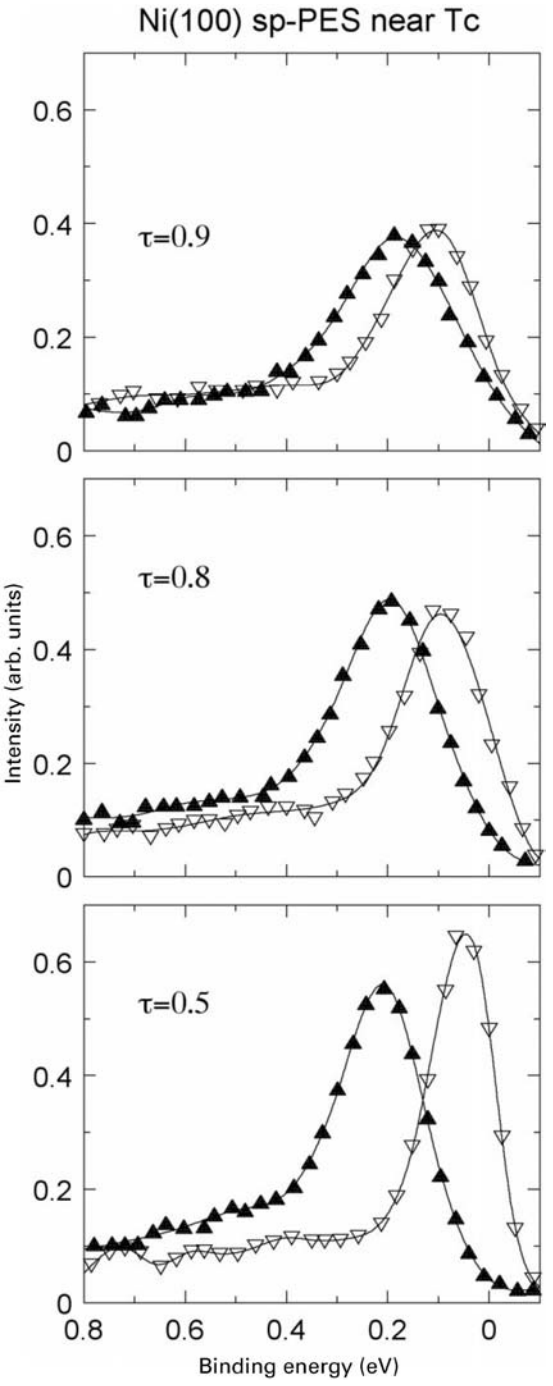

***Figure 4***
Evolution of the normal emission spin-polarized photoemission spectrum of Ni(110) on approaching the Curie temperature $T_C = 627\,K$; $\tau = T/T_C$; photon energy 16.8 eV, probing the X point (Hopster *et al.* 1983).

*Introduction*), which was originally proposed to describe the interaction between magnetic impurities in nonmagnetic host materials. In this picture, the oscillation period of the coupling is related to the size and shape of the Fermi surface of the nonmagnetic interlayer. The oscillation period is given by $2\pi/k_N$, where $k_N$ is a Fermi surface nesting vector of the bulk band structure of the interlayer material. The small thickness of the interlayer may lead to quantization of the bulk bands in the direction normal to the film. This affects in particular the sp-like states of copper, which in bulk copper metal are free electron-like. Figure 5 shows spin-resolved photoemission spectra

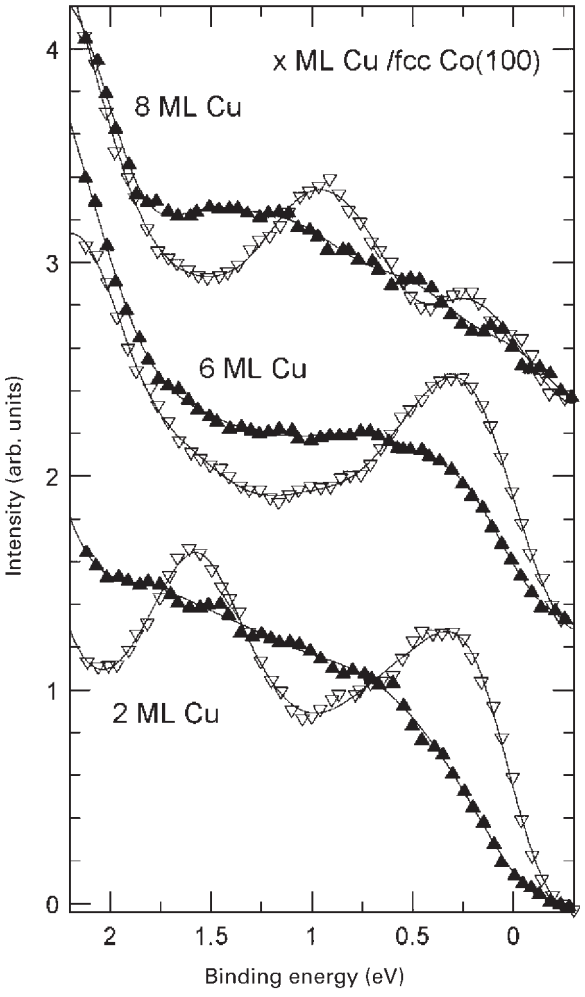

***Figure 5***
Spin-resolved photoemission from sp-like quantum well states of ultrathin copper grown on f.c.c.-Co(100) (Garrison *et al.* 1993).

for ultrathin copper films on Co(100) (Garrison *et al*. 1993).

The copper d states have binding energies of 2 V or more, so that the region shown is dominated by copper sp-like states (with some residual emission from cobalt d states for the lowest copper coverage). The minority (with respect to cobalt majority) spectra show clearly discrete states that occur with different binding energies for different coverages. In contrast, the majority states do not show discrete states, indicating that the quantum well states are strongly minority-polarized. Depending on the thickness of the copper layer, the quantum well states occur at different energies for certain thicknesses at the Fermi level. The intensity and spin polarization at the Fermi level oscillate with thickness, and this oscillation correlates directly with the oscillation of the interlayer exchange coupling between two f.c.c.-Co films separated by a copper film (Carbone *et al*. 1993). These experiments show that the spin polarization of the quantum well states induced by the confining magnetic interface causes the interlayer exchange coupling.

## 7. Spin-resolved Photoemission from Core Levels

Inner shells are completely filled, and consequently the total spin and angular momentum is always zero. This means that the integrated spectrum should have no spin polarization. However, ejection of an electron from an inner shell generates a hole which has a spin and, if one is not looking at an s level, an angular momentum. In a magnetic system, the spin of the core hole couples to the spin of valence electrons, and this may lead to different excitation energies depending on the spin of the photoelectron. From studies of the 3d ferromagnets it is known that at the leading edge of a core level spectrum one always finds minority spin polarization. One may state this as a generalized Hund's rule (see *Magnetism in Solids: General Introduction*), because minority spin for the photoelectron means that the spin of the remaining shell from which one electron is removed has majority character, i.e., is parallel to the spin of the majority electrons. Core level spin polarization can be used as an element-specific indicator of magnetic order. For a number of nonferromagnetic elements theoretical calculations predict a ferromagnetic ground state for a monolayer film of this element.

A famous example is antiferromagnetic chromium, which in the bulk has a mean magnetic moment of $0.6\,\mu_B$. For a chromium monolayer on iron an enhanced moment of $3.6\,\mu_B$ was derived, with ferromagnetic order within the chromium layer, coupled antiferromagnetically to the ferromagnetic iron substrate. Figure 6 shows a spin-resolved chromium 3p photoemission spectrum taken for a monolayer (0.15 nm) of chromium on Fe(100) (Hillebrecht *et al*. 1992). The spectrum shows a large spin polarization, which is opposite to that of the 3p spectrum of the iron substrate. This demonstrates the antiferromagnetic coupling between the iron surface and the chromium overlayer. The magnitude of the chromium 3p polarization indicates that the chromium moment is smaller than the predicted $3.6\,\mu_B$. This is caused by structural intermixing between chromium and iron atoms occurring during chromium deposition, leading to a higher chromium coordination.

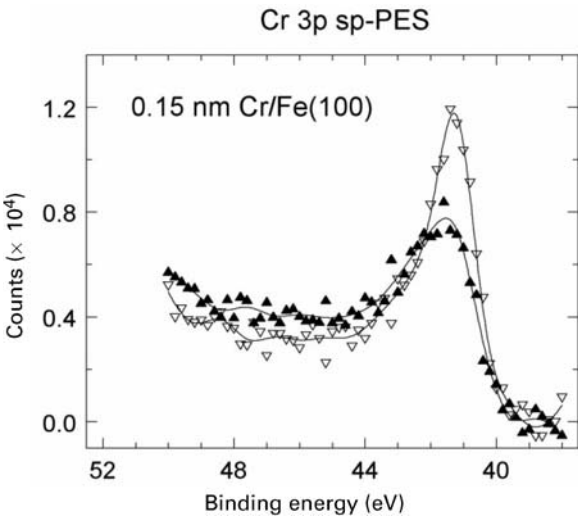

***Figure 6***
Spin-resolved 3p core level photoemission for 1.5 nm Cr/Fe(100) (from Hillebrecht *et al*. 1992). Photon energy 117 eV, normal incidence and emission. A constant background, matched to the spectrum on the low binding energy side, was substracted from the spectrum.

## Photomagnetism of Molecular Systems

Photoreactivity is a widespread phenomenon in organic and inorganic chemistry. A compound may change its structural and/or electronic properties under light irradiation. Light-induced charge separation or *cis–trans* isomerization processes under light are well-known examples. A phase transformation may occur, with or without hysteresis. If the light-induced new phase possesses sufficiently long lifetime and differs in optical and/or magnetic properties such that it can be easily detected by optical or magnetic means, the material bears the potential for possible technical applications in switching or display devices.

This article deals with light-induced changes of the magnetic and/or optical properties of transition metal compounds to long lived metastable states. Figure 1 sketches the general situation: A complex compound with ground state spin $S$ and orbital momentum $\Gamma$ converts under light of wavelength $\lambda$, to a more or less metastable state with different spin and orbital momentum $S'$ and $\Gamma'$. The metastable state lies higher in energy and usually has weaker metal–ligand (M–L) bonds and accordingly longer bond lengths $r$(M–L) than the ground state. This is the consequence of an increasing population of antibonding molecular orbitals and simultaneously decreasing population of weakly $\pi$-backbonding molecular orbitals. The energy barrier between the potential wells governs the lifetime of the metastable state, which in turn depends on the horizontal and vertical displacements relative to each other. Switching back from the metastable state to the ground state may be possible by using light of different wavelength $\lambda'$. The two-potential-well scheme of Fig. 1 refers to transition metal complexes with strong and intermediate field strength ligands. In weak-field complexes the potential with the longer M–L bond length would be the ground state, but light-induced switching is still possible.

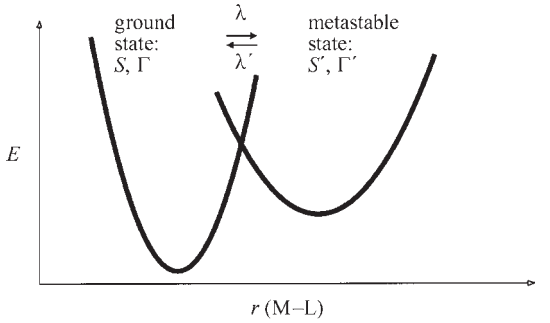

***Figure 1***
Schematic representation of the potential wells for the ground state with quantum numbers $S$ and $\Gamma$ and metastable state ($S'$ and $\Gamma'$) for a transition metal compound. The switching process between these states may be provoked by irradiation with light of wavelength $\lambda$, or $\lambda'$ for the reverse process.

There are various classes of transition metal compounds which all show light sensitive electronic structure changes accompanied by drastic changes of their magnetic and/or optical properties. Among the best known and extensively studied systems are those exhibiting:

- metal-centered thermal spin transition, e.g., spin crossover (SC) complexes of iron(II);
- metal-to-ligand charge transfer, e.g., nitroprusside complexes;
- metal-to-metal charge transfer, e.g., Prussian blue analogues;
- ligand isomerization with change of spin state, e.g., stilbenoid complexes;
- valence tautomerism, e.g., catecholate complexes of cobalt(II).

## 1. LIESST and Related Phenomena

The abbreviation LIESST refers to the phenomenon of light-induced excited spin state trapping, which was discovered in 1984 on $[Fe(ptz)_6](BF_4)_2$ (ptz = 1-propyl-tetrazole), an iron(II) coordination compound known to exhibit thermal spin transition between high-spin (HS, $^5T_2$) and low-spin (LS, $^1A_1$) states (see *Spin Transition Compounds* (Decurtins *et al*. 1984). The material, as a single-crystal, polycrystalline, or embedded in a polymer foil, converts from the LS to the HS state by irradiation with green light into the $^1A_1 \rightarrow {}^1T_{1,2}$ absorption band, followed by two successive intersystem crossing (ISC) processes $^1T_{1,2} \rightarrow {}^3T_{1,2} \rightarrow {}^5T_2$ to populate the HS state $^5T_2$. Radiative decay $^5T_2 \rightarrow {}^1A_1$ is spin and parity forbidden, and due to the considerably larger M–L bond distance in the HS state as compared to the LS state, which builds up an energy barrier between the potential wells of the two states (see Fig. 1), the lifetime of the metastable LIESST state can be very long (e.g., weeks at 20 K in the case of $[Fe(ptz)_6](BF_4)_2$) (Gütlich *et al*. 1994).

Thermal relaxation of the metastable LIESST state does not occur in a classical manner by passing over the barrier, but by nonadiabatic tunneling through the barrier, whereby the observed temperature dependence of the relaxation rate is due to thermal population of the vibronic levels of the $^5T_2$ manifold (Hauser 1995). Optical switching back from the $^5T_2$ LIESST state to the $^1A_1$ ground state is also possible by irradiation with red light for the initial excitation $^5T_2 \rightarrow {}^5E$ followed by two ISC processes $^5E \rightarrow {}^3T_{1,2} \rightarrow {}^1A_1$ (Hauser 1991). It has been found that LIESST and reverse LIESST may be observed with all iron(II) compounds exhibiting thermal SC, a major difference, however, being the lifetime of the light-induced LIESST state at a given temperature, which depends on the ligand field strength, viz., the weaker the ligand field strength, the smaller the difference $\Delta E^0_{HL}$ between the lowest vibronic levels of the HS and LS states, the longer the lifetime of the LIESST state. LIESST has also been observed in Langmuir–Blodgett thin films (Letard *et al*. 1999).

More recently, photophysical phenomena in iron(II) SC systems, which are related to LIESST have been observed. If a sample is continuously irradiated with green light while the temperature is raised and then lowered again, a thermal hysteresis may develop; this phenomenon has been termed light-induced thermal hysteresis (Desaix *et al*. 1998). In another case existing thermal hysteresis of an iron(II) SC compound was observed to shift to lower temperatures under continuous irradiation with green light, and to higher temperatures with red light (light-perturbed thermal hysteresis) (Renz *et al*. 2000). Finally there is the SOXIESST (soft x-ray induced excited spin state trapping) which uses a source of soft x rays to initiate the $^1A_1 \rightarrow {}^5T_2$ transition (Collison *et al*. 1997), but the relaxation mechanism should be the same as for LIESST.

## 2. NIESST Effect

The acronym NIESST stands for nuclear decay-induced excited spin state trapping. This phenomenon is closely related to LIESST, as it makes use of the nuclear decay and its energy release as an intrinsic molecular excitation source, whereas LIESST is the result of irradiation with an external visible light source. Thus the initial step of electronic excitation is different, but the final step of ligand field state relaxations has been found to be the same for both phenomena.

$^{57}$Fe Mössbauer emission (ME) spectroscopy has been a most elegant tool for the observation of metastable ligand field states at ca. 100 ns after electron capture decay of $^{57}Co(EC)^{57}Fe$ in transition metals compounds (Sano *et al*. 1984). A $^{57}$Co labeled compound is used as the Mössbauer source at variable temperatures vs. $K_4[Fe(CN)_6]$ as a single-line absorber. If $^{57}$Co is embedded in strong field surroundings, which causes LS behavior in the corresponding iron(II) compound like the *tris*-phen or *tris*-bpy complexes (phen = 1,10-phenanthroline; bpy = 2,2′-bipyridine), one observes the nucleogenic $^{57}Fe^{II}$ ions in LS ($^1A_1$) state at room temperature, which is the ground state in the corresponding synthesized iron(II) compound. Below ca. 200 K, however, one observes typical $^{57}Fe^{II}$-HS resonances in the ME spectra with increasing intensity towards lower temperatures at the expense of the $^{57}Fe^{II}$-LS resonances. In iron(II) SC systems with weaker ligand field strength one observes no more $^{57}Fe^{II}$-LS resonances in the ME spectra, even at very low temperatures where the corresponding synthesized iron(II) complex has already turned to the LS ($^1A_1$) ground state. The trapped HS state of the nucleogenic $^{57}Fe^{II}$ ion was found to have very similar lifetimes as the corresponding LIESST state under comparable conditions (Deisenroth *et al*. 1998). It was, therefore, concluded that NIESST and LIESST are closely related phenomena. Whereas the LIESST effect bears basically the potential for practical applications, NIESST is evidently of more academic interest and has contributed much to a deeper knowledge of mechanistic aspects in hot atom chemistry in the solid state.

## 3. Stilbenoid Complexes

Another elegant way to change spin states of some transition metal molecular compounds can be achieved using the well-known *cis–trans* photoisomerization of stilbenoid units incorporated as ligand molecules. This effect, called ligand driven light-induced spin change (LD-LISC), was first observed on the iron(II) complex $[Fe(stpy)_4(NCBPh_3)_2]$

(stpy = 4-styrylpyridine) (Boillot *et al*. 1996). This compound undergoes sharp thermal spin transition around ca. 190 K under its *trans* form whereas the *cis* form remains permanently HS. This is the consequence of the different ligand field strength for these two forms due to the different conformations of the coordinated ligand. Irradiation of a thin film of *trans*-$[Fe(stpy)_4(NCBPh_3)_2]$ with UV light around 140 K, that is in the LS area, resulted in a LS → HS conversion which was followed by absorption spectroscopy. This transformation was found to be incomplete, probably due to the rigidity of the matrix at this temperature. Thus light irradiation affords a *cis–trans* isomerization of the ligand with subsequent spin transition at the iron(II) center as a consequence of a change in ligand field strength.

It has recently become possible to observe the LD-LISC effect at room temperature for [Fe(4-methyl-4′-trans-styryl-bpy)$_2$(NCS)$_2$] (Boillot *et al*. 1999) and also for some iron(III) complexes but only in solution. The limiting point of this phenomenon is that it has for now only been observed in thin films or in solution, the reason being the enormous space required for the photoisomerization to proceed. This weak point regarding practical applications could be overcome by implementation of these photosensitive materials in organized media on the mesoscopic scale, such as Langmuir–Blodgett films, which is actually in progress.

## 4. Nitrosyl Complexes

The discovery of light-induced long lived metastable states ($>1 \times 10^9$ s) in $Na_2[Fe(CN)_5(NO)].2H_2O$ (Hauser *et al*. 1977) represents an important step in view of possible applications for optical information storage and data recording. Irradiating a single crystal of sodium nitroprusside (SNP) below typically 100 K with green light results in the subsequent population of two metastable states ($MS_1$ and $MS_2$) accompanied by a color change. It was also proved that it is possible to go from $MS_1$ to $MS_2$ with red light and more generally, that all possible photoswitching pathways between the ground state, $MS_1$ and $MS_2$, are accessible using an appropriate wavelength. Upon heating, radiationless relaxation is observed around ca. 200 K ($MS_1$) and 150 K ($MS_2$). The photoswitching mechanism involves a two-step process: a charge transfer transition from the metal *d* orbital to an antibonding $\pi^*$ NO ligand orbital followed by a relaxation into the metastable potential minima. It may also involve a reorientation of the nitrosyl group atoms upon photoexcitation. This possibility as well as the origin of the longevity of the metastable states is still debated. It should be mentioned that the photo switching of SNP differs from the LIESST phenomenon as the ground state and the metastable states are diamagnetic and as no change of the lattice constants is observed during the photoexcitation.

The existence of photo-induced metastable states is not restricted to SNP. It has also been found for instance for related complexes such as $XY[Fe(CN)_5(NO)]_2.10H_2O$ (X = Rb or Cs), $K_2[Ru(CN)_5(NO)].2H_2O$ and for $K_2[RuCl_5(NO)]$ (Woike *et al*. 1990); this latter compound points out the crucial role of the nitrosyl group for the photoswitching process.

Thus, SNP and its derivatives represent an appealing class of photochromic compounds, which are suitable for optical memory devices with a very high storage capacity and for holographic information storage (Haussühl *et al*. 1995). It is noteworthy that the effect is not limited to solids but also occurs in glassy matrices. Research efforts are currently underway towards materials with a faster population velocity and high decay temperatures. Chemical modification of the SNP system in a controlled manner might be the appropriate way to reach this exciting goal.

## 5. Prussian Blue Analogues

The design of molecular magnets with high Curie temperature ($T_c$) which can be switched by light represents a challenging topic in materials science. Particular attention has been devoted to the Prussian blue family, which can show spontaneous magnetization above room temperature (Ferlay *et al*. 1995). Soon after, the first photo-switchable, cobalt–iron cyanide was reported (Sato *et al*. 1996). $K_{0.2}Co_{1.4}[Fe(CN)_6].6.9H_2O$ possesses an f.c.c. structure in which cobalt(II) ions are bridged to iron(III) ions via cyano groups with a few cobalt(III)–iron(II) diamagnetic pairs also being present. Irradiation of a powdered sample with red light at 5 K results in an increase in the magnetization together with a rise of $T_c$ from 16 K to 19 K. This light-induced magnetization remains trapped at 5 K for several days in the dark. Switching back to the ground state was achieved by raising the temperature to 150 K or by irradiation with blue light.

Before the excitation, the cobalt(III) and iron(II) ions are in their diamagnetic LS states ($S = 0$ for both). Excitation with red light induces an electron transfer from the iron to the cobalt leading to cobalt(II) ions in the HS state ($S = 3/2$) and iron(III) ions in the LS state ($S = 1/2$), which couple antiferromagnetically. More interesting is that the reverse electron transfer is accessible with blue light. The local electron transfer switches increases the number of magnetic neighbors and as a result the ordering temperature (Verdaguer 1996). The key role of this phenomenon is not only the presence of $Co^{III}$–$Fe^{II}$ diamagnetic pairs but also crystal defects which render the network flexible and allow the extension of the light-induced electron transfer.

From an application viewpoint, the slow switching process (a few nanometers), as well as the low

temperature range of the observation of the phenomenon, are the weak points of this system. Anyhow, it represents the first example of fine-tuning of long-range magnetic ordering by light. Photomagnetic studies on related materials using different alkali cations are in progress to further explore this fascinating phenomenon.

### 6. Concluding Remarks

The photo-control of the magnetic and optical properties remains a challenging topic in material science in view of the possible implementation in optical switching and memory devices. Various examples belonging to this appealing class of materials have been covered in this article. There are no doubts that a sizeable number of new compounds, as well as new photophysical phenomena, may emerge in the near future from this rapidly evolving field. We can, for instance, mention a novel composite material comprising Prussian blue intercalated into photoresponsive vesicles based on azobenzene moieties, whose magnetic properties can be controlled by photoillumination (Einaga *et al*. 1999) or a nitrosyl derivative, *trans*-$[Ru(en)_2(H_2O)(NO)]Cl_3$ (en = ethylenediamine) which show a remarkably long lived metastable state up to 267 K (Kawano *et al*. 2000).

## Pnictides and Chalcogenides: Transition Metal Compounds

Research on the magnetic properties of 3*d* transition metal pnictides and chalcogenides has advanced enormously. Realistic energy band calculations as well as experimental techniques such as photoemission spectroscopy are available and play an important role in clarifying the variety of magnetic and related electronic characteristics. Chalcogens (M) (pnicogens (M′)), elements from the 6a (5a) group of the periodic table, have a valence electron configuration $ns^2np^4$ ($ns^2np^3$). The former group includes oxygen, sulfur, selenium, tellurium, and polonium and the latter nitrogen, phosphorus, arsenic, antimony, and bismuth. Chalcogens and pnicogens form many compounds with 3*d* elements. The total number

of transition metal (T) pnictides $T_nM'_m$ and chalcogenides $T_nM_m$ exceeds 150. This article does not include oxides (see *Transition Metal Oxides: Magnetism*), nitrides, or polonides.

The generally stronger electronegativity of chalcogens compared to pnicogens implies two principal differences between chalcogenides and pnictides. First, in chalcogenides like $Fe_7Se_8$ and $Fe_3Se_4$ ordering of vacancies in the crystals often occurs, whereas in pnictides vacancies are generally absent. A second important difference is observed in the magnetic and electronic characteristics. For example, NiS is antiferromagnetic with a nickel magnetic moment of $1.7\mu_B$ and undergoes a nonmetal to metal transition at $T = 263$K, whereas NiAs is a weakly paramagnetic metal. The most interesting chalcogenides and pnictides are of the types TM, TM′, $TM_2$, and $T_2M'$. This article briefly reviews the magnetic and electronic properties mainly of the typical compounds mentioned above. Further details can be found in the review by Beckman and Lundgren (1991).

## 1. Chalcogenides

### 1.1 Pyrite-type Compounds of $TM_2$

A pyrite-type structure is adopted by the $TM_2$ compounds with manganese, iron, cobalt, nickel, and copper. The nearest neighbor sulfur atoms to iron in $FeS_2$ are shown in Fig. 1. The 3*d* orbitals in the octahedral crystal field are split into the three $d\varepsilon$ (or $t_{2g}$) and two $d\gamma$ (or $e_g$) orbitals. The distorted octahedron

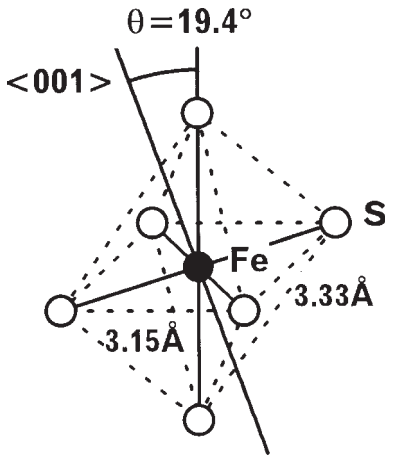

***Figure 1***
The iron atom in $FeS_2$ with the cubic pyrite-type crystal structure (space group *Pa*3) is surrounded octahedrally by six nearest neighbor sulfur atoms with the same Fe–S distance of 2.29Å. Two sides of the rectangle are not equal. If the position parameter, *u*, is just 0.5, the octahedron becomes perfect with $\theta = 0$.

and the influence from more distant neighbors cause further splitting of the $d\varepsilon$ and $d\gamma$ orbitals. The related energy levels are broadened into energy bands owing to the mixing with *s* and *p* orbitals of the neighboring atoms. The $MnM_2$ compounds have lattice parameters several percent larger than the other $TM_2$ compounds. Owing to strong electron correlation, they do not form energy bands and become antiferromagnetic with a local manganese magnetic moment of $5\mu_B$ in the high-spin state of the $d\varepsilon^3$ and $d\gamma^2$ configuration.

The Néel temperature, $T_N$, is 48K, 47K, and 87K for $MnS_2$, $MnSe_2$, and $MnTe_2$, respectively (Ishikawa and Miura 1991). Energy band calculations performed by Bullet (1982) for $TS_2$ with T = Fe, Co, Ni, Cu, and Zn are successful in explaining the magnetic and electric properties such as Pauli paramagnetic and semiconductive $FeS_2$ and ferromagnetic and metallic $CoS_2$, etc. However, the band calculations cannot explain semiconductive $NiS_2$ (antiferromagnetic with a nickel moment of $1.17\mu_B$). Note that the band description is not relevant for this strongly correlated electron system.

The band calculations predict $NiS_2$ to be a Mott–Hubbard insulator because of the existence of a half-filled 3*d* band at the Fermi level. Also, $NiS_2$ is regarded as an insulator of the charge-transfer type (Fujimori *et al.* 1996, 1997). Since the nickel atom appears in the octahedral surrounding as in Fig. 1, *p–d* charge transfer is likely to occur. The photoemission spectrum of $NiS_2$ has been explained by a cluster model with a charge transfer energy of 1.8eV, a *d–d* electron correlation energy, *U*, of 3.3eV, and a *p–d* transfer integral, $pd\sigma$, of −1.5eV.

Both $CoS_2$ and $CoSe_2$ are metallic. The former is ferromagnetic with $T_C = 125$K and a cobalt magnetic moment of $0.85\mu_B$, and the latter is apparently a Curie–Weiss-type paramagnet. The solid solutions $Co(S_xSe_{1-x})_2$ in the composition region $0.12 \leqslant x \leqslant 0.4$ show a very interesting metamagnetic transition at $T = 4.2$K (Adachi *et al.* 1970, 1979). The metamagnetism was successfully explained based on the energy band structure (Takahashi and Tano 1982). The magnetic characteristics of $Co(S_xSe_{1-x})_2$ at finite temperature are typical examples for which the self-consistent renormalization (SCR) theory is applied (Moriya 1979).

### 1.2 TM Compounds and Related Types

The TM compounds, which crystallize mainly as a hexagonal NiAs-type structure (Fig. 2(a)), often contain vacancies at the T site, and the crystal becomes distorted owing to vacancy ordering. Therefore, the magnetic and electrical properties of TM compounds are generally complex. For example, within the Fe–S system, FeS, $Fe_{1-x}S$ with $x < 0.075$, and $Fe_7S_8$ compounds have been found. The magnetic and electrical properties of such materials depend on the type of

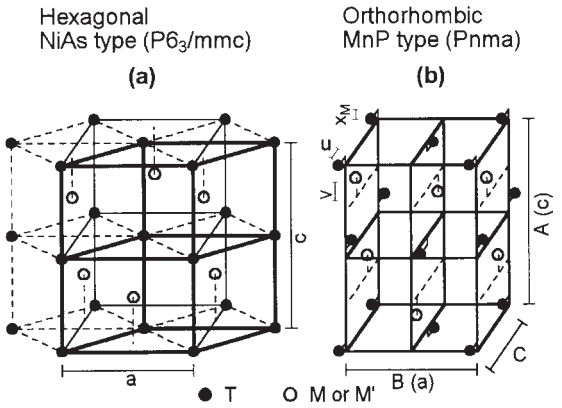

*Figure 2*
Crystal structures of (a) the hexagonal NiAs-type structure and (b) the orthorhombic MnP-type structure. The MnP- becomes the NiAs-type structure if $C = \sqrt{3}B/2$ and $U = V = X_M = 0$. The parameter $\delta$, which expresses a degree of the distortion from the hexagonal to the orthorhombic structure, is defined as $\delta = (C - \sqrt{3}B)/\sqrt{3}B$. The parameters $U$, $V$, and $\delta$ are generally less than 0.05, and $X_M$ is negligibly small in general. The lattice parameters $A$, $B$, and $C$ in (b) correspond to $c$, $a$, and $b$ ($= \sqrt{3}a/2$) in (a), respectively.

vacancy order, which varies with temperature as well as with the composition. Other known compounds with vacancies are $Fe_7Se_8$, $Fe_3Se_4$, $Cr_7Te_8$, $Cr_3Te_4$, and $Cr_2Te_3$. Generally, the TM systems with T = V, Cr, and M = S, Se show crystallographic similarities with the Cr–Te system.

The antiferromagnetic compound FeS with $T_N = 598$K undergoes an interesting transition at $T_\alpha = 420$K, which is called the $\alpha$ transition. At $T_\alpha$ the lattice parameters, magnetic susceptibility, and electrical resistivity measured along the $c$-axis ($\rho_\parallel \cong 0.2\Omega$cm for $T \leqslant T_\alpha$) change very sharply, while the resistivity perpendicular to the $c$-axis ($\rho_\parallel \cong 10^{-3}\Omega$cm) does not change significantly, and $\rho_\parallel \cong \rho_\perp$ for $T \geqslant T_\alpha$ (Wijn 1990). The coefficient of the electronic specific heat, $\gamma$, has been found to be zero within experimental error (Kobayashi *et al.* 1999), which suggests that FeS is an insulator at low temperatures. $T_\alpha$ of the $Fe_{1-x}S$ compounds is strongly concentration dependent. The mechanism responsible for the $\alpha$ transition is still not clear.

NiS shows an insulator to metal transition at $T_t = 263$K with increasing temperature. The low-temperature phase is antiferromagnetic with a nickel magnetic moment of $1.7\mu_B$ and the high-temperature phase is paramagnetic. The insulator phase is known to be of a charge transfer type and it is considered to be at the metal–insulator boundary. An energy gap of 0.1eV has been obtained for NiS (Fujimori *et al.* 1996). The paramagnetic state of NiS is not considered to be of a usual Pauli type (Takahashi and Kanamori 1991).

## 2. *Pnictides*

All the 3*d* pnictides are metallic with resistivities of the order of $10^{-3}$–$10^{-4}\,\Omega$cm at 300 K, and their magnetic properties are described by the itinerant electron model. TM′ and $T_2M'$ compounds are reviewed here. The TM′ compounds mainly crystallize either as NiAs-or MnP-type structures (Fig. 2), while the $T_2M'$ compounds crystallize as $Cu_2Sb$- or $Fe_2P$-type structures (Fruchart *et al.* 1969). The most interesting are the TM′ compounds. The magnetic moment per transition metal atom is displayed as a function of the lattice parameter for T = Mn and Cr in Fig. 3. Manganese pnictides are generally ferromagnetic, while chromium ones are antiferromagnetic except for Pauli paramagnetic CrP. The *B*-axis of CrP (the *B*-axis corresponds to the *a*-axis of the hexagonal NiAs-type structure; see also Fig. 2 and its caption.) is about 25% smaller than the *a*-axis of CrSb, while the *c*-axis (or the *A*-axis) of the chromium pnictides shown in Fig. 3 remains within about 2% variation. Therefore, $\mu_{Cr}$ seems to be a reasonable function of *a* (or *B*).

Somewhat analogous features are observed for manganese pnictides (Fig. 3). These findings imply somewhat the existence of a critical separation where the spontaneous atomic magnetic moment changes drastically. The crossover is located around MnAs

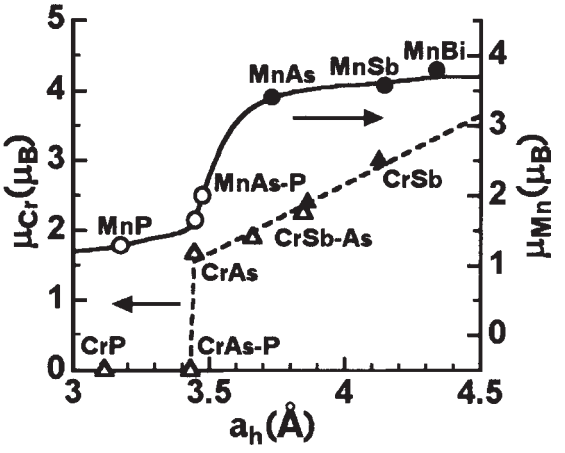

*Figure 3*
Relationship between the magnetic moment per T atom and the lattice parameter $a_h$, where $a_h$ means either the *a*-axis in (a) or the *B*-axis in (b) of Fig. 2. The filled and the open circles and triangles are the values for the NiAs- and the MnP-type structures, respectively. The data are taken from Wijn (1990) and Kallel *et al.* (1974).

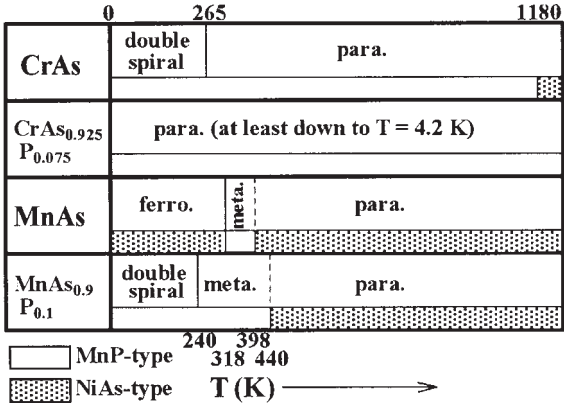

*Figure 4*
Some examples of the temperature dependences of magnetic and crystallographic properties of the pnictides (Wijn 1990, Selte *et al*. 1975).

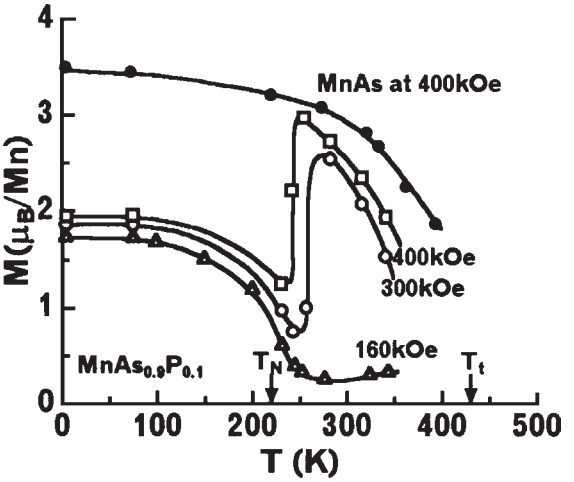

*Figure 5*
Temperature dependences of magnetizations at constant fields for MnAs and $MnAs_{0.9}P_{0.1}$. See also main text.

and CrAs. This conclusion is corroborated by the fact that both MnAs and CrAs undergo a first-order transition at $T = 318$ K and 265 K, respectively, where the magnetic order disappears, accompanied by an abrupt shrinkage of the *a*- or *B*-axis. Besides, the magnetic properties of MnAs and CrAs are also very sensitive to substitutions of other elements. Typical examples are summarized in Fig. 4. A substitution of only 7.5% of phosphorus for arsenic in CrAs yields a collapse of the double spiral magnetic order (Selte *et al*. 1975). The *B*-axis of CrAs extrapolated to $T = 0$ K is about 6.1% (or 0.21Å) larger than that of nonmagnetic $CrAs_{0.9}P_{0.1}$ (Suzuki and Ido 1993).

The substitution of phosphorus for arsenic in MnAs also has a strong effect on magnetic properties. Magnetic properties and the various phase transitions in these materials have been explained in the framework of energy band calculations together with SCR theory (Motizuki and Katoh 1984). A large field effect on the magnetic properties is shown in Fig. 5. At temperatures in the paramagnetic region of $240\,\text{K} < T < T_t$, a metamagnetic (field-induced) transition accompanied by a crystallographic transition from the MnP- to the NiAs-type structure is observed. The mechanism responsible for the various phase transitions mentioned above has not been fully clarified.

$Mn_2Sb$ with the tetragonal $Cu_2Sb$-type structure is ferrimagnetic with $T_C = 550$ K. This compound is interesting because of the strong effect of substitutions of other elements such as chromium for manganese. For example, $Mn_{1.9}Cr_{0.1}Sb$ undergoes a first-order transition from antiferromagnetic to ferrimagnetic order at $T = 300$ K with increasing temperature. The magnetic structures in the $Cu_2Sb$-type compounds have been explained on the basis of energy band calculations (Shirai and Motizuki 1992).

The ground state magnetic and electrical properties of 3*d* metal chalcogenides and pnictides can be explained on the basis of the electronic structures. However, numerous phase transitions induced at finite temperatures by the external field and/or by the temperature change remain unexplained theoretically. Detailed band calculations should be extended to compounds with complex magnetic structures such as CrAs, etc. SCR theory has been exploited to explain the magnetic properties at finite temperatures.

Some magnetic and electrical properties often depend strongly on the crystallographic states, especially for the chalcogenides. In addition to the application of new experimental techniques, preparation of single crystals and polycrystals with well-controlled composition and the related better experimental data may enhance progress in this field. High-pressure studies in the area up to about 10GPa may throw new light on the physics of these materials.

## Radiation and Particle Detectors

Superconducting radiation and particle detectors measure the energy deposited by photons or particles that interact with the detector. Superconducting detectors measure this energy with orders of magnitude more accuracy than semiconductor detectors. Most superconducting photon and particle detectors operate at temperatures below 1 K. At this low temperature, the energy deposited by the photons and particles of interest is not obscured by the thermal energy of the detector. It is the low temperature of operation that allows superconducting detectors to measure the energy of each incident photon or particle with high precision.

Superconducting radiation and particle detectors are energy dispersive, that is, they provide spectral information by measuring the energy of particles or photons absorbed in the active volume of the detector. Superconducting detectors can often be constructed so that almost every incident particle or photon interacts with the detector. Thus, these detectors can provide a combination of high resolution and high quantum efficiency which is not available in more conventional detectors.

The quest for new detectors with high resolution and high efficiency has been strongly motivated by x-ray astrophysics. However, superconducting detectors are now being developed to study astronomical objects at energies from the infrared to gamma-rays. Superconducting x-ray detectors are also being developed for laboratory plasma experiments and the measurement of nuclear materials. These detectors are being used to improve x-ray fluorescence analysis of many types of materials ranging from integrated circuits to proteins. Superconducting detectors are also used to search for proposed weakly interacting massive particles (WIMPs), which may compose the "dark matter" of the universe. They may also be useful for studying ions and very large molecules.

Various detector designs have been developed which take advantage of the unique thermal and electrical properties of low-temperature superconductors.

### 1. *Microcalorimeters*

A microcalorimeter is a small detector used to measure the total energy of incident photons or particles. As illustrated in Fig. 1, the device consists of an absorber, which is heated by individual photons or particles, and a thermal sensor, which measures the resulting change in temperature. The absorber and thermal sensor are in good thermal contact, while the assembly is isolated from the cold bath by a weak thermal link. The temperature rise due to an incident

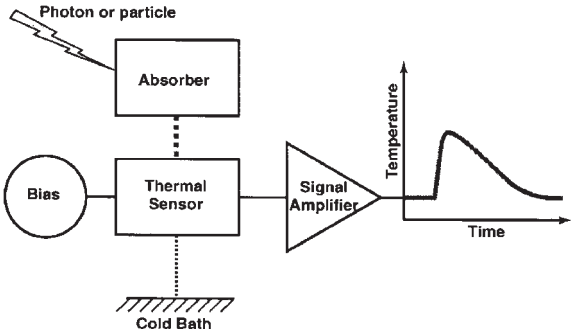

*Figure 1*
Schematic diagram of a microcalorimeter photon or particle detector.

particle is $\Delta T = E/C$ where $E$ is its energy and $C$ is the heat capacity of the device. A typical microcalorimeter operates at 0.1 K where its heat capacity can be so small that even optical photons will raise the temperature by a significant amount.

In addition to having a low heat capacity absorber, the microcalorimeter must include a sensitive thermal sensor. Thermistors have provided the best results to date. The sensitivity of the thermistor is typically parameterized by $\alpha$

$$\alpha \equiv \frac{T}{R}\frac{\mathrm{d}R}{\mathrm{d}T} \tag{1}$$

If a low-noise amplifier is used such that the dominant noise contributions are from the thermal fluctuations in the detector and the Johnson noise in the thermistor, then the limit to the accuracy one can measure the energy is

$$\Delta E_{\mathrm{FWHM}} = \xi 2.35\sqrt{k_{\mathrm{B}} T^2 C} \tag{2}$$

where $k_{\mathrm{B}}$ is the Boltzmann constant and $\xi$ is a prefactor that depends on $\alpha$ and the power dissipated in the detector by the bias circuit.

For semiconducting thermistors, $\alpha \sim -5$ and $\xi \sim 3$. Values of $\xi < 1$, and therefore better energy resolution, can be achieved with a superconducting transition-edge sensor (TES). A TES is a superconducting film operated at the transition between the superconducting and normal state where the change in resistance versus temperature is very steep and $\alpha > 100$ can be obtained. The transition temperature of a TES can be tuned to almost any value with the proper combination of superconducting and normal metals. When the photon or particle deposits energy in the microcalorimeter, the temperature quickly increases, and then returns to the operating temperature. The

time constant for a device operating without bias power is $C/G$ where $G$ is the thermal conductivity of the weak link. When bias power is applied to the thermistor, electrothermal feedback can significantly lengthen or shorten the pulse.

For the TES, a constant voltage bias is usually used. With a constant voltage bias, $V$, the detector is heated above the base temperature by the bias power $P = V^2/R$. When the detector is heated by a photon or particle, its temperature increases, thereby increasing the resistance, $R$, of the TES. This increase in $R$ decreases the bias power providing negative electrothermal feedback. This feedback reduces the pulse length. For a TES device with a large $\alpha$, electrothermal feedback can shorten the pulse time by more than an order of magnitude. In this case, the prefactor in Eqn. (2) is given by $\xi \approx 2.5/\sqrt{\alpha}$, which can be much less than one. A high-bandwidth ($>1$ MHz) superconducting quantum interference device (SQUID) current amplifier is typically used to operate the low-resistance voltage-biased TES detectors.

While the resolution achieved with microcalorimeters has been remarkable, the results are not generally limited by Eqn. (2). For instance, Eqn. (2) assumes that 100% of the photon or particle energy is converted to heat in the absorber. In real devices, however, some of the particle's energy can either excite long-lived states in the absorber material, or leave the detector before being measured by the thermal sensor. In both cases, the energy resolution is degraded. For optimal results, one must therefore find absorber materials with good photon or particle absorption properties, low specific heat, and good thermalization properties. Insulators and semiconductors can have very low specific heat, but statistical fluctuations in the generation of long-lived electronic states typically degrades the energy resolution to a much worse value than Eqn. (2). Good results, however, have been obtained with high-purity germanium and silicon when all the trapping centers are filled by infrared photon excitation prior to the measurement. Normal metals have excellent thermalization, but they also contain much more specific heat. Semimetals, bismuth in particular, provide an excellent combination of good thermalization with low specific heat. Superconductors cooled far below their transition temperature have low specific heat, and their small energy gap can minimize statistical fluctuations from trapped states. Tin appears to work exceptionally well.

X-ray microcalorimeters are typically $<1\,\text{mm}^2$ in area, and several microns thick. When cooled to $T \sim 0.1$ K, resolutions of about 5 eV full width at half maximum (FWHM) have been obtained at 6 keV, and 2 eV at 1.4 keV. The response time of these devices generally limits their count rate to a few 100 counts per second. These results have been achieved with TES devices and with germanium neutron-transmutation-doped thermistors attached to tin-foil absorbers by epoxy. For comparison, a good energy-dispersive semiconductor detector has a resolution 20 times worse, about 110 eV FWHM at 6 keV. Optical TES devices have also been developed, where $400\,\mu\text{m}^2$ pixels operating at $T \sim 80$ mK provide single photon counting with a resolving power of about 15, and count rates as high as $3.0 \times 10^4$ counts per second. Another thermal sensor under development uses the change in magnetization of a paramagnetic material. A resolution of 13 eV FWHM at 6 keV has been obtained using an erbium-doped gold sensor and a $0.01\,\text{mm}^2$ gold absorber.

Larger microcalorimeters are being developed to improve our understanding of the nonbaryonic matter of the universe. When a proposed WIMP particle scatters off a nucleus in a semiconductor crystal, the energy transferred to the detector is divided between electron–hole pairs and thermal energy. By measuring both the electron–hole pairs, and the prompt phonons, dark-matter detectors can differentiate nuclear-recoil events from electron-recoil events which tend to produce more electron–holes for a given energy input. This allows electron-recoil events due to background radiation to be excluded from the measurement, increasing the sensitivity to WIMPs by two orders of magnitude. A similar differentiation has been achieved by comparing the scintillation light and thermal energy collected when photons and particles scatter in calcium tungstate crystals. Despite their modest size ($<1$ kg), superconducting WIMP detectors have achieved more sensitivity than much more massive detectors operating at higher temperatures where it is not possible to reject background interactions to such a high degree.

## 2. *Superconducting Tunnel Junctions*

The superconducting tunnel junction (STJ) detector typically consists of a superconductor-insulator-superconductor (SIS) thin-film structure where the insulator is a very thin ($\sim 2$ nm) native-oxide layer, usually $Al_2O_3$. The STJ is cooled below 1/10 of the superconducting transition temperature to condense almost all its electrons into Cooper pairs. An incident photon or particle breaks some of these Cooper pairs and produces electronic excitations called quasiparticles. When the Josephson current is suppressed by a magnetic field and the junction is biased at a nonzero voltage, these excess quasiparticles tunnel through the insulating barrier, producing a current pulse (see *Josephson Junctions: Low-$T_c$*). The number of quasiparticles produced is $N_{\text{qp}} = E/\varepsilon$, where $\varepsilon$ is the average energy required to produce a quasiparticle. For most superconductors, $\varepsilon \approx 1.7\,\Delta$ where $\Delta$ is the superconducting energy gap (see *Electrodynamics of Superconductors: Flux Properties*; *Electrodynamics of Superconductors: Weakly Coupled*). Quasiparticle can tunnel back and forth through the barrier of an

STJ detector and this multiple tunneling can increase the measured signal.

If a low-noise amplifier is used such that the total noise in the measurement is dominated by the statistical fluctuations in the generation and tunneling of quasiparticles, then the resolution of the STJ detector would be limited by

$$\Delta E_{\mathrm{FWHM}} = 2.35\sqrt{E\varepsilon(F + F')} \qquad (3)$$

Where $F$ is the so-called Fano factor that parameterizes the statistical fluctuations in the generation of quasiparticles, and $F'$ is a term which describes the noise associated with the variations in how many times each quasiparticle tunnels through the barrier. Monte Carlo simulations find that $F \approx 0.2$ for most superconductors. The total integrated current measured with the device is $Q = nN_{\mathrm{qp}}$ where $n$ is the average number of times a quasiparticle tunnels through the barrier. Typically $n = \Gamma_{\mathrm{tun}}.\tau_{\mathrm{life}}$ where $\Gamma_{\mathrm{tun}}$ is the tunneling rate, and $.\tau_{\mathrm{life}}$ is the quasiparticle lifetime. For a symmetric STJ detector with multiple tunneling, $F' = 1 + 1/n$. Thus the multiple tunneling of quasiparticles can produce a bigger signal, but usually increases the statistical noise.

In general, a high tunnel rate, $\Gamma_{\mathrm{tun}}$, will produce larger signals and better results. The tunnel rate is inversely proportional to the barrier thickness and the thickness of the superconductor. The barrier can be only so thin before it becomes leaky, allowing resistive current flow and excess noise. A thin superconductor will have a high tunnel rate, but poor x-ray absorption efficiency. It is possible, however, to use two or more superconductors to concentrate the quasiparticles from a larger absorbing layer into a thinner layer next to the tunnel barrier. If the superconducting energy gap of the absorbing layer (typically niobium or tantalum) is larger than the energy gap of the layer next to the tunnel barrier (typically aluminum), then quasiparticles created in the higher-gap material can emit a phonon while in the lower-gap material. As illustrated in Fig. 2, the quasiparticle is then trapped in the lower gap material close to the barrier. Quasiparticle trapping can be used to improve the performance of an STJ x-ray detector.

In general, STJ photon detectors have not achieved the resolution described in Eqn. (3), but the discrepancy is mostly understood. STJ detectors are generally operated with room-temperature current or charge amplifiers. The noise contribution from these amplifiers depends on the resistance of the STJ. This noise contribution is typically measured during intervals when no photons strike the detector. When this quiescent noise estimate is subtracted in quadrature from the measured resolution, the estimated intrinsic resolution can approach the limit in Eqn. (3). Better agreement is obtained with measurements of the electronic noise contribution when a photon

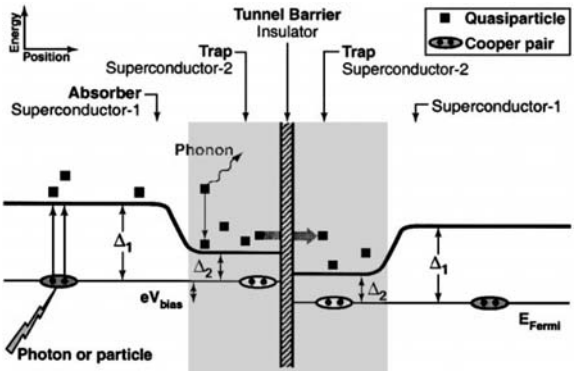

***Figure 2***
Energy levels in a symmetric superconducting tunnel junction photon or particle detector.

strikes the detector. The quasiparticles created by the photon causes a reduction in the STJ's resistance and an increase in electronic noise. This increase tends to bring the measurements into closer agreement with the limit described in Eqn. (3).

Five-layer STJ detectors of $Nb/Al/Al_2O_3/Al/Nb$ and $Ta/Al/Al_2O_3/Al/Ta$ have successfully been implemented as both x-ray and optical detectors. For x-rays below 1 keV, these detectors have good absorption efficiency and resolution between 2 eV FWHM and 10 eV FWHM, and can operate at temperatures as warm as 0.5 K. At 6 keV, the resolution achieved is about 25 eV FWHM, and the efficiency of these detectors is not as good. A notable exception is a $Al/Al_2O_3/Al$ STJ coupled to a lead film through a thick insulating barrier. In this case, the photon energy is converted to phonons in the lead, which pass through the insulator into the aluminum where the phonons break Cooper pairs. A resolution of 12 eV FWHM at 6vkeV was obtained with this device, and the lead film provides very high absorption efficiency even at 6 keV. Compared to the calorimeters developed so far, the STJ detectors can operate at higher count rates. STJ x-ray detectors have been operated at count rates up to $2.0 \times 10^4$ counts per second with little degradation in energy resolution. STJ detectors have also been successfully implemented to measure individual optical photons with a resolving power of about 15.

Quasiparticle trapping is a widely used technique to collect quasiparticles at various locations on a superconducting film or crystal. When a photon or particle interacts with the superconductor, the resulting quasiparticles will diffuse throughout the material, until recombining or becoming trapped. If most of the quasiparticles end up in the trapping centers adjacent to STJs, then both the energy and the position of the absorption event can be determined. Position-sensitive detectors have been successfully fabricated in both one and two-dimensional geometries. An energy

resolution of 13 eV FWHM at 6 keV and a spatial resolution of 0.5 μm in a 20 μm length has been obtained with an epitaxial tantalum strip detector with STJs at each end. The detector response time is limited by the diffusion of quasiparticles in the epitaxial film, and the lifetime of the quasiparticles trapped near the STJs. The count rate capability of these imaging strips is typically less than 1000 counts per second. Similar systems have also been shown to work with optical photons.

## 3. Hybrid Detectors

Microcalorimeters and STJ detectors have been combined in several interesting ways. One example is the aluminum STJ described above with a lead absorber. In some WIMP detectors, pads of aluminum are deposited on semiconducting crystals. Each aluminum pad is coupled to a TES. When a photon or particle is absorbed in the crystal, nonequilibrium phonons are generated as well as electron–hole pairs. The phonons are absorbed in the aluminum pads where they break Cooper pairs creating excess quasiparticles. These quasiparticles then diffuse in the aluminum and collect in the TES. The quasiparticles heat the TES, creating a current pulse in the amplifier.

Another interesting hybrid detector is the normal metal-insulator-superconductor (NIS) tunnel junction microcalorimeter. In this detector the photon or particle heats the electrons in the normal-metal film. This heating causes more electrons to tunnel through the insulating barrier into the superconductor. This current pulse is measured using a SQUID current amplifier. While the NIS tunnel junction uses tunneling, it is the temperature rise of the electrons in the normal metal that determines its ultimate performance. The resolution is thus limited by the microcalorimeter Eqn. (2) with $\xi \sim 1.3$. The best energy resolution obtained with an NIS tunnel junction microcalorimeter is 22 eV FWHM at 6 keV.

An interesting feature of the NIS tunnel junction is that the tunneling of hot electrons out of the normal metal is a cooling process. If the energy of these electrons can be removed from the system, the temperature of the normal metal can be lowered below the bath temperature. This property has been exploited to build microrefrigerators from NIS tunnel junctions. These microrefrigerators may be useful for cooling detectors or other small low-power devices from 0.3 K to 0.1 K, or from 0.1 K to as low 20 mK.

## 4. Superconducting Granules

A superheated superconducting granule (SSG) particle detector consists of small type-one superconducting spheres suspended in a dielectric. The spheres are cooled below their transition temperature, and then a magnetic field is applied. The magnetic field is adjusted to a value just below the field required to drive the spheres into their normal state. In this configuration, a small temperature increase within a sphere will cause the sphere to undergo a sudden phase transition to the normal state. When a sphere is in the superconducting state, the magnetic field is screened from its interior by the Meissner effect. During the phase transition to the normal state, the magnetic field penetrates the sphere. This results in a sudden change in magnetic flux, which can be measured by coils surrounding the spheres. Small (30 μm in diameter) spheres of tin or zinc are typically used. At 0.1 K, the heat capacity of these spheres is small enough that only a few electron volts of energy are needed to produce a phase transition.

Unlike microcalorimeters which measure the total energy deposited, SSGs measure only that the energy deposited was above a certain threshold. Some energy information from a constant source can be obtained by scanning the magnetic field. The sensitivity of the SSG particle detector is limited by variations from sphere to sphere in the energy required to produce a phase transition. Various fabrication techniques have been developed which provide a threshold accuracy of about 2%. With this accuracy, it is possible to distinguish between ionizing particles that induce several spheres to undergo phase transitions, and nuclear recoils that excite only one sphere. Detectors with billions of spheres are used for WIMP-search experiments.

# Random Access Memories: Magnetic

A variety of magnetic random access memory (MRAM) technologies have been explored over a period of many decades. Their advantages include an unlimited number of read-write cycles, random access to any address, radiation hardness, and nonvolatility (namely, the state of the memory does not require periodic refreshing and is maintained even when power is removed from the memory).

MRAM was originally in use for 30–40 years as magnetic core memory, which was then the only affordable RAM, although very labor-intensive and having a high cost per bit, before the advent of static RAM (SRAM) and dynamic RAM (DRAM) in the form of integrated circuits. It should be noted that while core memory has disappeared from most computers, there are still a number of applications for it in specialized systems, primarily military and space systems. Early interest, centered on magnetic bubble technology, was not successful, and involved an upper layer of permalloy patterned into a T-I bar structure and a lower layer of a garnet material with a single anisotropy direction perpendicular to the surface. Magnetic thin films were considered as an alternative to core memory. Since about the early 1990s, there has been a renewed interest in MRAMs by replacing thin film with anisotropic magnetoresistive (MR) bit structures. However, these nonvolatile memory technologies are of comparatively poor performance and thus limited in their applications. The small number of suppliers would be a concern for systems requiring long-term maintenance or likely upgrade (Jorgensen 1979, Daughton 1992).

The demand for nonvolatile radiation-hard memory has continued with additional pressures for higher density, lower power, higher speeds, and lower cost per bit. The present efforts to develop mainly three different versions of nonvolatile solid-state memories are a response to this. First, an MRAM using the spin-valve (SV) effect has been shown to have a fast switching signal (see *Magnetic Recording Systems: Spin Valves*). Second, an erasable programmable read-only memory (EPROM) employing the Hall effect to detect the fringe field of a ferromagnetic storage element has also been proposed. The third development underway is so-called spin-dependent tunneling (SDT) MRAM. This article reviews progress in MRAMs and outlines the prospects for future developments.

## 1. MRAM Using the Spin-valve Effect

MRAM using the spin-valve (SV) effect is evolved from that using the MR effect. A spin-valve is composed of two ferromagnetic (FM) layers (such as Permalloy or cobalt) with a spacer layer of a nonmagnetic conductor (typically copper). In principle, in the sandwich structures exhibiting the SV effect the resistance is lower when alternate magnetizations are parallel than when they are antiparallel (Daughton and Chen 1993, Matsuyama *et al*. 1997). The access time of the MRAM depends on sense signal, and currently this is limited by the 2% MR thin-film materials used today. The improvement in sensing time with larger signals is roughly equal to the square of improvement in signal. This is because, for a given signal-to-noise ratio (SNR), the sense system bandwidth may be increased by the square of the sense signal improvement. A 10-fold improvement in signal is possible with SV materials, and this would improve read access times of the densest MRAMs to about the same level as DRAMs (Daughton 1992).

Figure 1 is an MRAM architecture using the FM(hard)–conductor–FM(soft) SV sandwich proposed by Wang and coworkers in 1995 (Wang and Nakamura 1995a). This memory requires SV bit lines and word lines. In an SV sandwich there are two kinds of ferromagnetic layers, which possess different coercivities. As shown in Fig. 2, this memory operates on the general principle of storing a binary datum in the magnetically hard layer (cobalt) and sensing its remanent state by switching the magnetically soft layer (NiFe) in such a way that the magnetic state of the hard layer remains unaltered. The parallel and antiparallel states between magnetizations will give a different readout.

Addressing any desired element in a two-dimensional array is a basic requirement for MRAMs. This is realized by means of the ''astroid-shaped'' switching characteristics of a uniaxial anisotropic ferromagnetic thin film. As depicted in Fig. 3, the switching field in the longitudinal direction is lowered when a transverse field is applied. The word lines and bit lines,

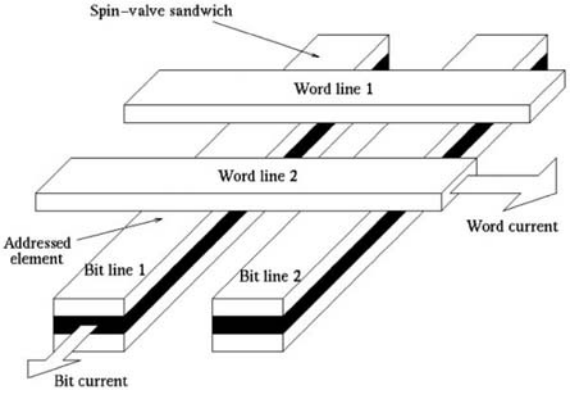

***Figure 1***
SV-MRAM architecture using SV sandwich. The word lines and SV bit lines, which are orthogonal to each other, are used for selection purposes. The shorting bars between elements to reduce the bit line resistance are not shown in this figure.

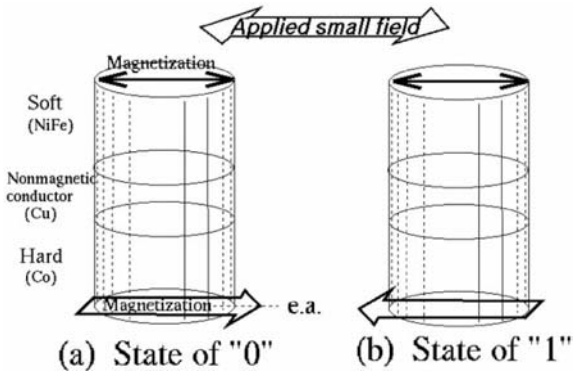

***Figure 2***
Schematic drawing of SV-MRAM. This memory operates on the general principle of storing binary datum in the magnetically hard layer (e.g., Co) and sensing its remanent state by switching the magnetically soft layer (e.g., NiFe) in such a way that the magnetic state of the hard layer remains unaltered (after Wang and Nakamura 1995a). The parallel and antiparallel states between magnetizations will give a different readout (spin-valve effect).

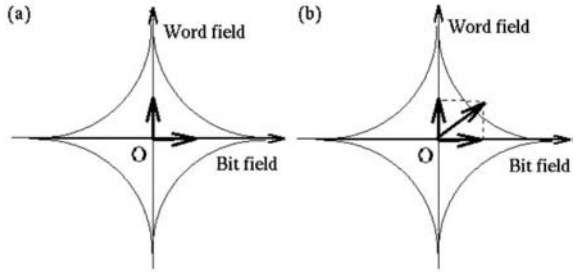

***Figure 3***
How to address a desired element in a two-dimensional array with the aid of astroid-shaped switching characteristics? (a) Neither the word field (with selected value) nor the bit field (with selected value) by themselves are able to switch the element; (b) both fields act together to produce a combined field vector greater than the switching threshold of the addressed element.

which are orthogonal to each other, are used for selection purpose (see Fig. 1). A word current passes through one of the word lines and a bit current through one of the bit lines. The bit current is assumed to flow mainly along the intermediate layer (e.g., copper) of the SV sandwich owing to its large conductivity. These two currents combine at one and only one intersection point, i.e., the addressed element. As depicted in Fig. 3(a), neither the word field (current) with selected value nor the bit field (current) with selected value is by itself able to switch the

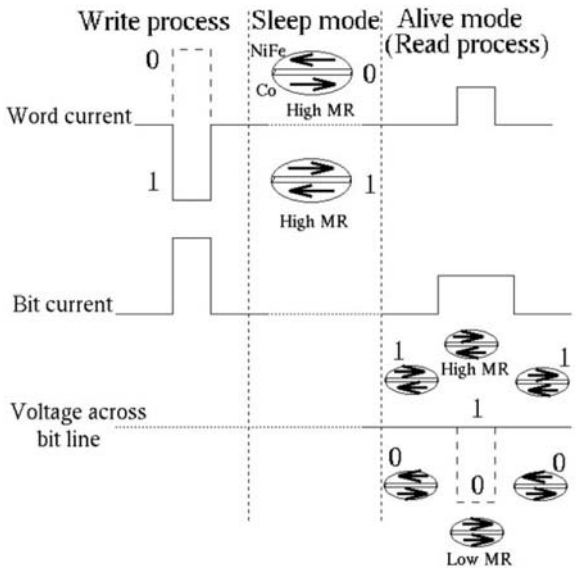

***Figure 4***
Magnetization configuration of an SV-MRAM element and its expected writing and reading timing diagram. In the absence of external field (sleep mode), the alternate magnetizations are antiparallel due to the inter-layer antiferromagnetic coupling.

element. In Fig. 3(b), if both fields act together, they are able to produce a combined field vector greater than the switching threshold of the addressed element. In such a way, a writing or re-writing operation is realized (Wang and Nakamura 1996a).

Magnetization configuration of an SV-MRAM element and its expected writing and reading timing diagram is shown in Fig. 4. During a write operation, the sign of the word current will define the stored bit value, "0" or "1." In the absence of external field (sleep mode), the alternate magnetizations are antiparallel, owing to the interlayer antiferromagnetic coupling, giving small self-demagnetizing fields and small external stray fields on nearby memory elements, both of which could help with element stability. During a read operation (alive mode), data readout is performed by monitoring the voltage response of the SV bit line against a positive word current, whose value is not sufficient to switch the hard layer, but switches the soft layer if it opposes the soft layer's magnetization. A different voltage, depending on whether a "0" or "1" is stored, should appear across that SV bit line. In the experimental pulse sequence (Wang and Nakamura 1995a), the sense current applied into the bit line is 5 mA and a sense output voltage of 8 mV appears. The read/write energy is quite low. Furthermore, the test indicates that a stable readout state involving $3 \times 10^8$ repeated reversals, by field cycling, of the soft layer's

magnetization is achieved, without gradual decay and eventual erasure of the hard layer's magnetization. Thus this SV-MRAM is confirmed to have a non-destructive readout (NDRO) property.

## 2. EPROM Using Hall Effect

An erasable programmable read-only memory (EPROM) using the Hall effect to detect the direction of magnetic moment of a ferromagnetic storage element has been proposed by Timoshkov *et al*., as shown in Fig. 5 (Timoshkov *et al*. 1996). The magnetic film of high coercivity and perpendicular anisotropy is used for data storage, and the Hall element for data reading. The insulating layer between them produces electrical isolation of the functional layers. The data recording process is realized by magnetizing the perpendicular anisotropy layer. The magnetic flux $B_Z$ of this layer penetrates through the Hall element, and the data read process is carried out by the Hall effect in the semiconductor material. The read time for such a memory is limited only by the relaxation time of the Hall effect processes and is equal to $10^{-12}$–$10^{-13}$ second. The equation for the Hall voltage $U_X$ is

$$U_X = r_{\mathrm{H}} \frac{I_Y B_Z}{ned} f(l/a) \tag{1}$$

where $r_{\mathrm{H}}$ is the Hall factor depending on prevalent scattering mechanism of the carriers, 1.18–1.93; $I_Y$ is the sense current; $e$ is unit electric charge, $1.6 \times 10^{-19}$ C; $n$ and $d$ are the carrier concentration in the semiconductor (data reading) layer and its width respectively; and $f(l/a)$ is a correction function, which is equal to 0.90–0.95 for a reasonable ratio of the length to the width of the data reading layer $l/a = 2-3$.

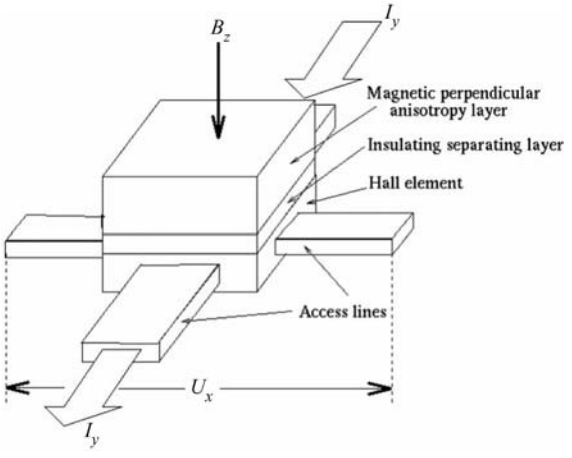

***Figure 5***
An EPROM using the Hall effect to detect the direction of magnetic moment of a ferromagnetic perpendicular storage element (after Timoshkov *et al*. 1996).

## 3. MRAM Using Spin-dependent Tunneling (SDT) Effect

The SDT effect (Julliere 1975, Miyazaki and Tezuka 1995, Moodera *et al*. 1995, Boeck 1998) is a special current-perpendicular-to-plane (CPP) giant magnetoresistance (GMR) effect, based on FM–tunnel–barrier–FM spin-polarized junctions. The tunneling resistance between two ferromagnetic metal layers that are separated by a thin insulator depends on the relative orientation of the magnetization of each layer.

Work by Wang *et al*. on the MRAM using the SDT effect began in 1994 (Wang and Nakamura 1995b, 1996b), and led initially to the successful fabrication of a $2 \times 2$ bit SDT-MRAM, based on Co/$Al_2O_3$/80NiFe tunnel junctions. Figure 6 is its scanning electron microscopy (SEM) picture and schematic. The chiplet has eight contact pads, which provides the required flexibility in connecting the test site to the peripheral select/drive circuitry. The spin-tunneling junction dimensions varied between 2 and 50 μm. All the spin tunneling samples Co(100 nm)/$Al_2O_3$(3–8 nm)/80NiFe(100 nm) were prepared by radio frequency (rf) sputtering with argon. The intermediate $Al_2O_3$ was formed by oxidation in the atmosphere. Uniaxial magneto-crystalline anisotropy in ferromagnetic films, important both for memory storage and for the way that a bit is selected, was induced by a magnetic field applied during sputtering. Contact windows were opened in the insulator to allow the orthogonal top leads and bottom leads to access the junctions directly. The top leads are visible as brighter regions in the SEM picture, whereas the bottom leads are darker.

As shown in Fig. 7, the structure of the SDT-MRAM is relatively simple, compared with the semiconductor memories. Having an active memory-cell transistor, flash EEPROMs (electrically erasable programmable ROMs) typify semiconductor memories. The minimum element area of a tunneling cell is 4.84 $\lambda^2$, where $\lambda$ is the resolution limit of the lithography used to fabricate the memory elements. Progress in photolithography technology should enable the reduction of $\lambda$ beyond the 200 nm limit (Daughton 1992). Compared with the minimum size of a memory-element transistor, over $10\lambda^2$ (also shown in Fig. 7), the SDT-MRAM can potentially be at least twice as dense.

The spin-tunneling junction was designed with a circular shape to benefit the formation of single-domain structure, based on the micromagnetic simulation result (He and Wang 1999), as shown in Fig. 8. For each MRAM element there should exist only two possible states of magnetization, e.g., left and right. Clearly this is the case for an elliptic or circular

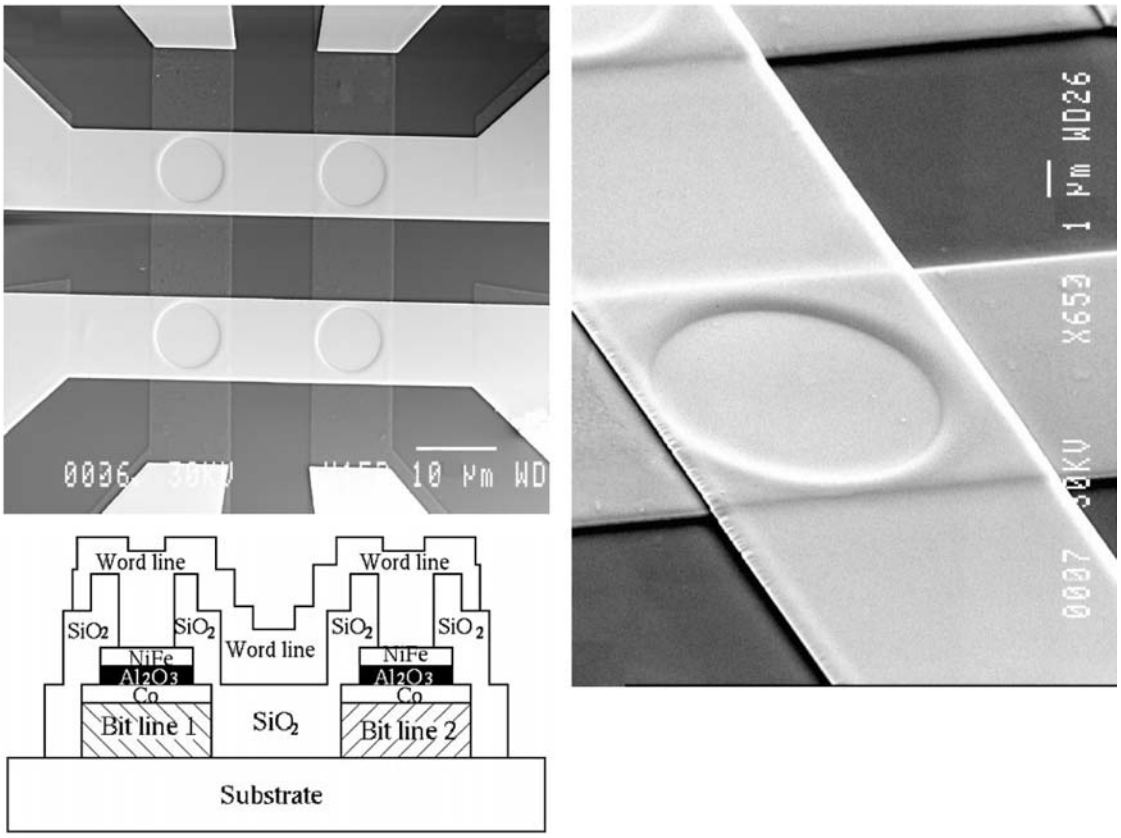

***Figure 6***
SEM micrographs of a $2 \times 2$ bit SDT-MRAM chiplet showing the test site containing 8 contact pads and 4 circular tunnel junctions, each 10 μm in diameter, the schematic cross-section (note the CPP structure) and a single-tunnel junction bit. The top leads are visible as bright regions in SEM whereas the orthogonal bottom leads are darker (after Wang and Nakamura 1996b).

island. In detail, for a single domain island one can be sure that the island switches completely in a proper writing process. A multi-domain state found in the square patterned island would lead to a miscellaneous logic in a one bit per island recording system. This is because more than two states are possible and the island might not have switched completely after writing. As a consequence, the magnetization of the island becomes unstable and the result of a next writing process may be unpredictable.

An isolated memory element was tested. Figure 9 illustrates the R(H) response's minor loops operating in the mode in which only the magnetically soft layer is switched by applying a field of $\pm 1.6\,\mathrm{kA\,m^{-1}}$ and the sample is initially saturated by $+3.2\,\mathrm{kA\,m^{-1}}$. Note that the MR hysteresis at zero field represents different magnetization combinations, thereby yielding different resistance values.

The on-chip parallel write/read operations were successfully performed. Writing the information involves a switching of the soft layer's magnetization, ideally without affecting the reference (hard) layer's magnetization. (In a memory device, independent switching of the magnetically soft layer is achieved by making the other layer either magnetically hard or exchange-biased by an antiferromagnetic layer, e.g., MnFe.) Reading the information only requires a measurement of magnetoresistance. An output voltage change of 96 mV, as shown in Fig. 10, between the binary bit states against a sine-wave sense voltage of 160 mV, 1 MHz has been observed. This is a reproducible readout state.

Ultra-dense magnetic solid-state MRAMs will probably be limited by the minimum signal level. As a comparison, we first deduce the signal level in conventional current-in-plane (CIP)-type MR or SV MRAM. Its signal is given by

$$\mathrm{Signal}_{\mathrm{CIP}} = fJ_{\max}\lambda\Delta\rho \qquad (2)$$

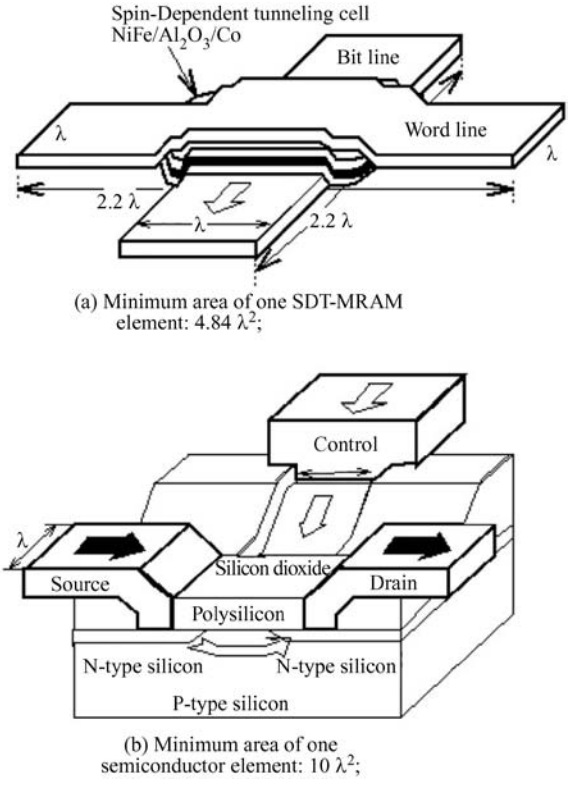

***Figure 7***
Structure comparison of the SDT-MRAM and the semiconductor memory. In (b) a field effect transistor (FET) comprises a source and a drain contact to send current through a semiconductor channel and a gate control to modulate the carrier density in the channel. Here $\lambda$ is the resolution limit of the lithography used to fabricate the memory elements.

where $f$ is a factor smaller than one which depends on the mode of storing and sensing information, $J_{\max}$ is the maximum current per cross-sectional area allowed by thermal dissipation, and $\Delta\rho$ is the change of resistivity. Thus at the maximum current density, the signal level is proportional to the element size $\lambda$. As the storage density increases, the signal level will decrease. In contrast, the signal of SDT-MRAM results in

$$\text{Signal}_{\text{CPP}} = fJ_{\max}t\Delta\rho \tag{3}$$

where $t$ is the total thickness of the spin-tunneling junction. As illustrated in Fig. 11, at a maximum sense current density, the signal level of SDT-MRAM is obviously independent of its cross-sectional area $\lambda^2$. This result is so attractive that the density of SDT-MRAM should not be limited by signal degradation. It is suggested that density-independent signal level is

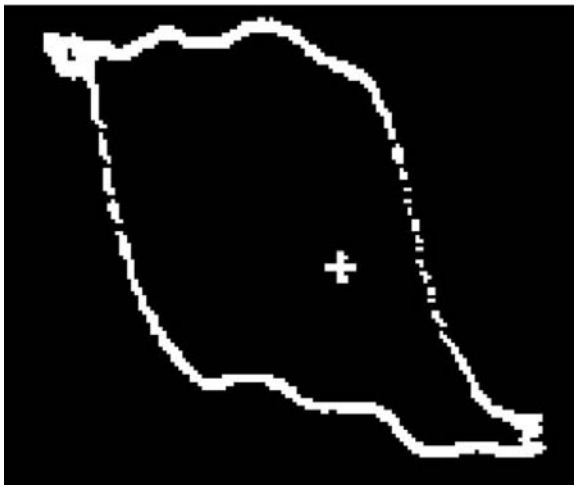

***Figure 9***
Measured resistance versus applied field R(H) for $Co/Al_2O_3/80NiFe$. The applied field is limited at $\pm 1.6\,\text{kA m}^{-1}$ and the sample is initially saturated by $+3.2\,\text{kA m}^{-1}$. Note that the MR hysteresis at zero field represents different magnetization combinations thereby yielding different magnetoresistances (after Wang and Nakamura 1995b).

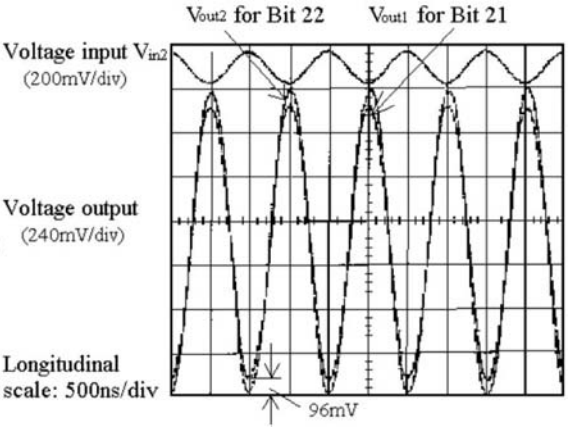

***Figure 10***
Reproducible read waveform. An output voltage change of 96 mV (after an amplifier) between the binary bit states against a sine-wave voltage excitation (the above) of 160 mV, 1 MHz has been observed. The vertical scale is 1.2 V/div and the horizontal scale is 500 ns/div.

the biggest advantage of CPP-type SDT-MRAM, compared with CIP-type MR or SV MRAM.

It is pointed out that the SDT-MRAM's signal remains constant while the CIP MRAM's signal drops with increasing density. However, the Johnson noise with SDT-MRAM may become a limiting factor in scaling the MRAM element to submicron sizes because this component of noise becomes increasingly important and may even dominate the total noise. What matters for practical application is SNR. Even the larger signals available from SV structures do not make SV-MRAM attractive for mainstream RAM applications. In order to achieve reasonable memory array densities many SV elements (of number $n$) have to be electrically connected in series, which means that the actual signal available when reading one particular element is MR/$n$ (see Fig. 1 for reference). Thus, a severe practical problem is encountered that ultra-dense CIP SV-MRAM will be limited by low SNR. By contrast, as illustrated in Fig. 6, the high MR signal from the individual junction element can be fully utilized in a cross-point architecture by connecting each element in parallel. In this case, the SNR in an $n$ bit $\times$ $n$ bit SDT-MRAM is independent of $n$, which is normally a big number. As a result, although SNR in both CIP and CPP MRAMs falls with increasing density, the SNR for the CPP SDT-MRAM remains much larger than for the CIP type MR or SVMRAM.

So far, the experimental results of SDT-MRAM are only for a low-density case in that only $2 \times 2$ bit elements are included. For a dense or ultra-dense MRAM, the cross-talk from an addressed element to adjacent elements may cause mis-selection and creep problems (after many such disturbances the magnetic

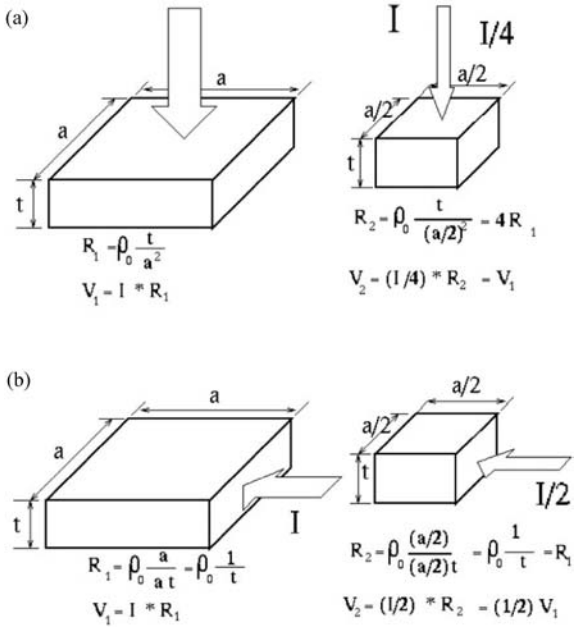

***Figure 11***
Halving the dimension of an MRAM cell will cause different results on signal amplitude. In the CPP design of (a), signal remains; in the CIP design of (b), signal drops by a factor of 2. Note that both (a) and (b) are at a maximum sense current density.

state of these bits creeps either to some intermediate state or may completely reverse). Note also that the driving field required to switch the layer increases as a result of the decreased length of the element, owing to the demagnetization effect. To address these issues, a finite element method (FEM) was used to study the electromagnetic behavior of SDT-MRAM (Wang *et al.* 1997). Three keepered SDT-MRAM designs have been considered, as shown in Fig. 12. A low-cost conventional keeperless MRAM design (Fig. 12(a)) is taken as our reference. To localize the field, an improved partially keepered MRAM design (Fig. 12(b)) differs from the reference MRAM by the addition of partial keepers, with high permeability, above the bit lines and underneath the word lines. The third design, known as the continuously keepered MRAM design, is shown in Fig. 12(c). In this design, additional continuous keepers with 0.1 μm thickness are formed. It was hypothesized that the drive field would be confined within the nearly closed keeper, effectively enhancing the driving field and reducing interference between adjacent cells. The continuously keepered MRAM design was found to reduce the cross-talk by a factor of five and reduce the driving current by a factor of four, compared with a conventional keeperless design, which will be the most favored approach for achieving $10^9$ bits cm$^{-2}$ areal density.

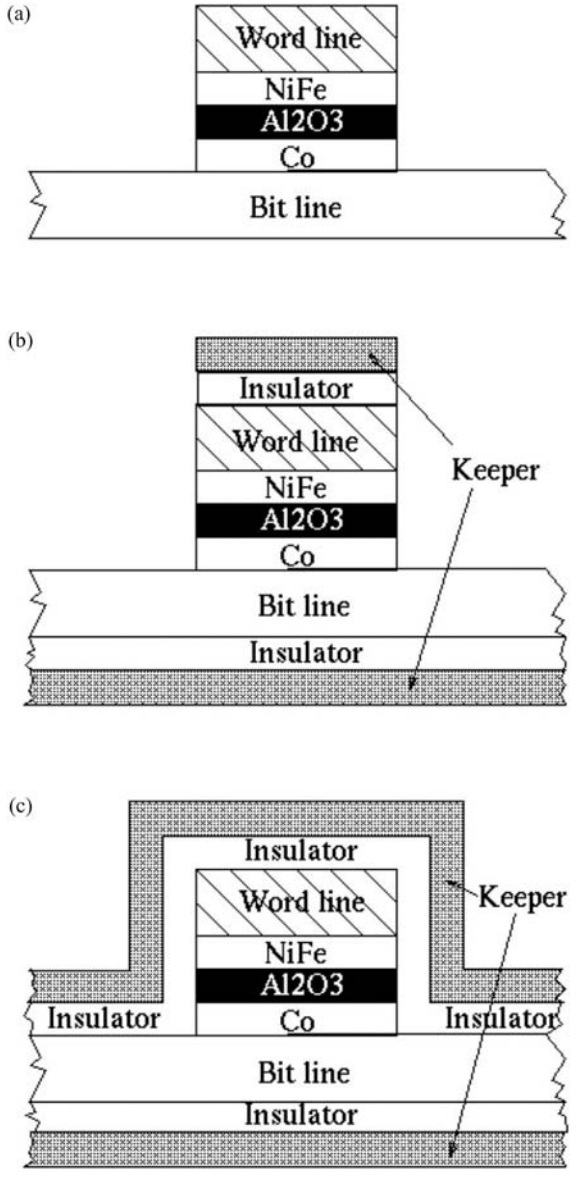

***Figure 12***
Three keepered SDT-MRAM designs: (a) conventional keeper-less MRAM design; (b) improved partially keepered MRAM design; (c) further improved continuously keepered MRAM design (after Wang *et al.* 1997).

## *4. Conclusions*

Read-access time and storage density are the twin keys to computer data storage devices. Although new electronic devices, processor organizations and software systems have contributed to enormous advances

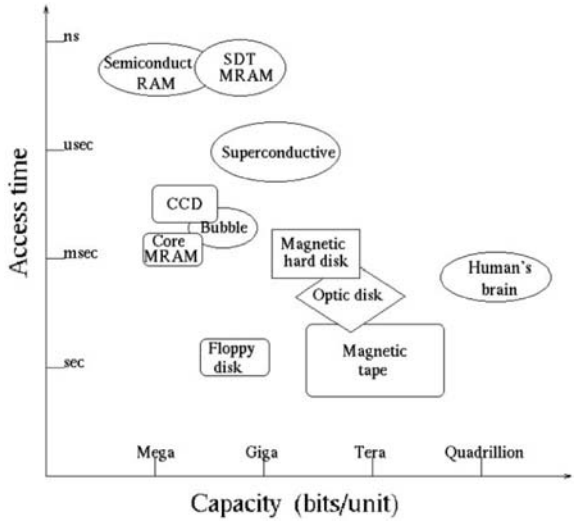

***Figure 13***
The position of SDT-MRAM in various data storage devices.

in computer technology, they would have been worthless without the faster and denser memories that were developed with them. The SDT-MRAM outlined here, the most promising candidate for magnetic nonvolatile memory, is likely to achieve very high densities. From Fig. 13 it can be seen that SDT-MRAM, which is simply structured, may in some applications potentially exhibit excellent properties superior to semiconductor memories and/or magnetic disks. In particular, the density-independent signal level is the biggest advantage of CPP-type SDT-MRAM, compared with the conventional CIP-type MR or SV MRAM, whose signal level is inversely proportional to the square root of the storage density. Furthermore, it has also been demonstrated that although the Johnson noise makes a large contribution to the total noise, it does not significantly degrade the performance of the device, because the SNR for the SDT-MRAM remains much larger than for the CIP MR or SV MRAM even at high storage density.

Another important parameter for SDT-MRAM is the intrinsic RC time constant of the device. Because of the insulator between electrodes, junctions also act as a parallel plate capacitor. The reason that the RC time constant is important for memory application is because of speed limitations in reading data from a memory element. The RC time constant is independent of the area of the junction and exponentially dependent on the thickness of the barrier and can be reduced until the processing difficulties with thin barriers prevent further reduction in thickness. For modern MRAM applications, the equivalent

resistance for SDT devices must be at the lower end of the resistance range. Parkin *et al*. found that the resistance-area products of magnetic tunnel junctions can be varied from $10^9\,\Omega\mu m^2$ to as low as $60\,\Omega\mu m^2$ by varying the aluminum thickness and properly oxidizing it (Parkin *et al*. 1999). Incomplete oxidation leads to the presence of metallic aluminum in the barrier, which results in a rapid suppression of the tunnel junction magnetoresistance. Based on these facts, the RC time constant for the junctions should be of the order of nanoseconds (Wong *et al*. 1998, Sousa *et al*. 1999). Nevertheless, such a SDT-MRAM has to be read with a silicon sense amplifier. This means a mixed silicon-tunneling structure: the X-Y decoders/sense amplifiers in an array in silicon with "holes" to be filled in by tunneling array. Thus, the speed of the device will probably be limited by silicon technology. (Today, the speed of experimental silicon devices has improved to 1 ns and will be expected to dip below this in future.) There is no significant access-time advantage for the tunneling design as compared to the bipolar devices.

As well as the continuing developments which are always to be expected in semiconductor memory technology, it is also interesting to note other novel technologies, such as the spin-dependent tunneling (SDT) effect. In the immediate future DRAM will continue as the densest semiconductor memory, but MRAM using the SDT effect looks set to take the lead in the medium and longer term and is a very important development for applications where non-volatility, higher density, radiation hardness and lower power are required. Prototypes are out, technology is maturing, and the advances mentioned in this article would speed up the pace of the application of MRAM, since a microstructured junction might serve as a high-capacity and low-power substitute for conventional semi-conductor memories.

## Rare Earth Intermetallics: Thermopower of Cerium, Samarium, and Europium Compounds

The thermoelectric power, $S$, is known as a transport property that is very sensitive to details of the electronic structure at the Fermi energy. Cerium compounds exhibit widely different types of anomalous physical properties owing to the hybridization of cerium $4f$ electrons and conduction electrons. There is already an accumulation of experimental data for $S$ for a large number of cerium compounds; however, there has been no review article concerning these data, as far as is known. The aim of this article is to give an overview and discussion of these data for $S$ for different types of cerium compounds.

This article is based on previous review papers by Sakurai (1993), and Sakurai *et al*. (1996). Anomalous physical properties of cerium compounds are of interest with respect to highly correlated electron systems (see *Electron Systems: Strong Correlations*). Doniach (1977) considered a competition of two interactions: the Kondo interaction between the cerium $4f$ electrons and the conduction electrons (characteristic temperature $T_K$) and the RKKY interaction between the $4f$ electrons on different lattice sites via the conduction electrons (characteristic temperature $T_N$

for an antiferromagnet or $T_C$ for a ferromagnet). The former interaction causes the cerium 4*f* electrons and the conduction electrons to form a hybridized nonmagnetic singlet state for temperatures $T < T_K$, but the cerium 4*f* electrons regain their magnetic moment for $T > T_K$. The latter interaction gives rise to an antiferromagnetic state of the cerium 4*f* electrons for $T < T_N$ (or a ferromagnetic state for $T < T_C$) and to a paramagnetic state with a random orientation of the magnetic moments for $T_N$ (or $T_C$) $< T$.

These characteristic temperatures $T_K$ and $T_N$ (or $T_C$) are exemplified in Fig. 1 as functions of the hybridization strength, *J*, between the cerium 4*f* electrons and the conduction electrons. We can distinguish in Fig. 1 four regions, I–IV, where cerium compounds have distinctly different physical properties. In region I, where $T_K \gg T_N$ (or $T_C$), cerium compounds are in a fluctuating or intermediate valence state, thus exhibiting no magnetic moment in a wide temperature range $T < T_K$. In region II, with $T_K \approx T_N$ or $T_C$, the compounds lose the magnetic moment of their localized $Ce^{3+}$ ions owing to the hybridization between the cerium 4*f* electrons and the conduction electrons, and the effective masses of the electrons become very large (heavy fermion) for $T < T_K$. In region III, where $T_K$ is slightly smaller than $T_N$, cerium compounds order magnetically with reduced ordered moments owing to the Kondo effect. Finally, in region IV, where $T_K \ll T_N$, cerium compounds are in an almost unperturbed antiferromagnetic state with the magnetic moment determined from crystal field effects experienced by the local $Ce^{3+}$ ion.

The $S(T)$ curves for a CeNi single crystal are shown in Fig. 2 as a typical compound of region I together with the nonmagnetic LaNi reference sample

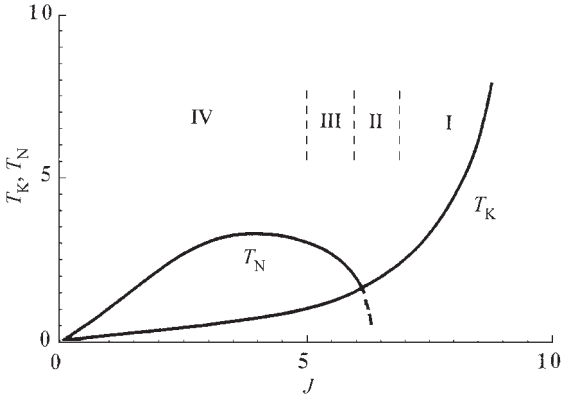

***Figure 1***
Kondo temperature, $T_K$, and the Neel temperatures, $T_N$, plotted as a function of the hybridization, *J*, between cerium 4*f* electron and the conduction electron band (after Doniach 1977).

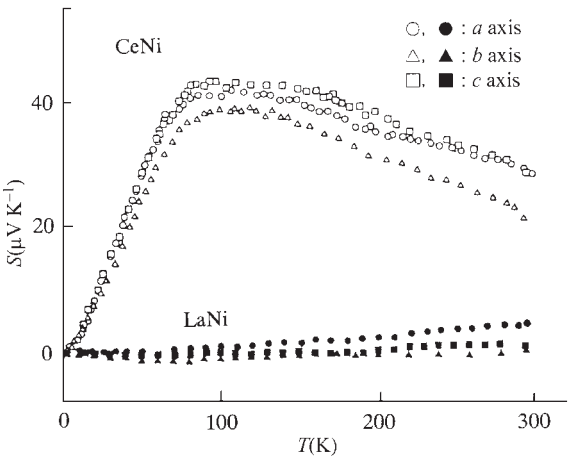

***Figure 2***
*S* of an intermediate valence compound CeNi and its nonmagnetic counterpart LaNi (single crystals) along three crystal axes plotted as a function of temperature, *T*.

(Sakurai *et al*. 1996). The absolute values of *S* for LaNi along the three principal axes of the orthorhombic crystal are small, and the $S(T)$ curves behave nearly linearly. This behavior can be approximated by the linear relationship $S(T) = aT$, where $a =$ const. over a wide temperature range. This formula can be derived from the Boltzmann equation for normal metals (see also *Boltzmann Equation and Scattering Mechanisms*, and *Kondo Systems and Heavy Fermions: Transport Phenomena*), with the constant *a* basically representing conduction electron properties at the Fermi level, described by the density of states (DOS) function (Ziman 1960).

On the contrary, the absolute values of *S* for CeNi along the three principal axes are much larger than those for LaNi, and the $S(T)$ curves exhibit broad peaks with maximums around 100 K, indicating that *a* is not a constant but depends on *T*. An enhancement of the DOS takes place at the Fermi level owing to the formation of nonmagnetic Kondo singlets at low temperatures. Thus, *a* is much larger for CeNi than for LaNi. With the increase of *T*, the thermal excitation breaks the Kondo state causing a gradual recovery of the cerium magnetic moments, hence the value of *a* decreases. A gradual recovery of the Curie–Weiss law is known to take place when *T* is larger than the temperature of the maximum in *S* vs. *T*. In this scenario the Kondo interaction predominates by far over the RKKY interaction, and the effect of the crystalline electric field (CEF) has not been taken into account. Additional examples of these types of materials are $CeSn_3$, $CePd_3$, $CeNiAl_4$, and $CeNi_2Ge_2$ (Sakurai *et al*. 1996).

The $S(T)$ curves of $CeCu_6$ (Onuki and Komatsubara 1987) and CePtIn (Fujii *et al*. 1987) are shown in

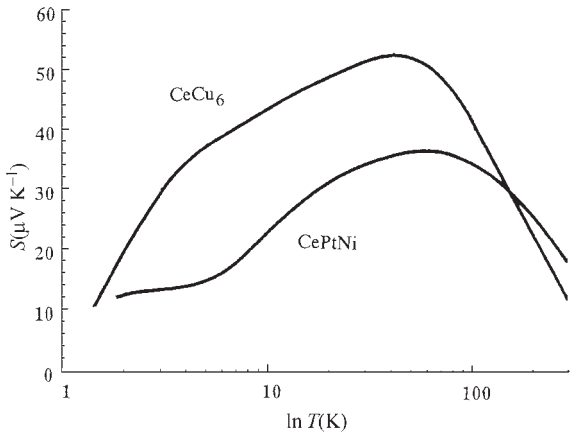

***Figure 3***
$S$ of two polycrystalline heavy fermion compounds $CeCu_6$ and CePtNi plotted as a function of ln$T$.

Fig. 3 as typical compounds of region II. Both compounds exhibit $T_K$ values of only a few kelvin without any magnetic order but they are characterized by a very large enhancement of the electronic specific heat, $\gamma$, at low temperatures. The two curves in Fig. 3 resemble each other, showing a large and broad maximum at 50–70 K with shoulders at around 5 K. For temperatures $T > T_K$, the cerium 4*f* electrons are in a local and dilute ionic state and experience a CEF with the Kondo effect acting as a small perturbation. The RKKY interaction can be neglected. The Seebeck coefficient in this parameter region has been theoretically investigated by Bhattacharjee and Coqblin (1976) and Kashiba *et al.* (1986). According to these calculations a positive peak of the $S(T)$ curve is expected at a temperature around about 1/3 to 1/6 of the overall CEF splitting. The main $S$ peaks of the two compounds in Fig. 3 are ascribed to interplay of the Kondo effect and CEF effect splitting. The main peaks for the two compounds in Fig. 3 are reminiscent of the peak of CeNi in Fig. 2; however, they are of different origins.

The following discussion concerns the initial slope of $S$ vs. $T$ for $T \to 0$. It is well known that $S \to 0$ for $T \to 0$ and the initial slope of $S(T \to 0)$ reflects details of the DOS at $E = E_F$ (Ziman 1960). For $CeCu_6$ and CePtIn a very large value of $10\,\mu VK^{-2}$ is observed. In comparison, the value for CeNi in Fig. 2 is around $0.5\,\mu VK^{-2}$ and the value for LaNi, the reference sample for CeNi, is around $0.01\,\mu VK^{-2}$. Thus, the initial slope of $S(T)$ is apparently closely related to the electronic specific heat, $\gamma$.

The initial slope of $S$ is plotted in Fig. 4 as a function of $\gamma$ for several cerium compounds belonging to regions I and II. They are $CeSn_3$, CeNi, $CePd_3$, CeNiIn, and $CeNiAl_4$ in region I, and $CeCu_6$, $Ce_{0.1}La_{0.9}Cu_6$, $CeInCu_2$, CePtIn, $CeCu_3Ga_2$, $CeCu_3A1_2$, $CeCu_4Al$, and $CeCu_4Ga$ in region II (Sakurai 1993).

The estimation of the initial slope of $S$ is noted to depend on the temperature range of measurements especially for the compounds belonging to region II. When the value for $CeCu_6$ in Fig. 3 is estimated from the temperature range above the shoulder around 5 K, the value becomes smaller. $S(T)$ measurements performed for $CeCu_6$ down to 10 mK show another structure below 1 K and the establishment of the relationships $S = aT$ and $\rho = cT^2$ ($c$ = const.) is possible only in a very low temperature range, below 30 mK (Sato *et al.* 1987). The initial slope of $S$ estimated below 30 mK approaches a value of $30\,\mu VK^{-2}$. Thus, in Fig. 4 the values obtained for cerium compounds belonging to region II for the different temperature ranges are plotted separately (Sakurai 1993).

The proportionality between the initial slope $dS/dT$ for $T \to 0$ and the electronic specific heat coefficient, $\gamma$, is confirmed by the experiment, as shown in Fig. 4. In view of the difficulties of obtaining an accurate estimation of the initial slope of $S$, the scatter of points near the origin of Fig. 4 is not significantly important. The very large initial slope of $S(T)$ for the cerium compounds in region II is a direct consequence of the DOS at the Fermi level for $T < T_K$ originating from the hybridization of the cerium 4*f* electrons and the conduction electrons mediated by the Kondo interaction.

According to the theory of Kawakami *et al.* (1987) for the Kondo interaction of dilute cerium impurity systems, the initial slope of $S$ and $\gamma$ exhibit the same enhancement factor at low temperatures. It has been demonstrated that the initial slope of $S$ originates from the asymmetry of the conduction electron state density at the Fermi energy but may also depend on additional interactions of the conduction electron system.

In region III the cerium compounds are so-called Kondo antiferromagnets showing both the Kondo effect and a long-range antiferromagnetic order. Only a few systems are known with a ferromagnetic ground state.

The $S(T)$ curves of CePdSn and CePtSn are given as examples of Kondo antiferromagnets (Sakurai *et al.* 1996). Both compounds show antiferromagnetic order below 7 K, and are characterized by a Kondo resistivity behavior. The $S(T)$ curves of the two compounds shown in Fig. 5 have maximums around 100 K and minimums at around 20 K. The positive peaks are ascribed to the Kondo effect in the presence of the CEF splitting of the ground state multiplet level of the cerium 4*f* electron, similarly to the positive peaks for $CeCu_6$ and CePtIn.

The narrow minimums at low temperatures are characteristic of cerium compounds in region III. The position of the minimums is typically two or three times larger than the ordering temperature, $T_N$, and hence can be taken as an experimental

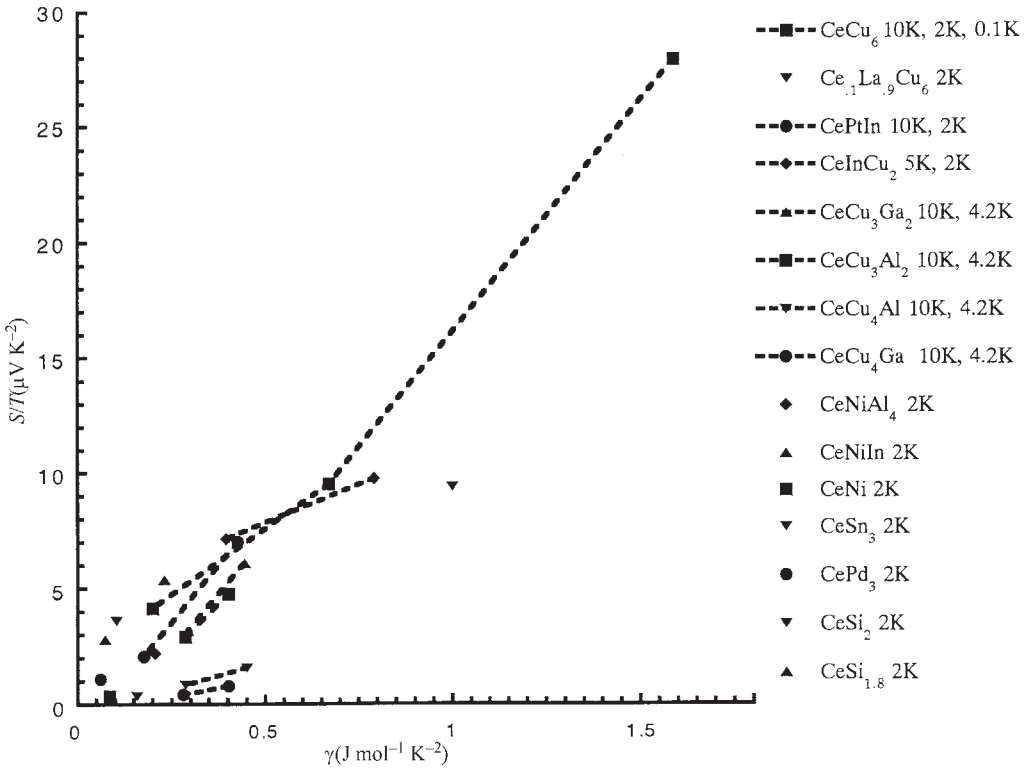

***Figure 4***
Initial slope of the thermoelectric power $S/T$ at $T = 0$ plotted as a function of the electronic specific heat coefficient, $\gamma$, for several heavy fermion and intermediate valence compounds (see text for details).

indication of the onset of short-range antiferromagnetic correlations.

According to Fischer (1989), a resonance term in $S$ appears for cerium compounds having strong magnetic correlations between the cerium moments. This term gives rise to a negative $S(T)$ contribution centered around $T^* = \Gamma/k_B$, where $\Gamma$ is the half width of the quasi-elastic peak deduced by inelastic neutron scattering, which is a measure of the correlation between the cerium moments. Thus, it is concluded that the resonance term of $S$ proposed by Fischer (1989) gives a theoretical explanation of the minimums in $S$ vs. $T$, which seems to originate from the onset of short-range antiferromagnetic correlations. $S$ vs. $T$ curves similar to those shown in Fig. 5 have been observed in many Kondo antiferromagnets, e.g., in $CeAl_2$, $CePb_3$, $CeCu_2$, CePtGa, CePtGe, $CeCu_2Ge_2$, $CePd_2Si_2$, and many others (Sakurai *et al.* 1996).

Various cerium compounds belonging to region II show $S(T)$ behavior typical for systems of region III. Examples are $CeAl_3$ (Jaccard and Flouquet 1987), $CeCu_2Si_2$ (Jaccard *et al.* 1985), and $CeRu_2Si_2$ (Amato *et al.* 1988). These compounds are characterized by a very large enhancement of $\gamma$ with no long-range antiferromagnetic order. In spite of the absence of long-range magnetic order in $CeRu_2Si_2$, the existence of short-range magnetic correlation has been verified by neutron scattering experiments (Regnault *et al.* 1988). The minimum in the $S$ vs. $T$ curve for this compound is observed along the $c$-axis but not along the $a$-axis.

The transition of the $S(T)$ behavior from one region to another is sometimes clear and well defined. A striking evolution of $S(T)$ emerges from high-pressure studies of $S$ vs. $T$. The deep minimum in $S(T)$ for $CeCu_2Si_2$ centered around 20 K at zero pressure vanishes rapidly with pressure and the $S(T)$ curve shows positive values with a steep initial slope at higher pressures (Jaccard *et al.* 1985). The application of pressure (and hence a decrease of the interatomic distance) increases the hybridization between the cerium 4*f* band states and the conduction band states, and thus a change takes place from region III into region II.

Similar changes of the $S(T)$ behavior follow also from chemical pressure, realized by alloying a compound with an isomorphous one having a slightly smaller or larger unit cell volume. The $S(T)$ behavior

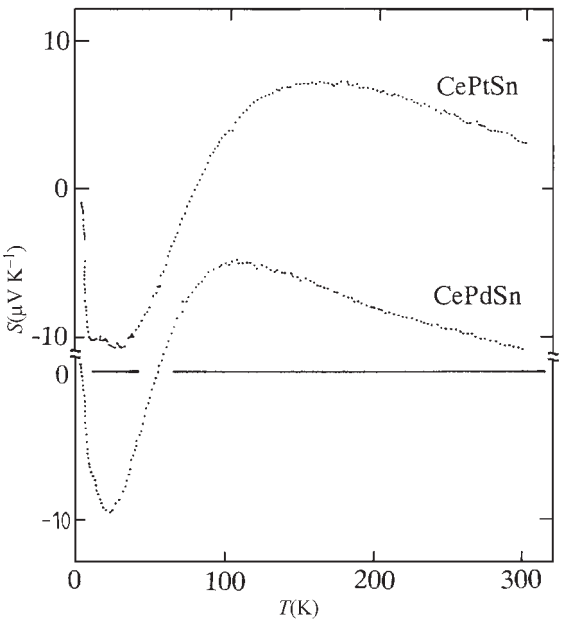

***Figure 5***
$S$ of two antiferromagnetic Kondo compounds CePdSn and CePtSn plotted as a function of temperature.

of $CePb_3$ belonging to region III changes in the pseudobinary system $Ce(Pb_{1-x}Sn_x)_3$ towards region II (Sakurai *et al*. 1996), and with further addition of tin, into region I. A similar change of the $S$ behavior from region III to region II has also been reported for $Ce(Cu_{1-x}Al_x)_5$ and $Ce(Cu_{1-x}Ga_x)_5$ (Bauer 1991). In contrast, a reverse change of the $S$ behavior from region II to region III has been reported for $Ce(Cu_{1-x}Au_x)_6$ (Bauer 1991), owing to the negative chemical pressure produced by the gold substitution.

Typical features of regions II and III frequently coexist. The measurement of $S(T)$ for CePdSn has been carried out down to 0.3 K (Huo *et al*. 1999). According to this experiment, a second positive peak of $S(T)$ at around 1 K is found, in addition to the positive and negative peaks shown in Fig. 4. The appearance of this peak may be associated with a weak enhancement of $\gamma$ of the compound occurring along with antiferromagnetic order.

Finally, Fig. 6 shows the $S(T)$ curve of $CePd_2Sn_2$ (Sakurai *et al*. 1996) as an example of cerium compounds in region IV. The compound has a $T_N$ value of 0.5 K, and no Kondo behavior is observed in its resistivity. The $S(T)$ curve is smooth and corresponds to small absolute value. It resembles that of the nonmagnetic counterpart $LaPd_2Sn_2$. Thus, the cerium 4*f* electrons in the compound are in well-localized states without significant hybridization with the conduction band states. Similar $S(T)$ curves have been reported for $CeMg_3$ (Sakurai *et al*. 1996).

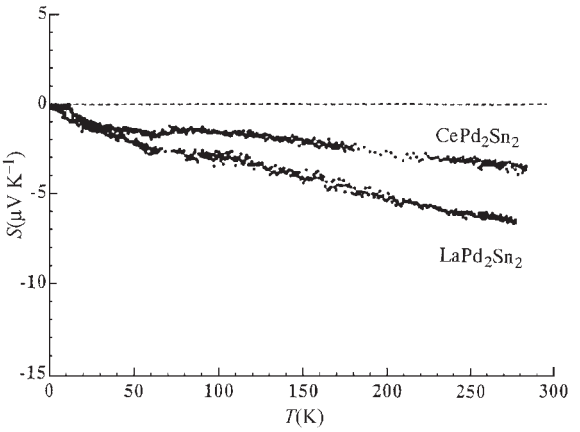

***Figure 6***
$S$ of an antiferromagnetic compound $CePd_2Sn_2$ having no Kondo character and its nonmagnetic counterpart $LaPd_2Sn_2$ plotted as a function of temperature, $T$.

The thermoelectric power, $S$, is surely a property that reflects very sensitively the various natures of the hybridization between cerium 4*f* electron states and conduction electron states, and it has been demonstrated that each of the four regions of the diagram of Doniach (1977) for the cerium compounds has a very different and characteristic behavior of the $S(T)$ curve. However, as discussed above, the boundaries between different regions are not always strictly defined and may well be changed by applying pressure or by alloying.

Moreover, four temperature parameters, $T_K$, $T_N$, $T^*$, and $\Gamma$, have been used to discuss the $S$ behavior, while the parameters of Doniach's diagram are only the first two. Thus, the descriptions given above are for the purpose of a general qualitative overview, and it is known that many exceptional cases exist.

## Rare Earth Magnets: Materials

Rare-earth permanent magnets (RPMS) are based on intermetallic compounds of rare-earth metals (R) and the transition metals iron or cobalt. The auspicious combination of properties of the rare-earth sublattice and the 3d sublattice lead to the spectacular development in hard magnetic materials: the former providing the high magnetic anisotropy, the latter the high Curie temperature and magnetization. The two most relevant classes of RPMs in application are based on (i) samarium and cobalt which exhibit very high coercivities and low temperature coefficients, and (ii) neodymium, iron, and boron which are unrivalled in terms of its maximum energy product.

In the present article a brief review will be given of these two compounds, but also of the other recently discovered hard magnetic iron-rich compounds such as $ThMn_{12}$-type compounds and the interstitial solid solutions of nitrogen and carbon in $R_2Fe_{17}$-type compounds. The most relevant intrinsic magnetic properties and micromagnetic parameters (for definition see *Hard Magnetic Materials, Basic Principles of*) of these compounds are listed in Table 1. Summaries of novel developments in manufacturing routes, with special emphasis on nanostructured magnets, will be given in the following sections.

The development of NdFeB-type alloys as starting materials for permanent magnets was triggered by both Sumitomo Special Metals (using the powder metallurgical route, Sagawa *et al.* 1984) and General Motors (employing the rapid quenching method, Croat *et al.* 1984). The usefulness of the tetragonal $Nd_2Fe_{14}B$-type compounds (see Fig. 1) led to numerous detailed investigations of the Nd–Fe–B system. Three stable ternary phases can be found: $Nd_2Fe_{14}B$ ($\Phi$), $Nd_{1+\varepsilon}Fe_4B_4$ ($\eta$), and $Nd_5Fe_2B_6$ ($\rho$). An instructive presentation of the ternary Nd–Fe–B system with low boron concentrations is given in the liquidus projection shown in Fig. 2, which marks the binary phases, ternary phases, and the important reactions (elucidated in the caption). The $\Phi$ phase is located in a region where $\gamma$-Fe is the primary solidification product.

The peritectic formation of the $\Phi$ phase at 1180 °C will be incomplete in a standard casting process as residues of primary Fe dendrites are left in the $\Phi$ grains, the latter in turn being surrounded by neodymium-rich liquid which will solidify at its eutectic temperature of 630 °C. The presence of the iron crystals is detrimental to the magnet's performance. This has important consequences for the manufacturing of this class of magnets. The analogous PrFeB-based compounds are of particular relevance for hot-deformed magnets and low-temperature applications as they show no spin reorientation down to 4.2 K (which occurs at 135 K for $Nd_2Fe_{14}B$), but have also been used more recently for melt-spun and HDDR (see *Magnets: HDDR Processed*) materials.

The intrinsic magnetic properties of the related $Nd_2Fe_{14}C$ are very similar to those of the corresponding borides: the magnetocrystalline anisotropy is slightly higher and the Curie temperature and magnetization slightly lower (see Table 1). The formation of the $R_2Fe_{14}C$ compound proceeds via a peritectoid reaction from the $R_2Fe_{17}C_2$ and RFeC phases. This solid-state transformation temperature can be increased very effectively with small boron substitutions for carbon (Eisses *et al.* 1991) and a better control of the microstructure (''ingot magnets'') compared to the NdFeB system is possible.

Unlike the $Nd_2Fe_{14}B$ phase, the hexagonal $SmCo_5$ compound (Strnat *et al.* 1967) with the $CaCu_5$ structure shows a relatively large homogeneity region in the Sm–Co phase diagram (Cataldo *et al.* 1996) as shown in Fig. 3. This region, however, becomes asymmetric when approaching the peritectic melting

***Table 1***
Structure type, intrinsic magnetic properties (Curie temperature $T_C$, anisotropy field $H_A = (2K_1 + 4K_2)/\mu_0 M_S$, anisotropy constant $K_1$, saturation magnetization $M_S$, upper limit of energy density $(BH)_{max} = \mu_0 M_S^2/4$), domain wall width $\delta_w$, and critical single-domain particle size $d_c$ of important permanent magnet compounds and for comparison α-Fe and $F_{23}B_6$ (note: cubic structure) as well as $Fe_3B$ (in-plane anisotropy).

| Compound | Structure type | $T_C$ (K) | $\mu_0 H_A$ (T) | $K_1$ (MJ m$^{-3}$) | $\mu_0 M_S$ (T) | $\mu_0 M_S^2/4$ (kJ m$^{-3}$) | $\delta_w$ (nm) | $d_c$ (μm) |
|---|---|---|---|---|---|---|---|---|
| $Nd_2Fe_{14}B$ | Tetragonal $Nd_2Fe_{14}B$ | 585 | 6.7 | 5 | 1.60 | 516 | 4.2 | 0.3 |
| $Pr_2Fe_{14}B$ | $Nd_2Fe_{14}B$ | 565 | 8.7 | 5 | 1.56 | 484 | ~4 | ~0.3 |
| $Nd_2Fe_{14}C$ | $Nd_2Fe_{14}B$ | 532 | 9.5 | | 1.41 | 396 | ~4 | ~0.3 |

The tetragonal $Nd_2Fe_{14}B$ structure (after Coey 1996).

temperature of 1292 °C. $SmCo_5$ magnets obtained by liquid-phase sintering are characterized by their high Curie temperatures and coercivities.

Commercially produced Sm–Co-type sintered magnets based on the 2:17 phase have usually a composition close to $Sm(Co, Fe, Cu, Zr)_{7.5}$. The most outstanding properties of this class of magnets are their very high Curie temperature and the low temperature coefficients of remanence and coercivity at elevated temperatures (recently up to 500 °C) in addition to their excellent corrosion characteristics. A major drawback is the use of costly Co metal. The homogeneity region of the 2:17 phase narrows with decreasing temperature and a fine cellular network of $SmCo_5$ phase precipitates from a single phase metastable precursor on appropriate low-temperature annealing (~800 °C). The cell interior with a rhombohedral 2:17 ($Th_2Zn_{17}$-type) structure shows twin boundaries in the basal plane and a so-called *platelet or z phase* rich in zirconium is also observed parallel to the basal plane.

The rhombohedral structure can be derived from the $SmCo_5$ structure by an ordered substitution of a dumb-bell of cobalt atoms for one-third of the samarium atoms. Unlike the $SmCo_5$ and $Nd_2Fe_{14}B$ magnets, which show a nucleation controlled

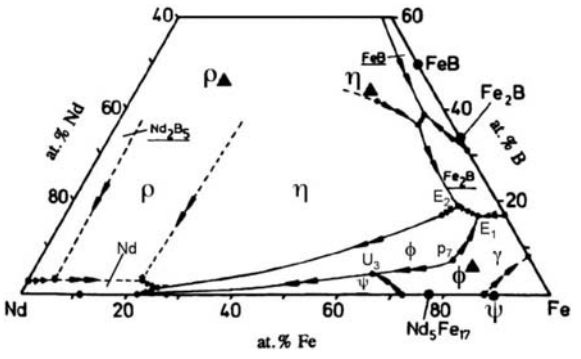

*Figure 2*
Liquidus projection of the Nd–Fe–B system. Important reactions are $p_7$ (1180 °C: L + $\gamma$-Fe $\rightarrow \Phi$), $U_3$ (1130 °C: L + $\gamma$-Fe $\rightarrow \Phi + \psi(Nd_2Fe_{17})$), $e_4$ (1115 °C: L $\rightarrow \eta + \Phi$), $E_1$ (1105 °C: L $\rightarrow \Phi$ + + $\gamma$-Fe + $Fe_2B$), and $E_2$ (1095 °C: L $\rightarrow \eta$ + $\Phi$ + $Fe_2B$) (after Knoch *et al*. 1994).

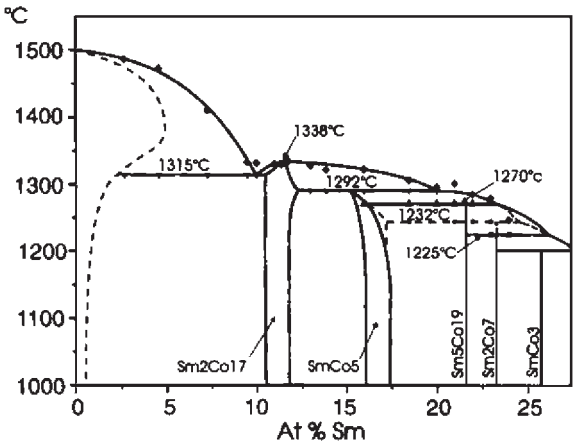

*Figure 3*
Sm–Co phase diagram (after Cataldo *et al*. 1996).

coercivity mechanism, a pinning controlled mechanism (see *Coercivity Mechanisms*) is dominant for the 2:17-type and the copper and zirconium additions are needed for an effective magnetic precipitation hardening achieved by an elaborated heat treatment. Finally, Fe addition is used in order to increase the remanence. Numerous detailed investigations on, for example, the location of the zirconium atoms in the $Th_2Zn_{17}$ structure and the sequence of solid-state transformations on aging have been carried out (see Ray and Liu 1992, Kumar 1988).

Interstitial nitrogen or carbon in rhombohedral $R_2Fe_{17}$ ($Th_2Zn_{17}$ structure) compounds changes the magnetic properties dramatically because not only the Curie temperature is increased due to the lattice expansion (in the case of nitrogen in $Sm_2Fe_{17}$ a 6% volume expansion and an increase in $T_C$ from 116 °C to 476 °C are observed) but also the crystalline electric field created by the nitrogen or carbon atoms, which occupy the large interstitial 9*e* sites, changes the magnetocrystalline anisotropy from easy-plane to easy-axis (Coey and Sun 1990). The corresponding $R_2Fe_{17}Z_x$ ($0 \leqslant x \leqslant 3$) nitrides and carbides are, in contrast to the binary $R_2Fe_{17}$ compounds, promising candidates for permanent magnetic materials. Ternary carbides $R_2Fe_{17}C_x$ ($x \leqslant 1.5$) can be prepared by standard casting techniques, higher carbon concentrations can be achieved by either substituting gallium for part of the iron in cast materials or by exposing fine particles of the binary compound to hydrocarbon gases at elevated temperatures (Skomski *et al*. 1995, Fuji and Sun 1995).

Similarly, a simple gas-phase nitrogenation can be carried out at 1 bar nitrogen gas and temperatures of about 400–500 °C. The absorption of nitrogen atoms takes place once the temperature is high enough to overcome the activation energy for the absorption process. This gas–solid reaction consists of adsorption of the gas molecules, their dissociation and subsequent chemisorption of, for example, nitrogen atoms, and long-range diffusion into the metal matrix. A detailed understanding of this irreversible nitrogenation process is necessary in order to optimize the final magnetic properties. It is still a matter of discussion whether in a thermodynamic equilibrium a solid solution or ternary nitrides with fully nitrided and nonnitrided layers are obtained. The relatively slow diffusion of the nitrogen atoms into the matrix makes it necessary to use fine ground particles.

Microcracks and grain boundaries provide fast diffusion paths so that shorter annealing times and lower temperatures can be used. However, the latter remain critical processing parameters as a decomposition in RN and Fe is the preferred reaction from a thermodynamical point of view. Long-range diffusion of metal atoms is required for this reaction and insufficient kinetics make the preparation of ternary nitrides possible despite the metastability of the latter compared to the binary nitride and iron metal. The limited thermal stability of the ternary nitrides restricts the applicability of this class of compounds to metal or polymer bonded magnets. The decomposition temperature can be increased by additions such as silicon or gallium and generally it can be stated that the carbides are superior to the nitrides in terms of their thermal stability. Very small grain sizes are needed for highly coercive powders and the appropriate processing routes have been reviewed by Müller *et al*. (1996).

The tetragonal Fe-rich $RFe_{12-x}M_x$ compounds ($ThMn_{12}$ structure) with M = Ti, V, Cr, and Mo, etc., are another family of materials with potential for permanent magnet applications. Their magnetocrystalline anisotropy is once again determined by the superposition of the Fe and R sublattice anisotropies.

The contribution of the Fe sublattice has the same magnitude as in the $Nd_2Fe_{14}B$ compounds and favors the tetragonal *c*-axis as the magnetically easy direction. But the crystal field-induced R sublattice anisotropy differs in sign and magnitude leaving only samarium as a suitable R element because for the other R elements either the *c*-axis is not favored or an antiparallel coupling to the Fe sublattice is observed.

$SmFe_{12-x}M_x$, magnetically hardened by melt-spinning or mechanical alloying (see *Magnets: Mechanically Alloyed*) shows high coercivity and Curie temperature but the remanence is somewhat low compared to $Nd_2Fe_{14}B$. Interstitial nitrogen, introduced using analogous procedures as described above, leads to a sign reversal of the R sublattice anisotropy and thus, of the second-order crystal field parameter. The consequence is that now the samarium-based compounds show easy-plane and the neodymium-based compounds easy-axis magnetocrystalline anisotropy. Nitrogen charging is limited to one nitrogen atom per formula unit and good results have been obtained for $Nd_{10}Fe_{75}V_{15}N_x$ (Wang *et al*. 1992). For more details the reader is referred to reviews by Buschow (1991, 1997) and Fuji and Sun (1995).

The monoclinic structure of the $R_3(Fe,M)_{29}$-type compounds can be described as alternating stack of 1:12 and 2:17 units which also present modifications of the $CaCu_5$ structure (e.g., Yang *et al*. 1994). Again, an enhancement of the Curie temperature, saturation magnetization, and a change to easy-axis magnetocrystalline anisotropy is observed upon nitrogenation. In terms of practical use the $Sm_3(Fe,V)_{29}N_4$ material appears to be most promising, having an anisotropy field and Curie temperature higher than $Nd_2Fe_{14}B$ and a slightly lower saturation at room temperature (Hu *et al*. 1996).

Finally, the interesting group of materials with the hexagonal $TbCu_7$-type structure (derived from the $Th_2Zn_{17}$ structure but without long-range ordering) is worth mentioning. These metastable compounds can be prepared by nonequilibrium processing and it has been reported that, for example, zirconium substitution for the rare-earth atom facilitates the formation of this structure and the hard magnetic properties are dramatically improved upon nitrogenation (e.g., $(Sm_{0.75}Zr_{0.25})(Fe_{0.7}Co_{0.3})_{10}N_x$, Sakurada *et al*. 1996).

In the twentieth century, the $(BH)_{max}$ doubled approximately every 12 years (see *Hard Magnetic Materials, Basic Principles of*). Nowadays about 90% of the limit for the energy density $(BH)_{max}$ (based on the $Nd_2Fe_{14}B$ phase) can be achieved in commercially produced sintered Nd–Fe–B grades (see *Magnets: Sintered*). At the end of 2000, however, it appeared that the search for novel hard magnetic compounds, helped by a basic understanding of the crystal field parameters, had somewhat stagnated and no further breakthrough is in sight. On the other hand, only a small number of ternary and quaternary systems has been investigated so far.

## Single-molecule Magnets

Molecular objects containing a large, but finite, number of magnetic centers whose magnetization relaxes slowly at low temperature are commonly called single-molecule magnets (SMMs) (Aromi *et al*. 1998). In a sense this is a misnomer, because the term magnet must rigorously apply only to systems in which the spin correlation length diverges, i.e., goes to infinity, and this is clearly not possible in a cluster with a finite size. However, the term is evocative, and it can be used, provided its true meaning is understood.

The first compound to show SMM behavior (Sessoli *et al*. 1993) was $[Mn_{12}O_{12}(CH_3COO)_{16}(H_2O)_4].4H_2O$ (Mn12Ac), which has a ground $S=10$ state and a large Ising-type anisotropy. The barrier for the reorientation of the magnetization is $\sim$65K, as shown in Fig. 1. The discrete levels in the potential wells are a clear indication of the quantum nature of the system. Classically the reorientation of the magnetization can occur by overcoming the barrier, and indeed below 15K the relaxation time of the magnetization becomes very long: at 1.5K it is 40 years. Therefore, Mn12Ac behaves like a bulk magnet and shows magnetic hysteresis as shown in Fig. 2. At zero field the magnetization may be either positive or negative, depending on the history of the sample.

Therefore, the SMM is bistable, and in principle it becomes possible to store information in one single molecule. Further, the hysteresis shows quantum effects (Friedman *et al*. 1996, Thomas *et al*. 1996) associated with the small size of the molecule. In fact the magnetization of a quantum object can reorient itself also by tunneling below the barrier. Evidence for this behavior is provided by the hysteresis loop of Fig. 2. In fact the flat regions in the hysteresis curve correspond to slow relaxation of the magnetization while the steps correspond to comparatively faster relaxation. The steps occur at $H_i=0.4$ T, where $i=0,1,\ldots$. At zero field, pairs of $\pm M$ levels, as depicted in Fig. 1, have the same energy: under these conditions tunneling is possible, and the relaxation time of the magnetization becomes comparatively fast. When a field is applied the levels change their energies and the degeneracy is lost, quenching the tunneling and lengthening the relaxation time. Since some of the levels increase their energies, and others decrease, at some given field pairs of levels will again become degenerate, allowing tunneling and shortening the relaxation time. The fields at which the crossings occur can be calculated once the energies of the levels are known in zero field, and they compare very well with the $H_i$ fields defined above.

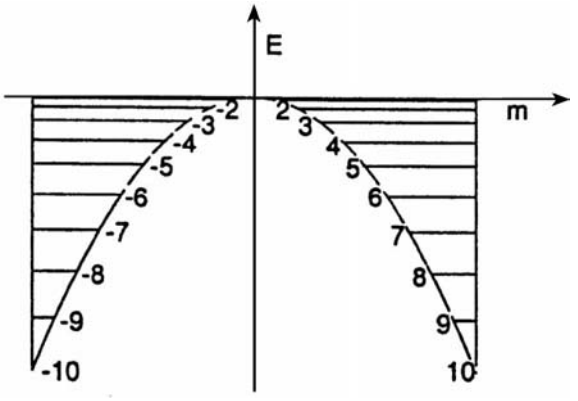

*Figure 1*
Energy levels and anisotropy barrier of the ground $S=10$ state of Mn12Ac. The levels are labeled by the $M$ component of the total spin $S$ ($-M\leqslant S\leqslant M$).

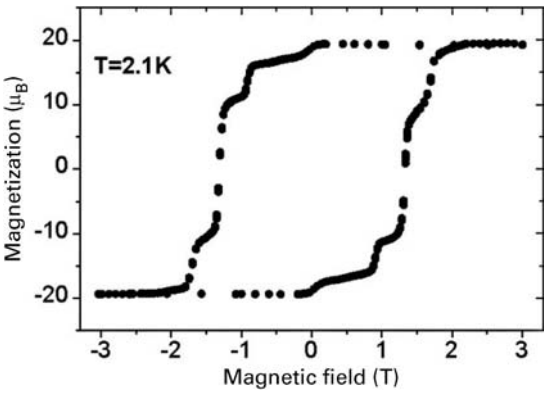

*Figure 2*
Magnetic hysteresis of a single crystal of Mn12Ac at 2.1K. The magnetic field is parallel to the tetragonal axis of the cluster.

The tunneling mechanism described above is a thermally activated one, in the sense that it does not occur within the lowest $M=\pm 10$ levels, but between higher $M$ levels which are thermally populated. In order to observe tunneling a transverse field is needed, which effectively couples the pairs of resonating levels. Mn12Ac has crystal-imposed tetragonal symmetry; therefore only hexadecupolar transverse anisotropy is allowed. Therefore, it is very small and the tunneling process is rather inefficient. In fact at low temperature, where only the lowest $M=\pm 10$ levels are thermally populated, no unambiguous evidence of direct tunneling is found and the relaxation time is very long. Matters have been found to be different in another cluster characterized by an $S=10$

ground state, $[Fe_8(tacn)_6O_2(OH)_{12}]Br_8$ (Fe8). Like Mn12Ac, the cluster also has Ising-type anisotropy, but with a non-negligible transverse quadrupolar anisotropy (Barra *et al*. 1996). The barrier is smaller than in Mn12Ac, $\sim$25K, and the relaxation times are shorter. Below 300mK the relaxation time of the magnetization becomes independent of temperature showing that the pure tunneling regime is achieved for this system (Sangregorio *et al*. 1997).

The detailed mechanism of tunneling is still a matter of debate, but magnetic nuclei, through the so-called hyperfine interaction, are expected to play an important role. Experiments in which the nonmagnetic nuclei of iron are substituted by the magnetic $^{57}$Fe, $I = 1/2$, show that the relaxation rate of the magnetization increases in the quantum regime, confirming that the magnetic nuclei are needed to assist the tunneling. A further confirmation came from a partially deuterated sample in which the relaxation time became longer, in agreement with the lower magnetism of deuterons compared to protons.

The main advantages of SMMs compared with other types of magnetic nanoparticles is that they are absolutely monodisperse, all identical to each other, perfectly known from crystal structure data, and their properties can be fine-tuned through the techniques of molecular chemistry. They have allowed for the first time the observation of quantum phenomena in mesoscopic matter that had been long looked for but had not been unambiguously proved experimentally. Beyond the quantum tunneling effects described above these systems have provided for the first time a confirmation of the Berry phase in magnets (Wernsdorfer and Sessoli 1999). This effect, which is similar to the Aharonov–Bohm effect in conductors, had been suggested to be operative in magnets (Garg 1998) but could not be confirmed until Fe8 became available. Therefore, SMMs can indeed provide a rich new physics, at the border between quantum and classical approaches.

In perspective, SMMs might be considered for applications in memory storage. Further, if the conditions for observing quantum coherence are met, they might be used for hardware for quantum computers. The other developments to be expected are the synthesis of larger clusters, which will be investigated for a large number of different properties, which can make them appealing for biocompatibility (for magnetic resonance imaging contrast agents, for instance, or for magnetic drug delivery).

The conditions for obtaining more efficient SMMs, i.e., systems operating at higher temperatures, are reasonably well understood. It is necessary to have molecules with $S$ values as high as possible in the ground state, with a high Ising-type magnetic anisotropy. In order to reach this goal it would be preferable to assemble individual magnetic centers with a large spin, like iron(III) or manganese(II) ($S = 5/2$), and manganese(III) or iron(II) ($S = 2$). In order to have high magnetic anisotropy it is useful to start from anisotropic centers. This can be achieved, for instance, by using Jahn–Teller distorted ions like manganese(III). Many attempts are being made to synthesize larger clusters that match these requirements. Some success has been achieved, not only by making obvious chemical variations on the Mn12Ac and Fe8 molecules, but also looking for new systems. This has been achieved using other metal ions, like nickel(II), chromium(III), and vanadium(III). It must be stressed that, although it may be easier to reach high-spin states starting from individual large spins, organic approaches can also be used. Several high-spin molecules have been obtained in this way, though with small anisotropy. However, if efficient strategies are developed for synthesizing large polymers, then the organic approach might turn out to be rewarding.

## Solids, Nuclear Magnetic Resonance of

The nuclear magnetic resonance (NMR) phenomenon was discovered in the mid-twentieth century. At about the same time, two different research groups showed that when samples were placed in a strong, homogeneous magnetic (applied) field, the sample could absorb and emit radiofrequency (RF) energy (Purcell *et al*. 1946, Bloch *et al*. 1947). A solid

material (paraffin) was one of the first samples used in the measurement of nuclear magnetic resonance; however, a wide resonance linewidth prevented any detailed interpretation of the spectra. Researchers quickly realized liquid samples provided substantially improved spectral resolution. With liquid samples and improvements in instrumentation that quickly followed, the chemical shift was discovered, along with the discovery of scalar (spin–spin or "through-bond") coupling. Chemical shifts are small perturbations of the exact resonance frequency of a given nucleus caused by differences in the electronic environment of the individual nuclei. Usually very small, chemical shifts are typically measured in parts per million (ppm) relative to the resonance position of some standard. Magnetic nuclei that share common electrons can couple with each other, giving rise to scalar coupling. This spin–spin coupling gives rise to fine structure (splittings) of the resonances of the nuclei involved. Of course, the discovery of these two NMR perturbations provided chemists with a powerful technique for obtaining structural information on liquid samples. In a short time commercial instrumentation was made available to chemists for the study of liquid or solution samples. Many experiments were developed which exploited chemical shifts and scalar coupling to obtain detailed structural information. NMR of solids was left to a relative few NMR research laboratories.

Work in this area was difficult and slow going, owing to enormous sensitivity and resolution problems caused mainly by two factors. First, magnetic nuclei in solid samples interact with each other through their magnetic dipole moments. This dipolar, through-space interaction can be much stronger than the through-bond, scalar interactions. The strength of the dipolar interaction is proportional to

$$\frac{3\cos^2\theta}{r^3} \tag{1}$$

where $\theta$ is the angle between a vector connecting the two interacting nuclei and the applied field, and $r$ is their interatomic distance. Thus, the exact resonance position of any nucleus depends on the position of the neighboring magnetic nuclei relative to the applied field direction. The exact magnetic field experienced by any particular nucleus will vary from molecule to molecule in any sample which is less than a perfect single crystal. These dipole–dipole interactions make it impossible to observe abundant spins (like protons) at high resolution in a solid by conventional NMR techniques. Usually, proton linewidths are broadened so all fine structure is hidden. In liquids however, rapid tumbling quickly averages Eqn. (1) over all possible values of $\theta$, effectively zeroing the dipolar effect.

A second possible source of broadening in solids is another orientation effect and is caused by the electronic environment of nuclei. Electrons near a nucleus shield it from the applied field causing slight perturbations in the resonance positions. This effect gives rise to the chemical shift, the most important perturbation of the magnetic resonance interaction. Electron density, however, may not be homogeneously distributed about a nucleus. In those cases where the electron density is not homogeneous about a nucleus, there will be an orientation dependence of the shielding. This results in another broadening effect in randomly oriented solids called chemical shift anisotropy (CSA). So, in a solid where the molecules are randomly oriented, chemical shifts (both the isotropic and anisotropic parts) and dipolar interactions with other nuclei cause resonance lines to broaden and overlap. (This broadened spectrum is actually made up of many narrower lines at slightly different chemical shifts due to these orientation effects.) For a more formal discussion of these effects see Yannoni (1982). Pines *et al.* (1973) published their discovery that nuclear magnetization could be transferred from an abundant higher spin, $I$, to a rare lower spin, $S$, in solid samples through a technique they called cross-polarization (CP).

An initial 90° pulse on the abundant spins is followed immediately by a strong RF field parallel (or antiparallel) to the abundant spin magnetization. This parallel RF field prevents the sample abundant spin magnetization from returning to its equilibrium position and this is called a "spin lock." Magnetization then transfers to the rare spins by simultaneously applying a RF field to these rare spins, which meets the Hartmann–Hahn condition (Hartmann and Hahn 1962):

$$H_I\gamma_I = H_S\gamma_S \tag{2}$$

where $\gamma$ is the magnetogyric ratio and $H$ is the applied field strength of the spins. In the absence of any relaxation, the magnetization of the rare spins is enhanced by a factor of $\gamma_I/\gamma_S$ beyond the magnetization expected for a conventional NMR experiment (a simple 90° pulse). During this CP contact time, the rare spin magnetization grows at an exponential rate characterized by the time constant $T_{IS}$ (curve (a) of Fig. 1). Relaxation effects will diminish this enhancement factor. As CP progresses, magnetization is exponentially decaying in a time characterized by $T_{1\rho}$ (curve (b) of Fig. 1). As long as $T_{1\rho} > T_{\mathrm{CP}}$, the observed enhancement as a function of CP time, $t$, is just

$$\frac{\exp\left(-\frac{t}{T_{1\rho}}\right) - \exp\left(-\frac{t}{T_{\mathrm{CP}}}\right)}{1 - \frac{T_{\mathrm{CP}}}{T_{1\rho}}} \tag{3}$$

(curve (c) of Fig. 1).

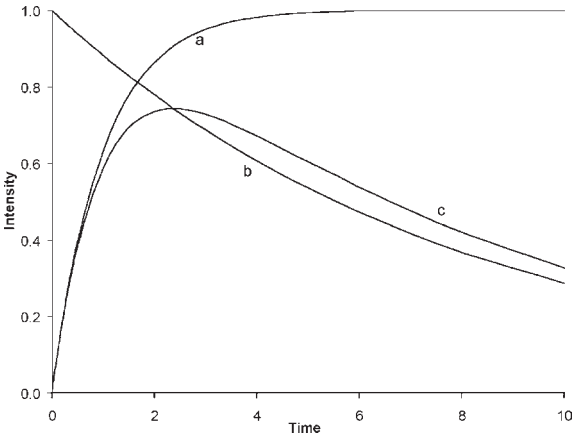

***Figure 1***
The theoretical CP dynamics are shown. Curve (a) illustrates the expected rare spin magnetization as a function of CP time in the absence of relaxation effects. The single exponential curve is characterized by a time constant, $T_{IS}$, the CP time. Curve (b) represents spin (either rare or abundant) relaxation. The exponential curve is characterized by a time constant, $T_{1\rho}$, which in this specific example is eight times the CP time constant. Curve (c), which is the expected rare spin magnetization as a function of CP time, is the combination of curves (a) and (b). The time axis is in units of $T_{IS}$ while the enhancement axis is in units of $\gamma_I/\gamma_S$, the theoretical maximum. Notice that for this example, maximum enhancement is achieved at a CP time of about $2.38 \times T_{IS}$ and is about 74% of the theoretical maximum.

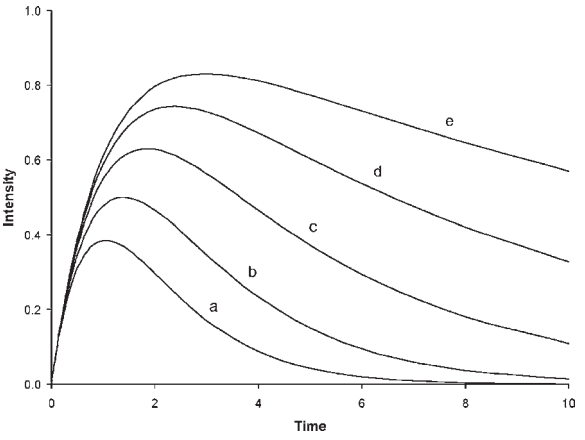

***Figure 2***
A family of curves showing the CP magnetization as a function of CP time. In each curve $T_{IS}$ is constant and $T_{1\rho}$ is varied. The ratio $T_{1\rho}/T_{IS}$ for each curve is: (a) 1.1, (b) 2.0, (c) 4.0, (d) 8.0, and (e) 16.0. Axis units are as in Fig. 1.

***Table 1***
The time of occurrence and the value of the maximum enhancement of CP for various values of $T_{1\rho}/T_{IS}$.

| $T_{1\rho}/T_{IS}$ | $t_{max}/T_{IS}$ | Enhancement[a] (%) |
|---|---|---|
| 1.1 | 1.05 | 38 |
| 2.0 | 1.39 | 50 |
| 4.0 | 1.85 | 63 |
| 8.0 | 2.38 | 74 |
| 16.0 | 2.96 | 83 |

a The enhancement is a percentage of the theoretical maximum, $\gamma_I/\gamma_S$.

As Fig. 2 and Table 1 illustrate, this relaxation effect can have a significant effect on the observed enhancement. It follows from Eqn. (3) that maximum enhancement is at a CP time of

$$\frac{\ln\left(\frac{T_{1\rho}}{T_{CP}}\right)}{\frac{1}{T_{CP}} - \frac{1}{T_{1\rho}}}$$

Besides this potential enhancement in magnetization, and therefore signal strength, CP offers another benefit: the CP process can be repeated after the abundant spin relaxes, irrespective of the state of the rare spin magnetization and/or relaxation rate. Of course, this is because the rare spin magnetization is totally derived from the abundant spins. Pines *et al*. (1973) also showed that a significant improvement in resolution could be achieved by decoupling the abundant spin during the acquisition of the rare spin signal. Schaefer *et al*. (1975) showed that if the CP experiment is performed while the solid sample is spinning at a sufficiently high rate (several thousand revolutions per second) at an orientation where Eqn. (1) is zero (magic-angle spinning, MAS), resolution approaching that of liquid samples can be obtained. A sample that is spinning at a rate larger than the CSA causes the CSA of each individual spin to be averaged to the isotropic chemical shift value. If the spinning rate is less than the CSA, spinning sidebands are observed. Figure 3 shows the effect of sample spinning rate on the $^{13}C$ cross-polarization magic-angle spinning (CPMAS) spectrum of General Electric Lexan (bisphenol A polycarbonate) resin. The top spectrum was obtained at high sample spinning and has minimal spinning sidebands. The bottom spectrum was obtained without sample spinning and shows broad, overlapped resonances. It can be seen from the middle spectrum, obtained at moderate spinning speeds, that the intensities of the spinning sidebands approximately mimic the shape of the nonspinning line shapes.

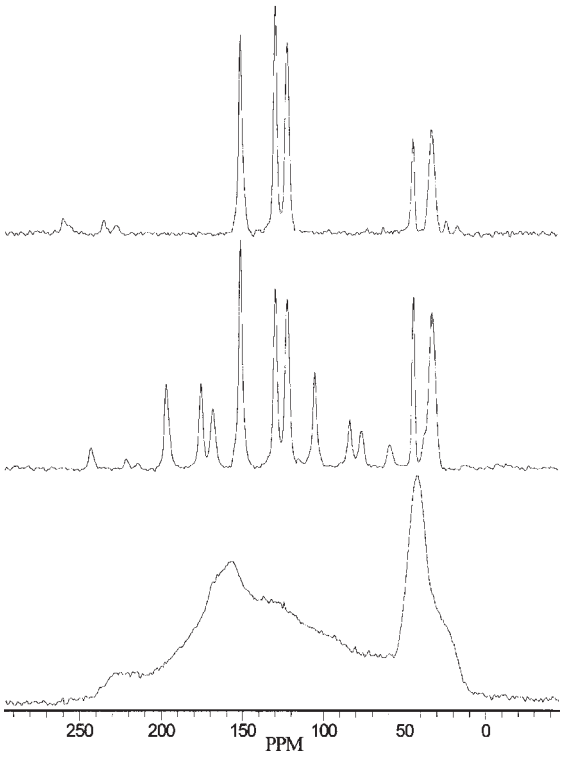

***Figure 3***
$^{13}C$ CP spectra of a sample of GE Lexan resin are shown spinning at three different rates. All spectra were obtained with a 2.5 ms CP with $\gamma_C H_C = \gamma_H H_H = 55$kHz. With the sample spinning at 7940 Hz, the top spectrum shows only minor spinning sidebands. For the center spectrum, the sample was spun at 3460 Hz and shows many sidebands. The chemical shift anisotropies of the aromatic resonances at 150–100 ppm are much larger than the aliphatic resonances at 50–20 ppm. The lower spectrum was obtained without spinning, showing overlapping resonances severely broadened by chemical shift anisotropy.

These important discoveries and the work on which they are based provide the foundation for the most popular form of high-resolution solid-state NMR, the CPMAS experiment. Conditions for the high-resolution observation of abundant spins (i.e., protons) were worked out later and combined MAS with multiple pulses during the acquisition of the signal (homonuclear decoupling) and will not be discussed in this article.

## *1. General Instrumentation*

While the requirements for CPMAS NMR are similar to those for liquid NMR, there are several important differences. Superconducting magnets provide stable, high-field, high-homogeneity applied fields for the NMR experiment. In fact, the quality of modern superconducting magnets is such that field/frequency stabilization (NMR lock) is not required. Room temperature access for the CPMAS probe is typically larger than for liquids NMR because of the special geometry and the higher RF power handling requirements, requiring physically larger electronic components. Also, due to the limited resolution of the typical CPMAS spectrum and the bulky and unusual geometry of the probe, room temperature homogeneity shim coils have only a modest impact on spectra quality and have been omitted on some solids-only NMR spectrometers.

RF field strength requirements for CPMAS NMR are typically 1–2 orders of magnitude higher than for liquid NMR resulting in power requirements ranging from almost 100 W to several kilowatts depending on the probe efficiency. The CPMAS probe is the most unique part of a solids NMR spectrometer. Several different designs are commercially available and all share the following features:

- A sample spinning system consisting of a rotor (spinner) made of a high-strength material to hold the sample. Turbine-like impellers are part of the rotor so that it may be spun by pressurized gas flowing over these features.
- A stator (spinner housing) which provides pressurized gas through a bearing surface in which the rotor will spin. The stator is mounted in the probe so that the sample spins at the magic angle (about 54.7°) relative to the applied magnetic field.
- A double-tuned RF coil (usually part of the stator) with suitable tuning circuitry to couple efficiently the high-power transmitters to the coil, resulting in the highest possible RF field strengths.

In addition, the probe may have other features such as spin rate detectors (analog or digital), spin rate controllers, or variable temperature control.

## *2. Sample Requirements*

Spectra of solid samples from a variety of sources can be successfully observed by CPMAS NMR. Obvious choices are crystalline, polycrystalline, and amorphous solids as well as plastics and liquid crystalline materials. Clathrates, inclusion complexes, composites, mixtures, melts, and other compounded materials are also possible. Powdered or granular material is easiest to spin, although anything which fits into the rotor will usually work. Physically large samples need to be reduced in size until particles are smaller than the inner dimensions of the rotor (internal diameters are typically 2–20 mm). Large particles are usually more difficult to spin and sometimes require some signal-free balancing material. With some constraints and care, spectra of highly viscous fluids and gels

(e.g., concentrated biological fluids, solutions and suspensions, and petrophysical fluids) can be run. In cases where spinning might eliminate liquid from the sample, they can be spun in special sealed or lined rotors. Materials that conduct electricity are usually not suitable for MAS. However, in some cases these samples can be spun by diluting the material with an appropriate insulator. In addition, samples which efficiently turn RF energy into heat present special problems. Because of the high RF power levels involved, an extremely low RF duty cycle is used and this usually limits the resolution of the detected signal.

## 3. Applications

In the simplest CPMAS experiment, chemical shift information of the rare spin nuclei is obtained. Alemany *et al.* (1983a) have shown that for most simple organic compounds, a 2.25 ms CP contact time will result in near-quantitative $^{13}C$ NMR intensities, making it routine to obtain reliable integration data. Quantitative results are often difficult or impossible to obtain in the case of multiphase compounds. This is especially true for engineered plastics that often are made up of at least two different components that have different physical properties, blended or bonded together to achieve a desirable physical performance.

For example, consider a silicone heat-cured elastomer that is made up of a very-long-chain, low-modulus, lightly cross-linked dimethylsiloxane polymer and a high-modulus fumed silica filler. Chemically, the fumed silica filler is submicrometer-sized amorphous silicon dioxide particles with the surface of the particles covered with hydroxide groups. The $^{29}Si$ CPMAS spectrum of a heat-cured elastomer is shown at the top of Fig. 4. The dimethylsiloxane polymer is observed as the sharp resonance at −23.5 ppm. The fumed silica is observed as two broad resonances below −100 ppm. The resonance at −113 ppm is from the amorphous fumed silica and the resonance at −103 ppm is from the surface silicon, directly bonded to the surface hydroxyl groups. Broad peaks at –21.5, −35.8, −57.2, and −66.8 ppm are due to various special methyl siloxanes found on the surface of the fumed silica. The bottom spectrum of Fig. 4 shows what is observed with a simple Bloch-decay experiment, i.e., not using CP. Because the $^{29}Si$ nuclei relax very slowly, this spectrum was acquired with very long relaxation times between acquisitions. The bottom Bloch-decay experiment more accurately represents the quantitative distribution of silicon in the sample. For this nearly quantitative spectrum, only the dimethylsiloxane polymer and fumed silica peaks are observed. The fumed silica peaks more quantitatively represent the distribution of silicon atoms between the surface and core of the fumed silica particles, with the surface peak just observable as a shoulder to the dominant core silica resonance. Owing to the limited number of acquisitions for this spectrum, the special surface methyl siloxanes cannot even be observed.

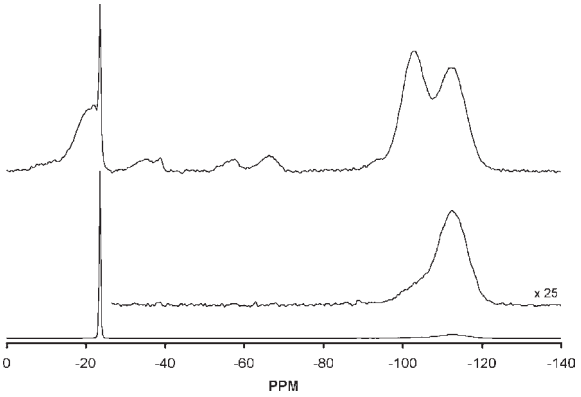

***Figure 4***
A comparison of $^{29}Si$ spectra is illustrated with and without CP for a heat-cured elastomer. The top spectrum is the CPMAS spectrum obtained with a 5 ms CP time, acquiring $10^5$ scans with a 2 s relaxation time. The bottom spectrum was obtained with a simple $^{29}Si$ 90° pulse. A 25-fold expansion of the high-field region is shown in the center. As in the CPMAS spectrum, high-powered proton decoupling was applied during the acquisition of the signal and the sample was spun at the magic angle at 7200 Hz. For this Bloch-decay spectrum, 1388 scans were acquired with a 150 s relaxation time. Each spectrum was acquired over several days.

The CP intensity for the silicon in the dimethylsiloxane polymer and the silica particles is not quantitative for different reasons. The polymer undergoes labile motion, interfering with CP from the methyl $^1H$ nuclei to the $^{29}Si$ nuclei resulting in a very long $T_{CP}$. Thus, only a very weak signal is observed from the polymer. The silica is immobile owing to the very high molecular weight and the three-dimensional structure of the resin making up the particle and should cross-polarize readily. However, the core silica resonance at −113 ppm cross-polarizes poorly because it does not have any $^1H$ nuclei nearby to provide polarization. It is not possible to obtain a quantitative CPMAS spectrum by lengthening the CP contact time. While a longer CP time would result in a stronger, more quantitative polymer resonance, the relatively short $T_{1\rho}$ of the silica would result in near-zero CP intensity from the silica. These kinds of problems are typically encountered when trying to obtain quantitative CP spectra of multiphase samples. Nonetheless, CPMAS spectra can be quite useful for these kinds of samples. In the case of the heat-cured elastomer illustrated here, the CPMAS

spectrum is very sensitive to the surface of the fumed silica and is a valuable research tool for understanding polymer–filler interactions at or near the filler surface.

While typical CPMAS resolution routinely obtained is still a couple of orders of magnitude poorer than that obtained in liquid NMR, it is usually possible to identify most chemical types of the rare spins. However, it is usually impossible to identify a unique chemical type in the presence of other similar chemical types due to the limited resolution. Successful strategies for the analysis of chemical processes in solids usually involve a comparison of the CPMAS spectra of related materials. For example, researchers have been able to deduce the chemical mechanism of the curing process of urea–formaldehyde (Maciel *et al*. 1983) and phenolic (Bryson *et al*. 1983) resins by comparing $^{13}C$ CPMAS spectra of resin samples subjected to different curing times. In the case of polymers, crystalline–amorphous morphology may be discernable through an analysis of observed line shapes. A variety of relaxation measurements can be performed in order to obtain information about molecular motion, micro- and macrostructure, and morphology. The abundant spin as well as the rare spin dynamics can be observed through the rare spin magnetization, along with the dynamics of magnetization transfer. Especially sensitive to lower frequency motions, measurement of $T_{1\rho}$ has been useful in the study of macromolecules (Belfiore *et al*. 1983).

Homonuclear decoupling technology has made available special decoupling sequences that selectively disable homonuclear dipole–dipole interactions. Applied to the abundant spins, several new solids techniques were developed. If the abundant spin dipole–dipole interaction is sufficiently weak, application of homonuclear decoupling makes it possible to observe (and use) scalar coupling between the rare and abundant spins. For example, Zilm and Grant (1982) have observed $^{13}C—^{1}H$ scalar coupling in adamantane and hexamethylbenzene. In another example, Terao *et al*. (1982) have used $^{13}C—^{1}H$ scalar coupling in camphor to obtain *j*-resolved $^{13}C$ spectra. While these and other similar results are very interesting, most solid samples do not have the required weak dipole–dipole interaction to allow the scalar coupling to be observed and/or exploited. In another more useful application of homonuclear decoupling, a two-dimensional experiment has been developed in which each rare spin becomes a sensitive probe of its local dipolar environment (Munowitz *et al*. 1981, Schaefer *et al*. 1983). In this experiment, multiple data sets are collected. In each sequential data set an evolving period of homonuclear decoupling is applied to the abundant spins before the detection of the rare spin signal. Projecting the processed data along the evolution axis shows a normal CPMAS spectrum. Slices along the evolution direction show the local dipolar field for each of the resolved nuclei. Because of Eqn. (1) and because of the rare spin resolution typically achievable, these spectra can be rich in distance and geometry information.

## 4. Limitations

While CPMAS NMR can approach the resolution of the NMR of liquids, it is typical for a CPMAS spectrum resolution to be limited to several ppm. Amorphous materials and polymers may have a distribution of isotropic chemical shifts for individual carbons due to a variety of carbon environments in the solid matrix. It has been shown that polymers that have undergone severe mechanical stress have broadened CPMAS spectra. VanderHart *et al*. (1981) have published a comprehensive study of resolution limitations of CPMAS NMR. The idea of applying continuous, unmodulated decoupling to the abundant spins during the acquisition of the NMR signal is to remove the dipolar effect of those nuclei, leaving only CSA as a source of broadening. This is difficult to achieve in practice as there is always some nonzero residual dipolar coupling. Bennett *et al*. (1995) described a simple phase modulation of the decoupling RF field that shows significant improvement over unmodulated decoupling.

The CPMAS technique relies upon the premise that equilibrium magnetization of the abundant spins is many times larger than that of the rare spins and those rare spins do not interact with each other. Systems containing rare spins that share a chemical bond present new problems. For example, a sample that contains a high enrichment of $^{13}C$ will show particularly broad carbon resonances as they interact with one another through their dipolar fields. Another more common situation that can limit resolution is the presence of quadrupolar nuclei. These nuclei orient their quadrupole moments in their molecular environment and can generate a powerful magnetic field along their quadrupole moments. This additional field adds to the applied field and modifies other spin interactions, resulting in line broadening (Naito *et al*. 1981). This effect can be minimized by increasing the applied field strength which decreases the relative contribution of the field generated by the quadrupolar nucleus (Maciel *et al*. 1983). Of course, this solution is not always available if no higher field NMR spectrometer with solid-sample capability is accessible. Even if higher field instruments are available, other complications can arise in very-high-field CPMAS NMR. As the applied field is increased, so does CSA, requiring higher sample spinning rates to obtain pure isotropic resonances and a minimum of spinning sidebands. More sidebands make spectral interpretation more difficult. When spinning rates begin to approach the magnitude of the Hartmann–Hahn RF field, this mechanical motion will begin to interfere with the CP dynamics, resulting in lower CP efficiency, until finally

no signal can be observed (Wind *et al*. 1988). In these cases, obtaining a spectrum with sample spinning sidebands is usually preferred. Alternatively, Dixon (1981) has devised a CPMAS NMR experiment to separate spinning sidebands from isotropic resonances, although this experiment may not always produce the desired results, sometimes distorting intensities due to relaxation effects.

Finally, in some cases, CP spin dynamics may not be suitable for a successful experiment. As shown in Fig. 2, if the $T_{1\rho}/T_{IS}$ ratio is too small, CP may become difficult or impossible to detect (Alemany *et al*. 1983b).

### 5. Summary

While $^{13}C$ and $^{29}Si$ CPMAS NMR was the focus of this discussion, other nuclei can be observed, including $^{15}N$, $^{119}Sn$, and $^{31}P$. It is also possible to generate CP intensity from nuclei other than $^{1}H$. For example, $^{13}C$—$^{19}F$ CPMAS spectra can be obtained for fluorinated polymers. In a number of respects CPMAS NMR is experimentally more demanding than conventional liquid NMR. However, CPMAS NMR is invaluable in the study of solids, providing both static (structural) and dynamic (motional) information. While there are some samples which cannot be studied by CPMAS NMR, this technique can be applied to a wide variety of materials, regardless of purity, crystallinity, or other physical attributes.

## Spin Fluctuations

### 1. Introduction

In general, the term spin fluctuations refers to fluctuations of the magnetic (electron spin) moment in magnetic systems, both ordered and paramagnetic ones. In the ground state (zero temperature, zero

applied magnetic field $H = 0$) of a ferromagnetic system of local moments, for instance, all moments are oriented in the same direction. Above a critical temperature, the Curie temperature $T_C$, the system is paramagnetic. At low temperatures, the excitations from the ground state can well be described as spin waves or magnons, that is, as independent collective excitations obeying Bose–Einstein statistics. With increasing temperature ($T$), the absolute value of the ''long-time averaged'' magnetization ($\boldsymbol{M}$) decreases as $M = M_0 - \alpha T^{3/2}$ (Bloch's $T^{3/2}$ law). The local, momentary magnetization, $\boldsymbol{M}_l(\boldsymbol{r})$, i.e. the short-time average over a small volume around $\boldsymbol{r}$, is written as $\boldsymbol{M}_l(\boldsymbol{r}) = \boldsymbol{M} + \boldsymbol{m}_l(\boldsymbol{r})$, where $\boldsymbol{m}_l(\boldsymbol{r})$, or simply $\boldsymbol{m}(\boldsymbol{r})$, represents the random, time-dependent deviation, or fluctuation. The components along the direction of $\boldsymbol{M}$, chosen as the $z$ direction, $m_z(\boldsymbol{r})$, are referred to as ''longitudinal'' fluctuations, the components in the $xy$-plane, $m_x(\boldsymbol{r})$, $m_y(\boldsymbol{r})$, as ''transverse'' ones. In this temperature range, the transverse fluctuations can be described either as spin fluctuations or equivalently as magnons. The length scale, over which averaging can be performed without blurring out the deviations, is determined by the so-called ''correlation length.'' With increasing temperature, apart from the fact that the spin waves can no longer be considered as independent excitations, the magnitude and the correlation length of the fluctuations increase. In the neighborhood of the transition temperature, the critical fluctuations are dominant, and the correlation length tends to infinity. In this ''critical region,'' ''renormalization group'' techniques can be applied, leading to the so-called ''scaling laws.'' At still higher temperatures, the correlation length gradually decreases down to an atomic scale. The system then behaves as a collection of independent local atomic moments.

For some specific models (e.g., the Ising model), spin fluctuations can be visualized by computer simulation (see, e.g., http://www.physics.cornell.edu/sss/Ising/Ising.html).

The behavior of spin fluctuations in an itinerant-electron band system is qualitatively the same. In the paramagnetic state, the fluctuations (heavily damped collective excitations) were originally called ''paramagnons.'' A large effect of spin fluctuations is expected for strongly enhanced paramagnets (on the verge of becoming magnetically ordered, see next section). If, moreover, the number of electrons (or holes) in the itinerant band is low, at high temperatures the fluctuations may effectively cause the (local) band to be (momentarily) fully polarized. Then, the system even roughly behaves as a system of local moments. This is illustrated in Fig. 1, showing the resistivity of the strongly enhanced paramagnets Pd, Np, and Pu, as analyzed by Jullien *et al.* (1974). The spin fluctuation contribution is obtained by subtracting the resistivity of a suitable, ''normal'' metal (Ag in the Pd case, Th for Np and Pu). In local-moment systems, the ''spin disorder scattering'' is saturated at high temperatures. Evidently, such saturation may occur in itinerant-electron systems as well. Jullien *et al.* fitted the calculated spin fluctuation contribution by fitting the spectrum of the fluctuations with wave vector $\boldsymbol{q}$ and frequency $\omega$, i.e. of the dynamical susceptibility $\chi(\boldsymbol{q},\omega)$, applying the ''fluctuation – dissipation'' theorem.

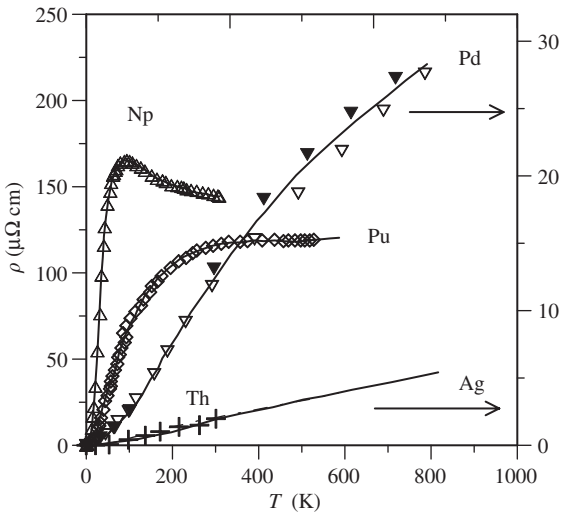

***Figure 1***
The resistivity of Pd, Np, and Pu as a function of temperature. The solid lines through the data points show the sum of the calculated spin fluctuation contribution and an experimentally determined, suitable ''nonmagnetic'' background (Ag for Pd and Th for Np and Pu; notice the difference in scales, chosen such that the background contributions coincide). For data and details, see Jullien *et al.* (1974).

This theorem is applied in most of the sophisticated spin fluctuation models, indeed. Each mode, $(\boldsymbol{q},\omega)$, behaves as a harmonic oscillator obeying Bose–Einstein statistics. Consequently, one may distinguish zero-point fluctuations (or quantum fluctuations) and thermal fluctuations. The different models are based on different approximations for the quantum fluctuations (as being dependent on the magnetization, for instance), for the change-over from spin wave behavior at low temperatures to fluctuating behavior at higher temperatures, for the necessary cut-off wave vector in the spectrum, for the difference between longitudinal and transverse fluctuations, and so on.

The occurrence of spin fluctuations is by no means restricted to simple ferromagnetic materials. They play an important role in antiferromagnetic and ferrimagnetic materials as well. The interplay of local (rare-earth) moments and an itinerant-electron matrix may enhance the effect of spin fluctuations (see, e.g., Duc and Brommer (1999) for details). In

magnetic perovskites (manganites, cobaltates) magnetic order may compete with charge order, giving rise to a very rich phase diagram. Spin fluctuations can play a decisive role in this competition. In high-$T_C$ superconductors, spin fluctuations are supposed to provide the necessary "glue" for electron pairing, playing the role of the phonons (lattice distortions, electron–phonon coupling) in the more conventional superconductors. In strongly correlated electron systems and Kondo systems, at low temperatures a collective (excited) state may be formed, giving rise to spin fluctuations too. At the so-called spin fluctuation temperature, the collective state is destroyed and the particular fluctuations do not play a role any more.

Nevertheless, here attention will be focused on itinerant-electron systems, mainly because the interest in spin fluctuations started with a long-standing controversy about the relative importance, in these systems, of, on the one hand, collective spin fluctuations and, on the other hand, independent single-particle excitations.

## 2. *Free-energy Considerations*

In the Landau theory of second-order phase transitions (see *Phase Transitions, Landau Theory of*), the free energy is expanded as a function of the order parameter, here the magnetic moment $M$:

$$F_{\text{magn}} = \frac{1}{2}AM^2 + \frac{1}{4}BM^4 + \cdots \frac{1}{6}CM^6 + \cdots \qquad (1)$$

In the Stoner–Edwards–Wohlfarth (SEW) model for itinerant electrons (see, e.g., Brommer and Franse 1990, and references therein), one takes $A = A_b - \lambda$, where $A_b$, like $B$ and $C$, depends on the band parameters, and where $\lambda$ represents the exchange energy $-(1/2)\lambda M^2$. The equilibrium condition $\partial F_{\text{magn}}/\partial M = \mu_0 H$ leads to

$$\mu_0 H = AM + BM^3 + CM^5 + \cdots \qquad (2a)$$

or, written in the "Arrott–Kouvel" form

$$\mu_0 H/M = A + BM^2 + CM^4 + \cdots \qquad (2b)$$

### 2.1 *Arrott Plots*

For very weak itinerant ferromagnets (VWIF), the $M^4$ term is ignored ($B>0$, for stability). As an example, some $M^2$ versus $\mu_0 H/M$ plots, so-called Arrott plots, are shown for $Ni_{42.9}Pt_{57.1}$ in Fig. 2. The deviations from the straight lines, at low $M^2$ and $\mu_0 H/M$ values, are ascribed to concentration variations (see Brommer and Franse 1990). Such straight Arrott plots were often considered as proof for a negligible spin fluctuation contribution.

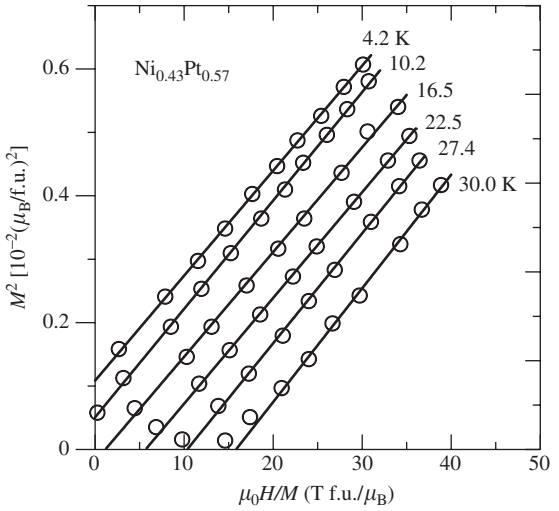

***Figure 2***
Arrott plots for $Ni_{0.43}Pt_{0.57}$. The straight lines represent the equation of state (Eqn. (2b)) $\mu_0 H/M = A + BM^2$ (for data and details see Brommer and Franse 1990, p. 352).

Spontaneous order ($M \neq 0$ for $H = 0$) occurs when the Landau coefficient $A$ is negative, with $M^2 = -A/B > 0$. When $A$ is positive, the system is paramagnetic, and $A$ is the inverse initial susceptibility. Applying Fermi–Dirac statistics for the independent, single-electron excitations, the temperature dependence of the "Landau co-efficients" $A$, $B$, $C$, and so on, can be determined. In the simplest model (see, e.g., Shimizu 1981 or Brommer and Franse 1990 for a much more elaborate approach), only $A_b$ is taken to be temperature dependent:

$$A_b(T) = A_b(0)(1 + T^2/T_F^2) \qquad (3)$$

For a simple itinerant-band structure with Fermi level $E_F$, $T_F$ is a temperature in the order of the Fermi temperature $E_F/k_B$.

### 2.2 *Stoner Enhancement*

The exchange interaction enhances the paramagnetic susceptibility by the "Stoner enhancement" factor $S$, defined as

$$S = A_b(0)/A(0) = A_b(0)/[A_b(0) - \lambda] = 1/(1 - \bar{I}) \qquad (4)$$

The last equality expresses the enhancement factor conventionally as a function of the Stoner parameter $\bar{I}(= \lambda/A_b(0) = N(E_F)I)$, where $N(E_F)$ is the density of states at the Fermi level of the itinerant band (recall that the Pauli susceptibility $A_b(0)^{-1}$ is proportional to this density of states). $I$ is again a measure for the exchange interaction. Since the unenhanced

inverse (Pauli) susceptibility $A_b$ is positive, the system can only become ferromagnetic for a positive $\lambda$ of sufficient magnitude. Note that for an itinerant ferromagnet $S$ is negative ($\bar{I}>1$: the Stoner criterion). Since $A_b(T)$ increases with increasing temperature, the first Landau coefficient in the Stoner model, $A_{St}(T) = [A_b(T) - \lambda] = A_b(0)(1 - \bar{I} + T^2/T_F^2)$ will eventually change sign, and the system becomes paramagnetic (see also Eqn. (7), next section).

### 2.3 Incorporating Spin Fluctuations

In a simplified version of the Moriya (1985) "self-consistent renormalization" (SCR) treatment of the spin fluctuations, the terms $M^{2n}$, in Eqn. (1), are replaced by $\langle |\boldsymbol{M}_l(\boldsymbol{r})|^{2n} \rangle = \langle |\boldsymbol{M} + \boldsymbol{m}(\boldsymbol{r})|^{2n} \rangle$. Taking the spatial average ($\langle\ \rangle$) in the homogeneous case, and omitting higher-order terms, one finds for the coefficient of the $M^2$ term:

$$\begin{aligned} A(T) &= A_{St}(T) + B(3m_z^2 + m_x^2 + m_y^2) \\ &= A_{St}(T) + (5/3)B\,m^2(T) \end{aligned} \qquad (5)$$

The second equality holds for an isotropic system near $T_C$, with $m_z^2 = m_x^2 = m_y^2 = m^2(T)/3$.

In the VWIF system under consideration, the spin fluctuation term in Eqn. (5) is positive, and consequently the change of sign will occur at a lower (Curie) temperature. This explanation for the apparent low Curie temperatures of the itinerant-electron systems was a great success of the spin fluctuation theory (see next section).

Band parameters (and thus the Landau co-efficients $A_{St}$, $B$,…) can be deduced from band calculations with still increasing accuracy. The necessity to consider also the spin fluctuations is clearly demonstrated by Aguayo *et al.* (2004) in a comparison of the "prototype" itinerant-electron systems $Ni_3Al$ and $Ni_3Ga$. Since both systems are Ni-based, the exchange parameter $\lambda$ or $I$ will be about the same for these compounds. The density of states is larger in $Ni_3Ga$. Hence, one would expect $Ni_3Ga$ to be the more enhanced (or more ferromagnetic) compound (because $\bar{I} = N(E_F)I$ is larger in Eqn. (4)). The opposite is true. Now, according to their calculations the $q$-dependence of the dynamic susceptibility is weaker in $Ni_3Ga$. Consequently, there are more spin fluctuations, and the positive contribution to $A(T)$ will be larger (see Eqn. (5)). In fact, $Ni_3Ga$ even remains paramagnetic down to 0 K!

### 2.4 Magnetovolume Effects

Differentiating the magnetic free energy (Eqn. (1)) yields the "magnetic pressure" $P_m$ as

$$VP_m = \frac{1}{2}A_\omega M^2 + \frac{1}{4}B_\omega M^4 + \cdots$$

where, $A_\omega = \partial \ln A(V,T)/\partial \ln V$, and analogously. Henceforth, the volume dependence of $B$ (and higher Landau co-efficients) will be ignored. Incorporating the spin fluctuations, one finds the (relative) "magnetic volume" $\omega_m = V_m/V$ as

$$\omega_m = -\kappa P_m = -\frac{1}{2}(\kappa A_{St,\omega}/V)[M^2 + m^2] \qquad (6)$$

where, $\kappa$ is the compressibility. The magnetic volume is proportional to $[M^2 + m^2]$, so there will be a contribution even in the paramagnetic state ($M = 0$).

### 2.5 Metamagnetic Transitions

In the Laves phase $RCo_2$ type compounds (R: rare earth, Y), the Co 3d-subsystem is a metamagnetic, itinerant-electron system. For $YCo_2$, an applied magnetic field exceeding $\sim 70$ T induces a jump of the Co moment up to $\sim 0.5\,\mu_B$/Co. Substitution of Al for Co stabilizes this "high-spin" state. $Y(Co_{1-x}Al_x)$ is paramagnetic for $x = 0.075$, but the moment jumps to $\sim 0.6\,\mu_B$/Co at the metamagnetic transition field of 33 T (see upper panel of Fig. 5). This behavior can be described by the free-energy expression, Eqn. (1), when the Landau coefficient $A$ is positive, whereas $B$ is negative, and $C$ is again positive for stability (see dashed fitting curve in Fig. 5; see also further discussion in Sect. 4).

According to Eqn. (5), in such a system with $B<0$, the spin fluctuation contribution in $A(T)$ would be negative, so would promote the transition. Stability criteria have been discussed extensively by Yamada *et al.* (2003). The order parameter ($M$) in Eqn. (1) can be taken to be the amplitude of the relevant antiferromagnetic ordering mode (staggered magnetization). So, the formalism can be applied to antiferromagnetic systems too. For $T > T_N$ ($\approx 100$ K), $YMn_2$ is an itinerant-electron paramagnet in which the Mn atoms have no magnetic moment. For $T < T_N$, the Mn subsystem becomes antiferromagnetic, with a large moment ($2.7\,\mu_B$/Mn) and a large volume increase (5%). On the basis of their band structure calculations, and including magnetovolume coupling terms in the free energy expression, Nakada *et al.* (2004) conclude that the Mn subsystem in itself would not order at all: spin fluctuations are necessary to "stabilize" the ordered system (see also Sect. 4).

### 2.6 Beyond SCR

There have been many attempts to develop the spin fluctuation theory beyond the Moriya SCR level. Noteworthy are the papers by Takahashi and colleagues, e.g., Takahashi (2001), in which the important role of the zero-point or quantum fluctuations is stressed. Kaul and co-workers claim to have found a solution for the transition from the low-temperature spin wave regime to the critical regime around $T_C$,

and provide and elaborately analyze experiments on mainly $Ni_3Al$ and related compounds (see, e.g., Kaul 1999 and Semwal and Kaul 2002).

### *3. The Curie Temperature of a Very Weak Itinerant Ferromagnet*

According to the Landau theory for second-order phase transitions, the ordering transition occurs when $A(T)$ changes sign (see Eqn. (1), case $B>0$). For an itinerant ferromagnet, $A(T)$ [$= A_{St}(T)$] is given by

$$A_{St}(T) = A_b(0)(1 - \bar{I} + T^2/T_F^2)$$
$$= (A_b(0)/|S|)(-1 + |S|T^2/T_F^2) \qquad (7)$$

$A_{St}(T)$ vanishes at the "Stoner temperature" $T_{St} = T_F/|S|^{1/2}$. When spin fluctuations are taken into account, $A(T)$ is given by Eqn. (5). In the simple treatment here, the temperature dependence of $B$ is neglected. Moreover, in the discussion on the Curie temperature only the behavior of $m^2(T)$ in the neighborhood of $T_C$ is needed. Here, the relation $m^2(T) \sim T^{4/3}$ is generally accepted. Then, with Eqns. (3) and (5), one may write

$$A(T) = A(0) + a_{St}(T/T_0)^2 + a_{sf}(T/T_0)^{4/3} \qquad (8)$$

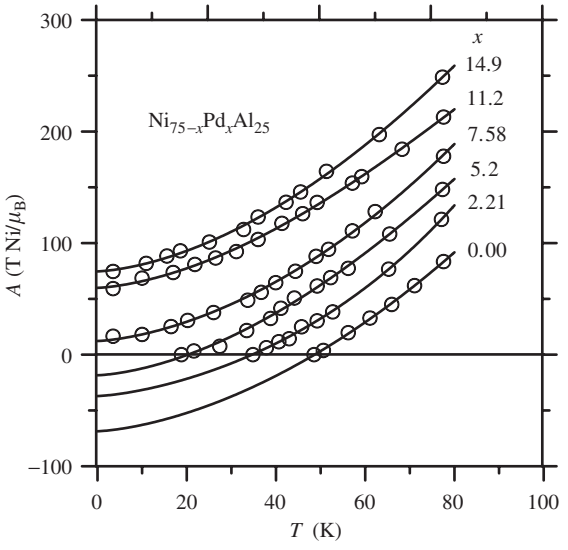

***Figure 3***
Analysis of the first Landau coefficient $A(T)$ for some $(Ni,Pd)Al_3$ compounds. Extending Eqn. (7), the solid lines represent fitting results according to: $A(T) = A(0) + a_{2St}(T/T_0)^2 + a_{4St}(T/T_0)^4 + a_{sf}(T/T_0)^{4/3}$. With, arbitrarily, $T_0 = 40\,K$ the fitting results for $Ni_{60}Pd_{15}Al_{25}$ are: $A(0) = 12.25\,TNi/\mu_B$, $a_{2St} = 25.6\,TNi/\mu_B$; $a_{4St} = 0.37\,TNi/\mu_B$, $a_{sf} = 27.36\,TNi/\mu_B$, giving directly the relative importance of these contributions in the total value of $65.6\,TNi/\mu_B$ at $T = T_0 = 40\,K$.

where $T_0$ is an arbitrary reference temperature, for ferromagnetic materials often chosen equal to $T_C$. As an example, Fig. 3 shows an analysis of the temperature dependence of the Landau parameter $A(T)$ for a series of $(Ni,Pd)_3Al$ compounds (data taken from fig. 5 in Brommer and Franse 1990). In fact, in order to obtain a consistent fit for all the curves, a term $\sim T^4$ has been added and the contribution of the spin fluctuation (i.e., the coefficient $a_{St}$ in Eqn. (7)) was assumed to be the same for all compounds. According to this analysis, the contributions of the Stoner $T^2$ term and the "spin fluctuation" $T^{4/3}$ term are of equal importance. It is easy to imagine that, for this kind of experimental results, reasonable fits could be obtained for a pure Stoner model as well as for a pure Moriya (spin fluctuation) model. Historically, in the debate on the importance of spin fluctuations versus Stoner excitations, it is understandable that the analysis of such measurements never convinced an opponent (for some more details see Brommer and Franse 1990).

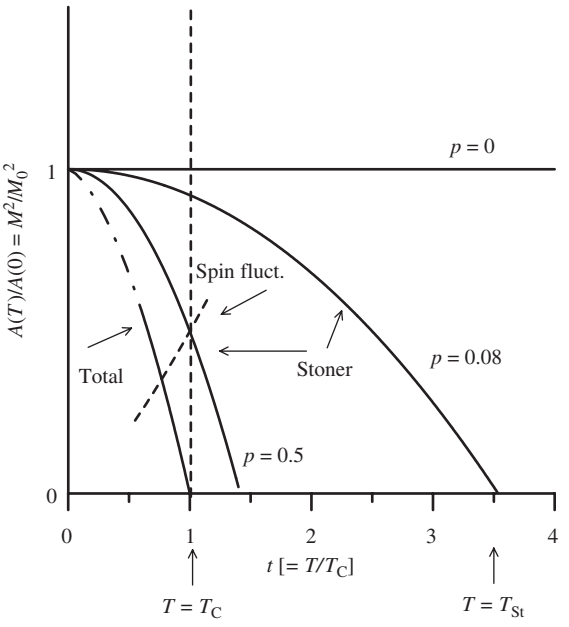

***Figure 4***
Schematic illustration of the reduction of the Curie temperature: $A(T)/A(0)$ [$= M^2/M_0^2$] is plotted vs. $t = T/T_C$. The solid lines represent $A_{St}(T)/A(0) = 1 - T^2/T_{St}^2$ (Stoner model). The skew dashed line represents the contribution of the spin fluctuations, $(5/3)Bm^2(T)/|A(0)| = (1-p)t^{4/3}$, for $p = 0.5$. Here, $p$ is the relative contribution of the Stoner excitations in $A(T_C)$. $p = 0$: Moriya model (Stoner excitations completely ignored), $p = 0.08$, value quoted for MnSi; $p = 0.5$: possible value for $ZrZn_2$ and $Ni_3Al$ (see Brommer and Franse (1990), table 5).

A striking success of the spin fluctuation approach was the explanation of the reduction of the Curie temperature with respect to the Stoner temperature. This is shown schematically in Fig. 4. With respect to the Stoner temperature, the Curie temperature is reduced by a factor $t_{St} = T_{St}/T_C$ $[= 1/\sqrt{p}]$, which is infinite for the pure Moriya model, 12.5 for MnSi ($p = 0.08$) and perhaps about a factor $\sqrt{2}$ for $ZrZn_2$ and $Ni_3Al$, for which the value $p = 0.5$ is adopted here.

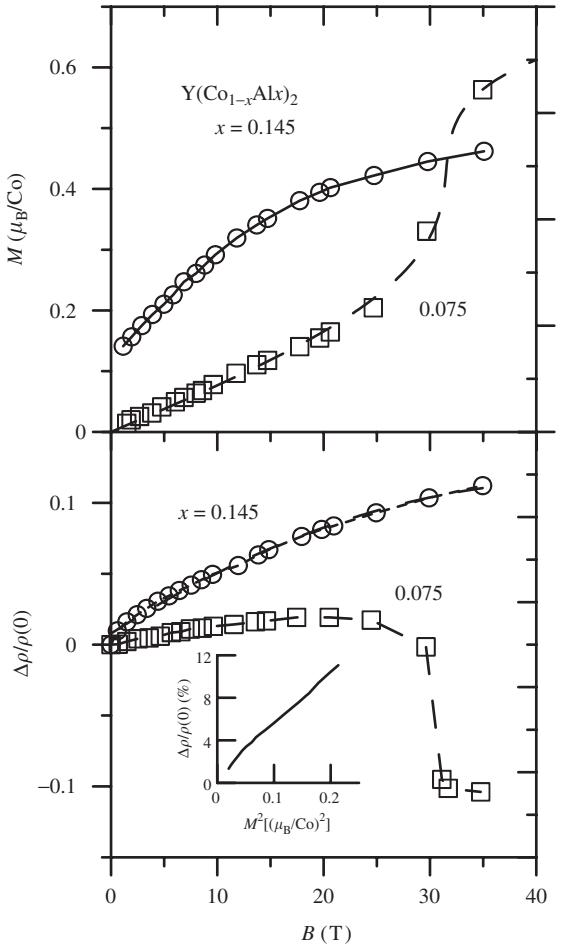

***Figure 5***
Magnetic moment per Co (upper panel) and the relative magnetoresistivity for the ferromagnetic (stabilized) compound $Y(Co_{0.855}Al_{0.145})_2$ and the metamagnetic compound $Y(Co_{0.925}Al_{0.075})_2$. The dashed line in the upper panel represents the fitting with Eqn. 2(a) for $x = 0.075$, with $A > 0$, $B < 0$, $C > 0$. The other lines are guides to the eye only. The inset in the lower panel shows the proportionality $\Delta\rho/\rho \sim M^2$ for $x = 0.145$, i.e., for the stabilized compound.

## 4. *Volume Effects*

### *4.1 Separation of Volume Effects and Spin Fluctuation Contributions*

Many itinerant-electron systems are based on transition metal ions, which are known to exhibit large magnetoelastic effects (see Eqn. (6)). The volume change may influence the properties of the material, for instance, the resistivity. Then, it may be difficult to distinguish the volume effect from the spin fluctuation effect. Figure 5 shows an attempt to separate the effects for two $Y(Co,Al)_2$ compounds. $Y(Co_{1-x}Al_x)$ is ferromagnetic for $x = 0.145$. The magnetic moment increases gradually from $\sim 0.1\,\mu_B$/Co up to $\sim 0.5\,\mu_B$/Co when the applied field is increased from 0 T to 40 T. It exhibits a positive magnetoresistance, proportional to $M^2$, and thus interpreted as a (or the) volume effect. For the metamagnetic compound ($x = 0.075$), the sharp drop in the magnetoresistance, accompanying the comparable, but now jump-like, increase of the Co moment, is ascribed to the suppression of the spin fluctuations, evidently exceeding the concurrent volume effect.

### *4.2 Huge Thermal Expansion in $YMn_2$ and $(Nd,Lu)Mn_2$*

Magnetovolume effects are very clear in $YMn_2$ and related Laves phase compounds (already discussed

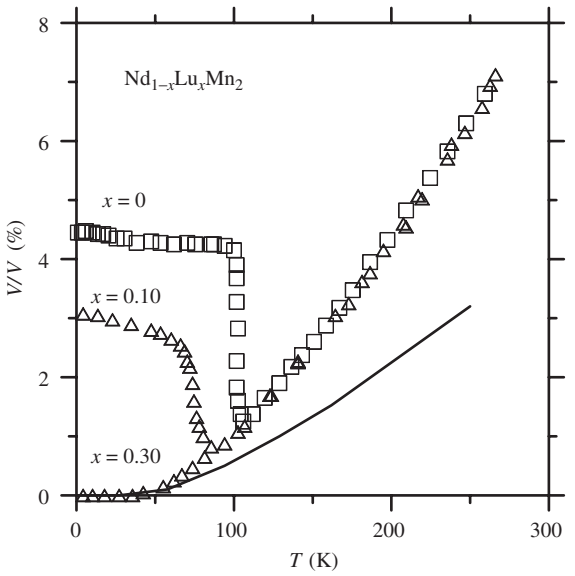

***Figure 6***
Thermal expansion of some $Nd_{1-x}Lu_xMn_2$ compounds ($x = 0.00$, 0.10, and 0.30). The solid line indicates the background thermal expansion (electronic and lattice contributions). The excess volume is assumed to be due to the magnetic Mn moment. For $T > T_N$, the excess thermal expansion is ascribed to spin fluctuations.

above). The large jump in the Mn moment at $T_N$ leads to a large jump in the volume, and concurrently to a large thermal hysteresis ($\approx 20$ K), clearly indicating a first-order transition. For $T > T_N$, a large thermal expansivity is found. This is ascribed to spin fluctuations in the (paramagnetic) Mn subsystem. On the basis of a combined analysis of specific-heat data and thermal-expansion for the related alloying system (Nd,Lu)$Mn_2$, Kim-Ngan *et al*. (1994) succeeded to separate the contribution of the spin fluctuations from the lattice contribution and other, electronic, contributions (Fig. 6). The excess volume is assumed to be due to the magnetic Mn moment. When for the antiferromagnetically ordered Mn-system at low temperatures the Mn moment is taken as $2.7\,\mu_B$/Mn, the mean fluctuating Mn moment would be $\sim 2.5\,\mu_B$/Mn at room temperature. So, the fluctuating Mn moments are quite comparable with local atomic moments (of fixed magnitude).

## Spin Transition Compounds

Octahedral complexes of transition metal ions with configurations $d^4$–$d^7$ exist in either the high-spin (HS) or low-spin (LS) state, depending on the nature of the ligand field. In weak fields the ground state is HS, the d electrons being distributed over the $t_{2g}$ and $e_g$ sets, whereas strong fields stabilize the LS state, the $t_{2g}$ set being completely occupied before electrons are added to the $e_g$ set (Fig. 1). For iron(II), for example,

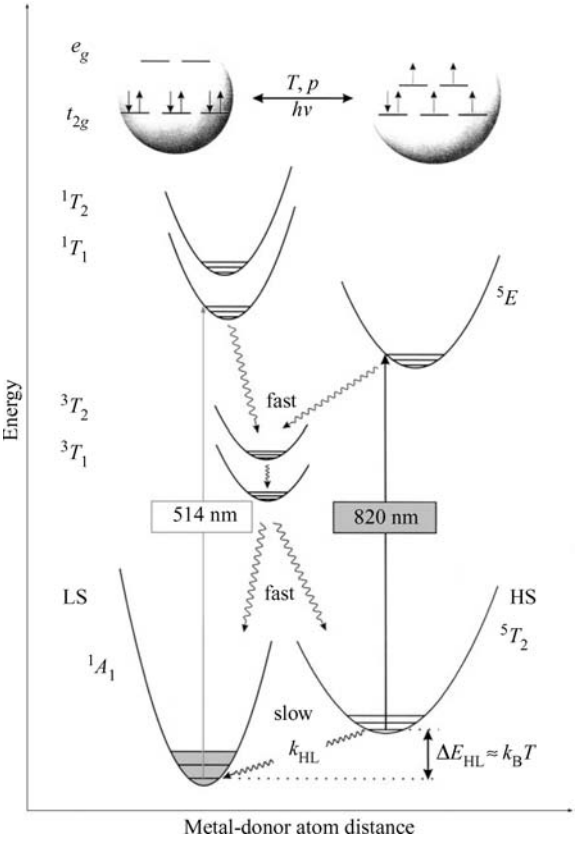

***Figure 1***
Representation of the interconversion of HS and LS states for iron(II) and the mechanism of the LIESST effect.

the two states are illustrated by $[Fe(H_2O)_6]^{2+}$, configuration $(t_{2g})^4(e_g)^2$, and $[Fe(CN)_6]^{4-}$, configuration $(t_{2g})^6$. For intermediate fields the energy difference between the lowest vibronic levels of the potential wells of the two states may be sufficiently small such that application of some relatively minor external perturbation effects a change in the state. This phenomenon is known as a spin transition (ST) or spin crossover. Materials which display STs are of interest because of their potential in electronic devices for applications such as data storage and displays. The first transitions were observed in the 1930s in iron(III) dithiocarbamates and these were later extensively studied in the 1960s (Martin and White 1968). Although STs have been observed for all the configurations $d^4$–$d^7$ for the first transition series, the greatest number has been reported for iron(II) (Gütlich *et al*. 1994).

## 1. Occurrence and Detection of Spin Transitions

A change in spin state effects fundamental changes in the electronic configuration and thus will affect all those properties of the system which depend on electronic structure. The most important of these are magnetism, color, and structure. In HS $Fe^{II}$, electrons partly occupy both the antibonding $e_g$ set and the nonbonding or weakly bonding $t_{2g}$ set, whereas in LS $Fe^{II}$ only the $t_{2g}$ set is occupied. This allows closer approach of the donor atoms in the LS state and hence a HS→LS spin transition is accompanied by a significant structural change involving a contraction in the metal–donor atom distances of about 0.2Å or 10%. For solid systems this change in molecular dimensions may bring about fundamental changes in the crystal lattice. For this reason STs in solid systems can follow a number of different paths. These differ principally in the degree of cooperativity associated with the transition. When this is low the transition will be gradual or continuous, but as cooperativity increases the transition becomes more abrupt and may be associated with a phase change and hysteresis. In some instances two-step transitions have been observed, while in others residual fractions of HS or LS species persist at the extremities of the transition.

An ST may be monitored and an ST curve (HS fraction vs. $T$) constructed by a variety of techniques. The curve reflects the nature of the change in population of the HS state with change in temperature. For iron(II), Mössbauer spectroscopy is particularly suitable for characterizing an ST since the spectral parameters associated with the HS and LS states clearly differ and the timescale of the technique generally allows the detection and evaluation of the separate spin states in the course of the transition.

Although the criterion for the occurrence of an ST may appear very restrictive, a large number (>150) of systems have been characterized. The majority are $Fe^{II}N_6$ systems involving heterocyclic donors. The first synthetic system, $Fe(phen)_2(NCS)_2$ (phen = 1,10-phenanthroline), was identified by König and Madeja (1966). Since then many species of similar composition have been shown to undergo transitions. In addition, derivatives of simple unidentate ligands such as isoxazole and tetrazoles, along with multidentate and polynuclear systems are known. Two strategies are widely effective in fine-tuning the field strength of model ligands so as to bring it into the crossover region:

(i) Incorporation of chemical substituents. If the substituent is adjacent to a donor atom this will destabilize the singlet state by hindering the close approach of the metal atom and is illustrated by $[Fe(mephen)_3]^{2+}$ (mephen = 2-methyl-1,10-phenanthroline) which is HS at room temperature but undergoes a transition to LS at low temperatures, in contrast to the unsubstituted $[Fe(phen)_3]^{2+}$ which is LS. Where the substituent is remote from the donor atom electronic effects may stabilize either state.

(ii) The replacement of six-membered heterocycles by five-membered ones. The principal effect here is to reduce both the $\sigma$-donor and $\pi$-acceptor character of the system, thus favoring the quintet state, illustrated by the spin crossover behavior of $[Fe(pyim)_3]^{2+}$ (pyim = 2-(pyridin-2-yl)imidazole), in contrast to the completely LS nature of $[Fe(bpy)_3]^{2+}$ (bpy = 2,2′-bipyridine).

## 2. Solution and Solid-state Behavior

STs are observed for systems in both solution and solid states, though the one system will not necessarily display a transition in both phases. In solution, interactions between the molecules undergoing spin change are virtually negligible and thus the course of the transition can be described by a Boltzmann distribution over all HS vibronic states and the LS state. The driving force for the transition is the considerable entropy gain of $\sim 50$–$80\,J\,mol^{-1}\,K^{-1}$ for the LS→HS conversion, made up of a magnetic component, $\Delta S_{mag} = R[\ln(2S+1)_{HS} - \ln(2S+1)_{LS}]$, $\sim 13\,J\,mol^{-1}\,K^{-1}$, and a larger vibrational entropy contribution arising from the much higher degeneracies in the HS state. The enthalpy change for the LS→HS conversion is typically 6–15 kJ mol$^{-1}$ and is associated primarily with rearrangement of the coordination sphere (metal–donor atom bond length increase). In the solid state there is electron–phonon coupling between the molecules changing spin state, resulting in cooperative interactions of varying degrees.

One of the most successful models for ST behavior takes as its basis the change in the metal–donor atom distance accompanying a transition (Spiering and Willenbacher 1989). It is proposed that such a

significant change at every "point defect" where an ST occurs sets up pressure (an "image pressure") which is communicated to the surroundings via phonon interactions. In the course of the ST, at many point defects the lattice expands and accelerates the ST in other metal centers. Thus, the nature of the cooperative interactions in a solid is elastic, and the model uses typical quantities from elasticity theory, e.g., bulk modulus and Poisson ratio, to account for the experimental results.

## 3. Effect of Pressure

The effect of increased pressure is to favor the HS→LS conversion because of the smaller volume of the LS form. From both solution studies and crystal structure determinations, $\Delta V$ has been estimated as typically 50Å$^3$ per octahedral unit. The study of the effects of high pressure on the course of STs in solid samples has revealed some subtle effects which include displacement of the transition temperature, change in the width of the hysteresis loop, and changes in the residual fractions of HS and LS species at the extremes of the temperature range for the transition (Ksenofontov *et al*. 1999).

## 4. Effect of Light

It has been observed that an $Fe^{II}$ spin crossover compound in the LS state is converted by light into the metastable HS state with virtually infinite lifetime at sufficiently low temperatures (Decurtins *et al*. 1984). This phenomenon became known as the light-induced excited spin state trapping (LIESST) effect. Later it was found that the reverse process is also possible. The mechanism for these photo-switching processes, a common feature of most $Fe^{II}$ spin crossover systems, is shown in Fig. 1. Green light is used for the spin allowed excitation $^1A_1 \rightarrow {}^1T_1$. A fast relaxation cascading over two successive intersystem crossing steps, $^1T_1 \rightarrow {}^3T_1 \rightarrow {}^5T_2$, populates the metastable $^5T_2$ state. Reverse LIESST is achieved by application of red light whereby the $^5T_2$ state is excited to the $^5E$ state with two subsequent intersystem crossing processes $^5E \rightarrow {}^3T_1 \rightarrow {}^1A_1$. As demonstrated by Hauser (1991), photo-switching from LS to HS is also possible via $^1A_1 \rightarrow {}^3T_1 \rightarrow {}^5T_2$. LIESST can be induced in spin crossover molecules embedded in polymer films and in KBr pellets, in addition to solid samples. It is worth noting that LIESST has also been observed for the conversion of a HS ground state to a metastable LS state by red light (Poganiuch *et al*. 1990).

The effect of light on spin crossover systems is being pursued vigorously and a number of phenomena have been reported. These include: light-induced thermal hysteresis (LITH), the effect of raising and lowering temperature under constant irradiation (Desaix *et al*. 1998); light-perturbed thermal hysteresis (LPTH), whereby the hysteresis associated with an ST is shifted to either lower or higher temperatures under irradiation of different wavelengths (Renz *et al*. 2000); and ligand-driven light-induced spin crossover (LD-LISC), whereby irradiation effects a *cis–trans* isomerization of the ligand, with subsequent ST at the $Fe^{II}$ center as a consequence of a change in field strength (Boillot *et al*. 1999).

## 5. Applications

The existence of hysteresis is a prerequisite for bistability, which in turn offers the potential for technical applications of ST systems such as thermal switches and sensors. Furthermore, the drastic color change generally accompanying an ST is promising for applications in displays (Kahn and Launay 1988).

The remarkable changes of ST behavior under applied pressure can be exploited in pressure sensors for applications where remote sensing of pressure could be achieved by a color change in a spin crossover material. The light-induced switching phenomena described above also offer much promise. Data storage using spin crossover materials, although now limited to low-temperature regions, may eventually play a role in holographic devices. Orientational experiments on "transient grids" of a HS/LS lattice have yielded highly promising refractive index results. The switching rates in the subnanosecond region at ambient temperatures may be a promising basis for optical switches. Patents covering these aspects have been registered.

## 6. Future Developments

Research on ST compounds has grown enormously both from a chemical point of view, allowing the more-or-less controlled synthesis of new materials with special properties, and regarding physical characterization using powerful techniques. Aspects which are the focus of many research groups include:

- synergism (coupling) of magnetic exchange between metal centers and ST at the metal atom; and
- detailed structural characterization of metastable states; important findings on the lattice parameters of a system in a LIESST-generated metastable state have emerged and detailed structural studies will allow greater understanding of light-induced phenomena in general.

## Spintronics in Semiconductor Nanostructures

Spintronics is a relatively new field of electronics which has been rapidly developing over the past few years. In order to understand the potential of this new kind of electronics, it is useful to consider the basic properties of the electron. One of these properties is the charge, which has been exploited up to now in conventional semiconductor electronics. The charge of a single electron is constant and local changes of charge can only happen via a current. However, the electron also has a second property, namely the spin. The spin can be seen as an angular momentum which—corresponding to a rotating charge—also induces a magnetic moment. Much in contrast to a macroscopic angular momentum the spin can only have two different (opposite) directions. It is quantized, with the axis of quantization given by an external magnetic field. So, whereas the electron charge has a constant value, the spin of an electron can have two different values called spin-up and spin-down which can be ''flipped'' from one value to the other. This property allows for the local creation of a spin population without a current (in contrast to a charge) but it also means that a spin population can vanish over time, while a charge population in the absence of a current cannot.

A well-known effect based on spin is ferromagnetism. In normal materials the spin of the electrons is distributed statistically. This means that 50% of the electrons have spin-up and 50% have spin-down. In ferromagnetic materials such as Fe, Co, or Ni, it is energetically favorable for a majority of the electrons to have the same spin direction. In this case the material exhibits a macroscopic magnetic moment and produces an external magnetic field. Until the mid-1980s, access to the magnetic properties was possible only via the magnetic field, using inductive pickup coils like in tape storage or computer disk applications.

In 1987 the situation changed, when a new effect was discovered. Baibich *et al.* (1988), Binasch *et al.* (1989), and Valet and Fert (1993) discovered that metallic multilayers (see *Multilayers: Interlayer Coupling*) composed of magnetic and nonmagnetic metals can exhibit a so-called giant magnetoresistance (see *Giant Magnetoresistance*). When an external magnetic field is applied to the system, the resistance of the layers decreases. It was soon thereafter determined that the effect was based on the spin polarization of the carriers. The spin polarization of the carriers in a material $\beta$ is a macroscopic quantity giving the average spin population of the electronic system:

$$\beta = \frac{n^{\uparrow} - n^{\downarrow}}{n^{\uparrow} + n^{\downarrow}} \tag{1}$$

where $n^{\uparrow}$ and $n^{\downarrow}$ are the number of carriers with spin-up and spin-down, respectively. It is clearly visible that for a nonmagnetic material $\beta$ is 0. In a conventional ferromagnetic material, its value can be up to 40%.

If we assume the same mobility for spin-up and spin-down electrons, without loss of generality, we can assume

$$\beta = \frac{\rho^{\uparrow} - \rho^{\downarrow}}{\rho^{\uparrow} + \rho^{\downarrow}} \tag{2}$$

where $\rho$ is the local conductivity.

In a homogeneous material this spin polarization can give rise to a spin-polarized current. As long as spin flips are neglected, we can derive two equations

for the spin-up and spin-down current, respectively:

$$\vec{j}^{\uparrow\downarrow} = \vec{E}\rho^{\uparrow\downarrow} \tag{3}$$

The spin polarization of the currents $\alpha$ is then defined as

$$\alpha = \frac{j^{\uparrow} - j^{\downarrow}}{j^{\uparrow} + j^{\downarrow}} \tag{4}$$

This corresponds to a picture in which two spin channels exist, which can be seen as fully spin-polarized noninteracting resistors. However, it is clear that the voltage applied to both resistors is always the same, because the interaction of electrons with an electric field is independent from spin, and current contacts are typically not spin selective. A spin-polarized current can thus only be obtained in a material where the carriers are already spin polarized.

The picture changes dramatically, when hybrid structures consisting of both spin-polarized and unpolarized materials are investigated. In this case, the continuity of the respective spin currents has to be maintained, unless a strong spin scattering is present. For a ferromagnet/nonmagnet/ferromagnet (FM/NM/FM) trilayer system this leads to the so-called two-current model, in which two spin channels are present. Each channel consists of three resistors, two for the two ferromagnets and one for the nonmagnetic material (Fig. 1). When the two magnetic layers are magnetized in parallel, the two spin channels have a different total resistance. When the alignment is antiparallel, the resistances of the spin channels are equal. Calculating the total resistance of the system yields different values for parallel and antiparallel alignment. The value for the parallel alignment is always lower than for the antiparallel alignment. This effect is termed giant magnetoresistance (GMR). Besides the appearance of a magnetoresistance, a second effect is also present; in the antiparallel state, the current through both spin channels is equal. However, in the parallel state, the two spin currents are different yielding a spin-polarized current in the nonmagnetic material.

The spin polarization of the current in the parallel state is equal to

$$\alpha = \beta \frac{R_{\mathrm{fm}}}{R_{\mathrm{sc}}} \frac{2}{2(R_{\mathrm{fm}}/R_{\mathrm{sc}}) + (1-\beta^2)} \tag{5}$$

and the normalized difference in resistance between the parallel and the antiparallel state is

$$\alpha = \frac{\beta^2}{1-\beta^2} \frac{R_{\mathrm{fm}}^2}{R_{\mathrm{sc}}^2} \frac{2}{4(R_{\mathrm{fm}}^2/R_{\mathrm{sc}}^2) + 2(R_{\mathrm{fm}}/R_{\mathrm{sc}}) + (1-\beta^2)} \tag{6}$$

GMR quickly made its way into applications like hard-disk read heads and field sensors (see *Magnetic Recording Systems: Spin Valves*) and also seemed desirable for integrating spin-based devices into conventional electronics.

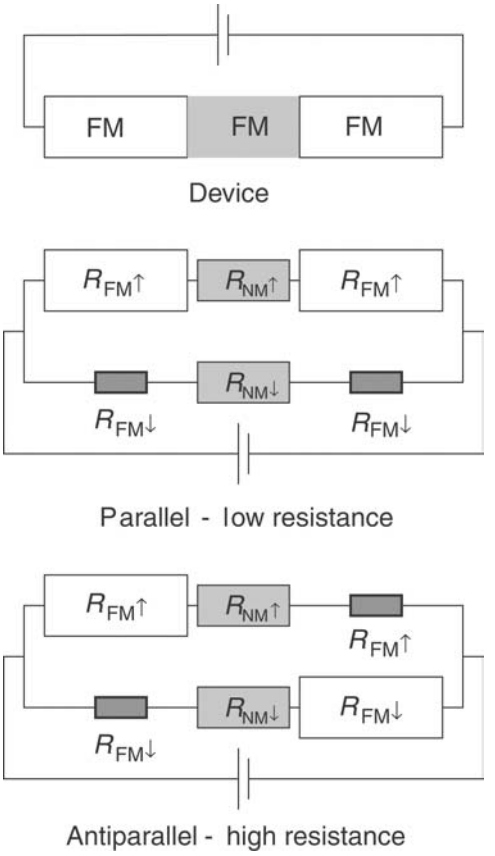

***Figure 1***
Resistor model (two-current model) for the semiconductor device with two ferromagnetic contacts (up), showing the configuration of the parallel and of the antiparallel magnetization of the contacts. The depicted size of the resistors indicates the higher and lower resistance of spin-up and spin-down channel, respectively. A straightforward calculation shows that the total resistance in the parallel configuration is lower than in the antiparallel case.

However, in metal-based devices high values for GMR can only be achieved when the thickness of the nonmagnetic material is only a few Å, a fact which limits the device resistance to fractions of an Ω and is incompatible with existing CMOS technology. Furthermore, these small dimensions leave no room for the manipulation of the spin. Indeed in 1990 a new concept for a semiconductor device for spin manipulation was published by Datta and Das in which a spin-polarized current through a semiconductor can be modulated by an electrostatic gate via the spin-orbit coupling. This device has come to be known as

the *Datta-transistor* (Datta and Das 1990). The authors claimed that the spin-polarized current should be obtained by using a GMR-like geometry with ferromagnetic metal contacts on a semiconductor mesa. Furthermore, optical experiments indicated that extremely long spin lifetimes and large spin-flip lengths can be obtained in semiconductors (Kikkawa and Awschalom 1999). Motivated by these results several research groups for more than half a decade tried to achieve the injection of a spin-polarized current (spin injection) into a semiconductor, however, without any results that could not be interpreted as side effects like magnetoresistance or Hall effect (Monzon and Roukes 1999).

The explanation for this failure is simple. If we replace the nonmagnetic metal in the GMR configuration (Fig. 1) by a semiconductor, it seems on first sight that the picture does not change. However, using real numbers for the resistance values shows that in comparison to the resistance of the semiconductor, the resistance of the ferromagnet can be neglected. Even when the spin polarization of the ferromagnet is 80% or 90%, the difference in resistance of both spin channels will be too low to induce any difference in the current of the two spin channels, and any current through the semiconductor remains unpolarized.

In Eqn. (5) this corresponds to $R_{\mathrm{fm}} \ll R_{\mathrm{sc}}$. This problem was first discussed in Schmidt *et al.* (2000) where the calculation was extended to a local description, in which spin flips in the ferromagnetic material are taken into account. In this case, the outcome is similar, only the resistance $R_{\mathrm{fm}}$ is replaced by $\lambda_{\mathrm{fm}}/\sigma_{\mathrm{fm}}$ which is the resistance of a sheet of the ferromagnet with the thickness of the spin-flip length. The spin polarization of the current in the semiconductor is thus proportional to the spin polarization of the ferromagnet $\beta$; however, it is reduced by a factor of $(\lambda_{\mathrm{fm}}/\sigma_{\mathrm{fm}})/(x_0/\sigma_{\mathrm{sc}})$ where $x_0$ and $\sigma_{\mathrm{sc}}$ are the length and conductivity of the semiconductor, respectively.

It seems obvious that one way to circumvent this conductance mismatch is to increase the value of $\lambda_{\mathrm{fm}}/\sigma_{\mathrm{fm}}$; however, ferromagnetic materials typically have a small spin-flip length and an extremely high resistivity would be needed, which will deteriorate the electrical properties of a device. One way to achieve such a high resistance contact has been discussed by Rashba (2000) and by Fert *et al.* (2001). Less obvious is the use of fully spin-polarized materials (see *Half-metallic Magnetism*) with $\beta = 1$. In this limit we obtain $\alpha = 1$ independent from the resistivity and the spin-flip length in the materials. This is possible because one of the spin channels is now completely blocked due to the absence of carriers.

Approximately at the same time as the conductance mismatch was identified, new experiments based on a different class of magnetic materials were published. When semiconductors are doped with magnetic ions (e.g., Mn or Fe), they can become ferromagnetic or strongly paramagnetic (see *Dilute Magnetic Semiconductors*). ZnMnSe is an example of these so-called dilute magnetic semiconductors (DMSs). Without external magnetic fields, the Mn-spins are not aligned or are antiferromagnetically coupled. However, at low temperatures and in an external magnetic field the material exhibits a giant Zeeman splitting. The $g$-factor can be larger than 100, leading to a splitting of the conduction band of up to 20 meV. At low temperatures, where $kT$ is smaller than the Zeeman splitting, the population of the two spin levels can be expressed by a Boltzmann factor. The upper spin level is thus completely depopulated and the material should act as a perfect spin aligning contact.

The first proof of high-efficiency spin injection using dilute magnetic semiconductors was obtained in 1999 using a light emitting diode (LED) fitted with a DMS contact. When an electron and a hole recombine in GaAs and emit a photon, the polarization of this photon is related to the spins of the hole and the electron via the quantum mechanical selection rules. When unpolarized holes recombine with spin-polarized electrons, there are two possibilities. In case light and heavy holes are degenerate, the circular optical polarization of the emitted photons is

$$P_{\mathrm{circ}}^{\mathrm{opt}} = \frac{\sigma^+ - \sigma^-}{\sigma^+ + \sigma^-} = \frac{(3n^\uparrow + n^\downarrow) - (3n^\downarrow + n^\uparrow)}{(3n^\uparrow + n^\downarrow) + (3n^\downarrow + n^\uparrow)} = \frac{1n^\uparrow - n^\downarrow}{2n^\uparrow + n^\downarrow} = \frac{1}{2}\alpha \tag{7}$$

When the degeneracy is lifted the circular optical polarization is equal to the electron spin polarization. A GaAs LED which is fed with unpolarized holes from the p-side and with spin-polarized electrons from the n-side will thus emit light with a circular polarization which is directly proportional to the electron spin polarization. Such a diode was fabricated (Fig. 2) and characterized at low temperature and in moderate magnetic fields between 0 T and 5 T. The hole confinement in the diode was weak in order to insure degenerate hole states. Figure 3 shows a typical electroluminescence (EL) spectrum of a spin LED. The maximum polarization obtained in the experiment was up to 46% indicating an electron spin polarization of more than 90% (Fiederling *et al.* 1999). A similar experiment was performed using ferromagnetic GaMnAs, however, with a strongly reduced efficiency (Ohno *et al.* 1999).

When DMSs are used as spin aligners however, electrical detection of spin-polarized transport is more difficult than for ferromagnets. The paramagnetic behavior makes it virtually impossible to achieve two small contacts with antiparallel magnetization and thus excludes GMR-like experiments. In addition, the magnitude of magnetoresistance effects due to spin injection is typically proportional to the square of the spin injection efficiency (Eqn. (6)).

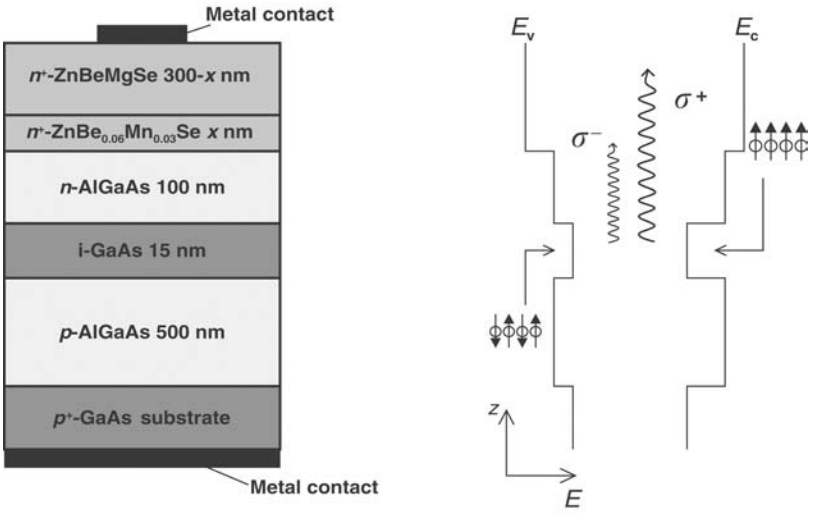

***Figure 2***
Layer sequence (left) and band structure (right) of the spin aligner LED. The device consists of a GaAs/AlGaAs LED which has a spin aligning *n*-contact. The electrons are aligned in the II–VI-layer and recombine in the GaAs with unpolarized holes coming from the GaAs substrate.

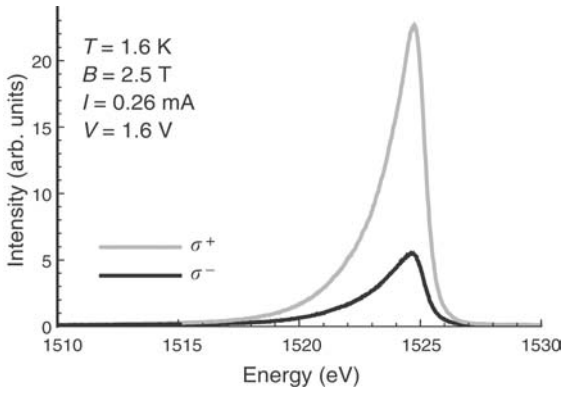

***Figure 3***
EL spectrum of a typical spin LED. The signal is strongly polarized.

While the latter would not present too big a problem due to the high spin injection efficiency demonstrated in the optical experiment, the realization of GMR could only be achieved using very small contacts with small ferromagnetic bias magnets that are difficult to realize.

However, the splitting of the electrochemical potentials which is always present in spin injection experiments can be used in electrical detection of the spin injection effect. When a nonmagnetic semiconductor is fitted with two dilute magnetic semiconductor contacts and a voltage is applied, a new magnetoresistance effect can be observed. While the DMS is not magnetized, current through the sample will lead to an identical slope for the electrochemical potentials of spin-up and spin-down electrons in the nonmagnetic semiconductor (NMS) (Fig. 4(a)). As soon as the DMS is magnetized, the electrochemical potentials will split at the interfaces leading to a kind of boundary resistance (Fig. 4(b)).

Much in contrast to giant magnetoresistance, this boundary resistance persists even if the spacing between the contacts is larger than the spin-flip length in the NMS (the effect can also be present in a single contact geometry). This boundary resistance will appear as a magnetoresistance, which can be up to 100% of the resistance of the NMS. The increase of the resistance can be attributed to the nonequilibrium distribution of spin currents in the spin channels of the NMS. At the boundary, one spin channel is suppressed over the range of the spin-flip length, reducing the total conductivity. In the ideal case of full spin polarization and no spin scattering, one spin channel is completely suppressed throughout the NMS leading to a reduction of the conductivity by a factor of 2. For a finite spacing of the contacts, the magnetoresistance can be shown to be

$$\frac{\Delta R}{R_{\mathrm{sc}}} = \beta^2 \frac{\lambda_{\mathrm{dms}}}{\sigma_{\mathrm{dms}}} \frac{\sigma_{\mathrm{sc}}}{x_0} \times \frac{2}{\dfrac{\lambda_{\mathrm{dms}}}{\sigma_{\mathrm{dms}}} \dfrac{\sigma_{\mathrm{sc}}}{\lambda_{\mathrm{sc}}} (1 + e^{-x_0/\lambda_{\mathrm{sc}}}) + 2 \dfrac{\lambda_{\mathrm{dms}}}{\sigma_{\mathrm{dms}}} \dfrac{\sigma_{\mathrm{sc}}}{x_0} e^{-x_0/\lambda_{\mathrm{sc}}} + 1 - \beta^2} \tag{8}$$

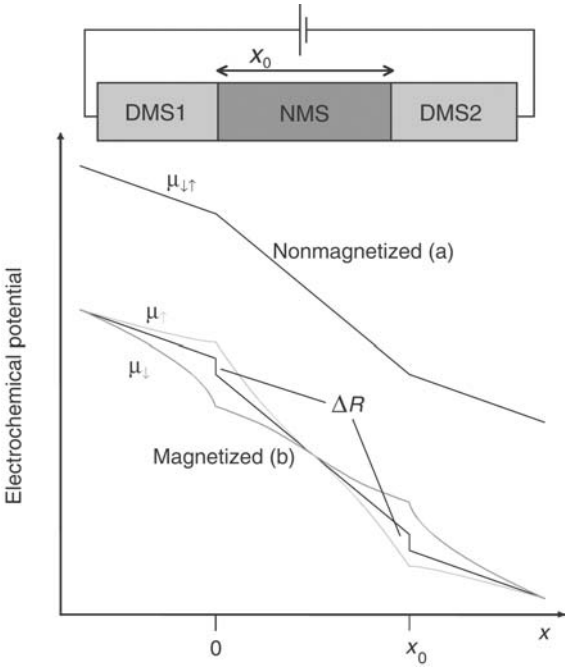

***Figure 4***
Schematic drawing of the device with two DMS contacts and plot of the electrochemical potentials for the two spin channels. Without applied magnetic field (a) the potentials are identical. As soon as a magnetic field is applied (b) the potentials split at the interfaces.

The effect has been observed experimentally in an all II–VI semiconductor structure where the NMS was ZnBeSe and the DMS was ZnBeMnSe. The observed effect was up to 25% of the total device resistance (Schmidt *et al*. 2001). The deviation from 100% can be explained by the fact that the contact spacing in this experiment was much larger than the expected spin scattering length in ZnBeSe.

Meanwhile, different experiments using optical detection and based on ferromagnetic metal contacts with tunnel barriers have been published (Motsnyi *et al*. 2002, Zhu *et al*. 2001). Although the efficiency obtained is not as high as in the case of DMS contacts, they show that based on a detailed understanding of the phenomena, novel approaches can lead towards room-temperature applications. In addition, over the past years a large research effort has been initiated and is ongoing which is dedicated to highly spin-polarized materials that are ferromagnetic at room temperature. These could replace DMSs and still maintain the same spin injection efficiency that is needed for device applications.

## SQUIDs: Amplifiers

Radio-frequency (RF) amplifiers virtually always involve semiconductors as active elements. Noise temperatures of about 2 K can be achieved with these devices at frequencies of several hundred megahertz (Bradley 1999), when the amplifier is cooled to liquid helium temperatures. Cooling the amplifier to still lower temperatures does not reduce the noise temperature further because of intrinsic noise sources in

the transistor. It is also questionable whether a transistor can be cooled to, say, 1 K because of the relatively large power dissipation.

At least at frequencies of several hundred megahertz, better results can be obtained by using a d.c. superconducting quantum interference device (SQUID) as an RF amplifier. For this device, the noise temperature continues to decrease linearly with the bath temperature as it is lowered to about 0.1 K (Wellstood *et al.* 1994). This is because the power dissipation in the SQUID is orders of magnitude lower than for a transistor, and because the only intrinsic noise source at frequencies above a few hertz is Nyquist noise in the shunts of the junctions.

## 1. Conventional d.c. SQUID Amplifier

The conventional d.c. SQUID amplifier (Hilbert and Clarke 1985) consists of two resistively shunted Josephson junctions (see *Josephson Junctions: Low-$T_c$*, *Josephson Junctions: High-$T_c$*) incorporated into a square washer of inductance $L$ over which is deposited a superconducting input coil of $n$ turns with inductance $L_i \approx n^2 L$. The SQUID is current and flux biased so that the flux to voltage transfer function, $V_\Phi = \partial V/\partial \Phi$, is close to a maximum. A signal current $I_i$ in the input coil generates a flux $M_i I_i$ in the SQUID and an output voltage $V_0 \approx M_i I_i V_\Phi$ across it, where $M_i$ is the mutual inductance between the input coil and the SQUID. With sufficiently large $M_i$ and $V_\Phi$, a relatively high gain can be obtained in this configuration. The conventional flux locked loop operation of the SQUID, which is used to linearize its transfer function, cannot be realized for the required high-frequency operation. This means that the amplitude of the input signal is limited to currents that produce flux changes in the SQUID of less than about $\Phi_0/4$. Fortunately, in most high-frequency applications the input signal amplitude is much less than that. If a SQUID with a flux noise of $10^{-6}\Phi_0 \mathrm{Hz}^{-1/2}$ is used one can still achieve a dynamic range of nearly $120\,\mathrm{dBHz}^{-1/2}$. Larger flux changes, caused, for example, by 50 Hz or 60 Hz fields, can easily be compensated by operating the SQUID in a slow flux locked loop, which maintains the flux bias at odd multiples of $\Phi_0/4$.

Using a SQUID amplifier with an input circuit tuned to 93 MHz, Hilbert and Clarke (1985) achieved a gain of about 18 dB and a noise temperature of about 1.5 K for a bath temperature of 4.2 K. Above 100 MHz, however, parasitic capacitance, $C_p$, between the input coil of inductance $L_i$ and the SQUID produces self-resonances and severely reduces the gain. The $L_i C_p$ parallel resonance can be moved to higher frequencies by reducing the number of turns, reducing their width, or increasing the thickness of the insulating layer that separates the coil from the SQUID. However, reducing the number of turns may reduce the mutual inductance between the coil and the SQUID to a value that is too small to produce a satisfactory gain. For the same reason the size of the SQUID hole should be made as large as possible (e.g., $200\,\mu\mathrm{m} \times 200\,\mu\mathrm{m}$).

Takami *et al.* (1989) have described a SQUID amplifier in which the input circuit is tuned to the desired resonant frequency by adjusting the thickness of the insulating layer between the SQUID and coil, thus varying the parasitic capacitance. To match the high resistance of the parallel $L_i C_p$ circuit to the $50\,\Omega$ signal source, the signal is coupled to the coil by a small (3 pF) capacitor. This scheme leads to a relatively high quality factor, $Q$, of the $L_i C_p$ circuit, a high input current at the resonant frequency, and thus a high gain. Gains have been measured of up to 23 dB at 150 MHz, and a noise temperature of about 0.7 K for a bath temperature of 4.2 K. Unfortunately, the high $Q$ of the resonant circuit decreases the bandwidth to about 1% of the operating frequency, which for many applications is too small. Increasing the bandwidth by decreasing $Q$ decreases the gain. Nevertheless, for narrow-band applications such as NMR, this coupling scheme provides a high gain, low noise amplifier for frequencies of up to a few hundred megahertz.

If operation at higher frequencies is required, the parasitic capacitance either has to be reduced or its influence removed with a resonance technique. Reducing the capacitance can be achieved by placing the input coil inside the SQUID hole. Because of the decreased coupling between coil and SQUID, however, the gain is quite small. Tarasov *et al.* (1995) have made a SQUID amplifier in this way, and reported gains of 8 dB at 700 MHz and a noise temperature of about 1.5 K. In an alternative design, Prokopenko *et al.* (1999) used a SQUID amplifier with a series resonant input circuit to achieve a gain of 10 dB at 3.8 GHz and a noise temperature of 5 K.

## 2. SQUID Amplifier with Microstrip Input Coupling

An alternative way of achieving high gains and low noise temperatures at high frequencies is to take advantage of the parasitic capacitance, by operating the input coil of a d.c. SQUID as a microstrip resonator. The input signal is no longer coupled to the two ends of the input coil, but rather between one end of the coil and the SQUID loop, which acts as a ground plane for the coil; the other end of the coil is left open. The microstrip resonator is thus formed by the inductance of the input coil and its ground plane and the capacitance between them. In this configuration, the parasitic capacitance no longer prevents currents from flowing through the coil.

For the case in which the impedance, $Z_s$, of the source coupled to one end of the microstrip is larger than its characteristic impedance, $Z_0$, and the other

end of the input coil is left open, the fundamental resonance occurs when the length, $l$, of the microstrip is equal to half the wavelength of the RF signal. In this mode, the microstrip resonator is analogous to a parallel tuned circuit and, neglecting losses in the microstrip and the SQUID, one calculates a quality factor $Q = \pi Z_s/2Z_0$. At the resonant frequency the current fed into the resonator is amplified by $Q$, producing a magnetic flux that is coupled into the SQUID via a mutual inductance $M_s = \alpha(LL_s)^{1/2}$, where $L_s$ is the microstrip inductance and $\alpha$ the coupling coefficient. One selects the resonant frequency by appropriate choice of the length of the coil. $Q$, which determines the bandwidth of the amplifier, can be varied by selecting the characteristic impedance of the microstrip; i.e., by choosing an appropriate width of the turns of the coil and thickness and dielectric constant of the insulating layer between the coil and SQUID. One has to keep in mind, however, that reducing $Q$ will increase the bandwidth and lower the gain, since the resonant current amplification is proportional to $Q$.

Since the conventional washer SQUID is an asymmetric device (the two Josephson junctions are situated close together rather than on opposite sides of the SQUID loop), one can either ground the washer or ground the counter electrode close to the Josephson junctions. Using the washer as ground plane for the input coil suggests one should ground the washer. However, it is also possible to ground the counter electrode and have the washer at output potential. In this case, depending on the sign of $V_\Phi$ (which determines the phase shift between input and output of the amplifier), one can obtain either a negative or positive feedback from the output to the input, and using positive feedback, the gain of such amplifiers can be enhanced substantially.

Using this configuration, Mück *et al*. (1998) measured gains of 20 dB up to a frequency of 1.3 GHz. Noise temperatures as low as 100 mK (at 400 MHz) have been measured when the SQUID is cooled to 0.4 K (André *et al*. 1999). This noise temperature is only about a factor of three above the quantum limit. The intrinsic noise temperature of the amplifier is typically 1/4 of the bath temperature, $T$, and, within measurement errors, scales with $T$.

The microstrip amplifier can be tuned by means of a varactor diode, which is connected to the open end of the microstrip. Changing the capacitance of the varactor diode by an applied d.c. voltage enables one to reduce the resonant frequency of the amplifier by nearly a factor of two. If gains higher than 20 dB are desired, two amplifiers can be connected in cascade.

### 3. Conclusion

For applications requiring extremely low noise temperatures at frequencies of several hundred megahertz and above, an RF amplifier based on a d.c. SQUID is a promising alternative to semiconductor amplifiers. Such applications include intermediate frequency amplifiers for superconductor–insulator–superconductor (SIS) mixers, NMR, or Axion detectors. Gains of more than 20 dB at frequencies exceeding 1 GHz have been obtained with such amplifiers and noise temperatures as low as 100 mK. An exciting possibility is the expectation that the quantum limit could be reached with a d.c. SQUID amplifier cooled to about 100 mK. A challenge for future work is the extension to higher frequencies. It should be possible to operate a SQUID amplifier at frequencies exceeding 10 GHz, probably by modifying the geometry of the SQUID from the square washer format to, perhaps, an in-line configuration. One may hope that the design and testing of such SQUID amplifiers will be undertaken in the not-too-distant future.

## SQUIDs: Biomedical Applications

A major application of SQUID systems (see *SQUIDs: The Instrument*) is in biomagnetism, a discipline where the faint magnetic fields associated with electrophysiological functions of the heart, brain, nerves, or muscles are detected with the ultrahigh field sensitivity of SQUIDs. Biomedical investigations

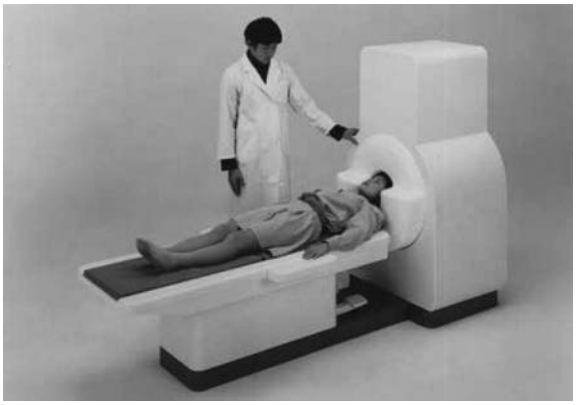

*Figure 1*
SQUID system for magnetoencephalographic investigations.

with magnetic markers or magnetic nanoparticles have also contributed to biomagnetic research. The magnetic fields under investigation in biomagnetism are very weak. Signal amplitudes that are typically measured are in the range $10^{-9}$–$10^{-14}$ T in a frequency range from d.c. to 1 kHz. This requires the sensitivity to magnetic fields that only SQUIDs provide. In addition, very efficient methods for suppressing electric and magnetic interference have to be used.

Modern biomagnetic systems are very complex. With only a few exceptions they are operated in a magnetically shielded room and contain up to 300 low-$T_c$ SQUID sensors maintained at liquid helium temperatures in nonmagnetic fiberglass-reinforced epoxy dewars. Data acquisition, computation, and visualization of results require state-of-the-art information technology. High-$T_c$ SQUIDs and liquid nitrogen cooling are a future prospect and could reduce system complexity and costs.

Figure 1 shows a typical system for magnetoencephalographic investigations. The patient's head is positioned in a helmet-shaped dewar with SQUID sensors fixed inside at the dewar wall in the vicinity of the head.

This article introduces several typical applications. Because of space limitations, only a few instructive examples of biomagnetic applications are covered here to demonstrate the broad spectrum of benefits of biomagnetic SQUID systems. More detailed overviews can be found elsewhere (e.g., Baumgartner *et al*. 1995, Weinstock 1996, Wikswo 1995).

## 1. Gastroenterology

From the physical and analytical point of view, this application is the simplest to handle. The source to be detected is a small magnetic sample, which may be easily modeled as a magnetic dipole with well-known specifications. Thus, if this magnetized sample is prepared and coated in an appropriate manner such that it can be administered without harm, then its passage through the gastrointestinal tract of a person may be monitored with a SQUID system provided with an algorithm to reconstruct the path of the pellet from field measurement results. Weitschies *et al*. (1997) provide further details of this method.

## 2. Peripheral Nerves

Another biomagnetic application that relies on a comparatively simple modeling of the source is the investigation of peripheral nerve function. The signal transmission through the nerve fiber may be modeled as an extended current segment, i.e., by a multipole expansion. If the spatiotemporal magnetic field distribution over the nerve is measured with a multichannel SQUID system, then the reconstruction of the current path may be well approximated.

In practice, difficulties result from the poor signal-to-noise ratio commonly accompanying these experiments. Even with the most sensitive SQUID systems available an averaging of up to $10^4$ stimuli is necessary to recover the relevant magnetic field signal from the noise. Particularly, the heart signal interferes strongly and has to be eliminated by advanced methods of signal processing. Nevertheless, Mackert *et al*. (1998) have been able to detect the blocking of nerve signal transmission.

## 3. Magnetoencephalography (MEG)

MEG is the most successful application of biomagnetic systems from the scientific and the commercial point of view. In 1998 more than 50 multichannel SQUID systems were installed and used for MEG investigations worldwide. The latest system generation contains more than 300 SQUID channels.

Most applications concern fundamental physiological and psychological brain research. Clinical applications concern preoperative evaluation and mapping of brain functions and localization of epileptic foci of patients suffering from epilepsy. For an overview on various aspects of MEG see Lounasma *et al*. (1996).

Technologically demanding is the construction of a nonmagnetic helmet-shaped dewar with a close warm/cold distance between the scalp and the pick-up coils of the SQUID. Another difficulty is to provide a spatially high density of sensor positions without signal cross-talk between the channels.

While all MEG SQUID systems are made using low-$T_c$ technology, there is hope that high-$T_c$ technology should overcome many of the problems mentioned above. The field sensitivity of high-$T_c$ SQUID systems has already proved sufficient for brain research. Somatosensory-evoked cortical fields have

been detected with a high-$T_c$ SQUID (Drung *et al*. 1996) having a white noise of $<10\,\mathrm{fTHz}^{-1/2}$.

## 4. Magnetocardiography (MCG)

Although the maximum amplitude of MCG signals is 1–2 orders of magnitudes higher than typical MEG signals it is necessary to achieve a similarly good signal-to-noise ratio, as the relevant signal components may be of comparably small amplitude. Clinically interesting applications are seen in the field of risk stratification of sudden heart death and myocardial vitality.

One way to derive relevant information from magnetic field maps is to recognize specific patterns or features in the field maps that can be considered as a ''fingerprint'' or ''signature'' of certain physiological or pathophysiological functions in which the physician is interested and wants to discriminate. A common approach is then to quantify these signatures by derived characteristic factors. For instance, patients who suffer from coronary artery heart disease, and thus have a high risk of a sudden heart death, show distinctive alterations in magnetic field maps compared to those of normal subjects. The factors mentioned above reflect these alterations and give a valuable indication as to this risk.

## 5. Source Localization

Many applications demand a ''localization'' of the physiological or pathophysiological function looked for. Technically, this requires a reconstruction of the current density distribution, the ''source,'' that generated the measured magnetic field pattern. Mathematically, this inverse problem, i.e., the calculation of the source distribution with the help of measured field values, is a so-called ill-posed problem, because principally no unique solution exists. However, with the aid of appropriate models an acceptable approximation of the source may be derived. The most common model is the equivalent current dipole, which is of good value in mapping localized brain functions such as evoked cognitive responses.

A more sophisticated algorithm (Fuchs *et al*. 1995 pp. 320–5) models the current density distribution of the investigated brain or heart function by many small current dipoles distributed over the cortex or the heart ventricle only at such positions that come into question on physiological grounds. In this way, the possible solutions of the inverse problem are effectively constrained. The proper anatomic geometry is derived from magnetic resonance imaging.

## 6. Towards Unshielded SQUID Systems

In order to suppress noise due to magnetic fields generated, for example, from power line hum, electric street cars, etc., biomagnetic systems are commonly operated in shielded rooms with thick walls consisting of several layers of mu-metal. Such shielded rooms make SQUID systems very expensive and prohibit a wider distribution of biomagnetic methods. Therefore, many approaches have been tried to reduce the need for passive shielding.

One way is to use gradiometer concepts, i.e., instead of measuring with one magnetometer the magnetic flux at one position, one determines the difference of magnetic flux of two adjacent positions (i.e., the approximation of the gradient of the magnetic field). As the source to be investigated is close to the sensors it provides a strong gradient as compared to a distant interfering source and thus the source signals are enhanced with respect to the interference.

Gradiometric configurations may be achieved with appropriately formed pick-up coils: vertical or planar gradiometers. Another way is to use two magnetometers and subtract their signals from each other electronically, thus forming ''electronic'' gradiometers. Similarly ''software'' gradiometers may be designed.

A modern solution is to configure the SQUIDs to form a reference system that provides all signal information for a sophisticated algorithm, which then generates the appropriate compensation signals to each of the SQUIDs in the measurement plane of a multichannel system. At sites with only moderate interference, such systems have successfully demonstrated an unshielded performance. However, in urban or clinical environments a passive shield may still be necessary. For a detailed analysis of the topic of interference discrimination see Vrba (1996 pp. 117–78).

With HTS SQUIDs unshielded operation is even more difficult owing to the sensitivity to trapped and moving flux lines in the high-$T_c$ material, particularly if the sensors are cooled and moved in the earth's magnetic field.

## SQUIDs: Magnetic Microscopy

Magnetic fields above sample surfaces can be imaged using a superconducting quantum interference device (SQUID) in a scanning SQUID microscope (SSM). Both low critical temperature (low $T_c$) SQUIDs (which have better sensitivity) and high $T_c$ SQUIDs (which can be operated at higher temperatures) (Koelle *et al.* 1999) have been used as SSM sensors. The best low $T_c$ SQUIDs have a flux noise of $\sim 2 \times 10^{-6}\,\Phi_0 \mathrm{Hz}^{-1/2}$, where $\Phi_0 = h/2e = 2.07 \times 10^{-15}$ Wb is the superconducting magnetic flux quantum. A SQUID magnetometer with this noise and a $100\,\mu\mathrm{m}^2$ pickup area can detect magnetic fields of $\sim 40\mathrm{pTHz}^{-1/2}$, a dipole source of $\sim 2500\,\mu_B \mathrm{Hz}^{-1/2}$, a monopole source (e.g., a superconducting vortex) of $\sim 2.5 \times 10^{-6}\,\Phi_0 \mathrm{Hz}^{-1/2}$, and a current line source of $\sim 1\,\mathrm{nAHz}^{-1/2}$. Smaller pickup areas are more sensitive for a dipole field source, while larger pickup areas are more sensitive for a current line source. The spatial resolution is about the size of the effective area, if the source–pickup area spacing is smaller than this size.

Many schemes have been used to scan the sample and couple magnetic fields into the SQUID (Kirtley and Wikswo 1999). Either (i) both sample and SQUID are cold (Figs. 1(a)–(c)), or (ii) the SQUID is cold but the sample is at room temperature (Figs. 1(d)–(f)). The second method has the advantage of not requiring sample cooling, with some sacrifice in spatial resolution. In either case, a bare SQUID (Figs. 1(a) and (d)), a SQUID inductively coupled with a superconducting pickup loop (Figs. 1(b) and (e)), or a superconducting pickup loop integrated into the SQUID design (Fig. 1(c)) can be used to detect the sample magnetic field. In Fig. 1(f), a ferromagnetic tip is used to couple flux from a room temperature sample to a cooled SQUID.

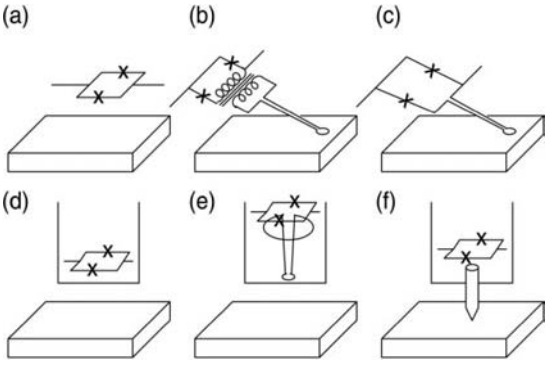

***Figure 1***
Various strategies for scanning the sample relative to the SQUID.

While early systems connected discrete SQUIDs to hand-wound pickup coils, integrated SQUID sensors are now commonplace. In these devices, commonly Nb–$AlO_x$–Nb thin-film SQUIDs, the SQUID junctions, shunt resistors, and modulation coil are connected to the pickup coil through a well-shielded, low-inductance lead structure. Pickup loop sizes as small as 4 μm in diameter have been fabricated: modeling indicates that pickup areas as small as $1\,\mu\mathrm{m}^2$ can be effectively attained. SQUIDs using microbridges as the Josephson weak links (micro-SQUIDs) (Wernsdorfer *et al.* 1996) have been fabricated as small as 1 μm in diameter. These micro-SQUIDs have two orders of magnitude higher flux noise than the best tunnel junction SQUIDs, but can be operated in higher ambient magnetic fields. Most SSMs scan the sample relative to the SQUID mechanically. While not as stiff or as fast as piezoelectric scanners, mechanical scanning affords much larger scan areas ($\sim 1$ cm as compared to $\sim 100\,\mu$m).

SSMs have been used in a number of applications in the fields of biomagnetism, corrosion science, nondestructive evaluation, and superconductivity (Wikswo 1995). Two applications in this last area will be briefly described here.

Exploration of novel superconductors often results in samples with small superconducting concentrations. The SSM is an ideal tool to image samples to determine which parts are superconducting. Figure 2 shows an example (Scott *et al.* 1997). Comparison of optical (Fig. 2(a)) and SSM (Fig. 2(b)) images of a diffusion couple of $Sr_2CuO_3 + 0.05\ KClO_3$ processed at high temperatures and pressures shows that certain regions (the dark gray areas labeled (e) in Fig. 2(a)) are superconducting. These regions are determined by electron microprobe to be $Sr_3Cu_2O_5Cl$.

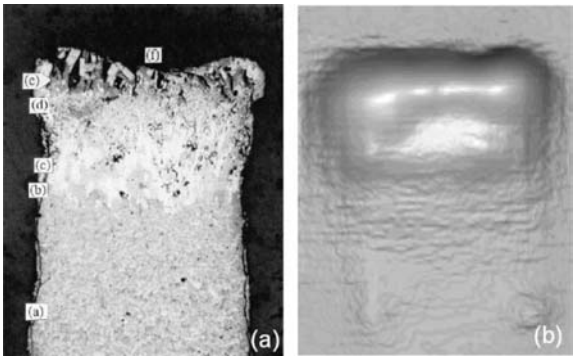

*Figure 2*
(a) Optical micrograph and (b) SQUID microscope image of a partially superconducting sample. The bright areas in (b) are superconducting (after Scott *et al*. 1997).

The SSM has also played a central role in phase-sensitive tests of the pairing symmetry of the high $T_c$ cuprate superconductors. While conventional superconductors have symmetric or s-wave pairing, there is now good evidence that several optimally doped cuprates have predominantly $d_{x^2-y^2}$ symmetry (see the polar plots in Fig. 3) (Scalapino 1995). With such momentum-dependent sign changes, SQUIDs can be designed with junction supercurrents that destructively interfere at zero applied field, rather than constructively interfering, as for conventional SQUIDs. The first phase-sensitive tests measured the interference patterns of such specially constructed SQUIDs (van Harlingen 1995).

Other phase-sensitive tests have employed the SSM (Tsuei *et al*. 1994, Mathai *et al*. 1995). Figure 3 is a SSM image of four thin-film, 58 μm diameter rings of the high $T_c$ cuprate superconductor $YBa_2Cu_3O_{7-\delta}$ (YBCO) epitaxially grown on a tricrystal substrate of $SrTiO_3$. The tricrystal geometry produces a high-energy, frustrated state for a d-wave superconductor. This frustrated state is relaxed by spontaneously generating a supercurrent around the ring, which produces a half-integer multiple of the superconducting flux quantum ($(n+1/2)\Phi_0$, where $n$ is an integer) threading the ring. The SQUID image of Fig. 3 is of the sample cooled in zero field. The three outer control rings have no flux trapped in them; the central frustrated ring has $\Phi_0/2$. A number of optimally doped cuprate high $T_c$ superconductors exhibit the half-flux quantum effect in this geometry, and therefore presumably have predominantly d-wave pairing symmetry.

In summary, magnetic microscopy with SQUIDs has the advantage of high sensitivity, but the disadvantages of the requirement of a cooled sensor and relatively modest spatial resolution. Progress is being made in improved instruments with warmed samples, and with higher spatial resolution.

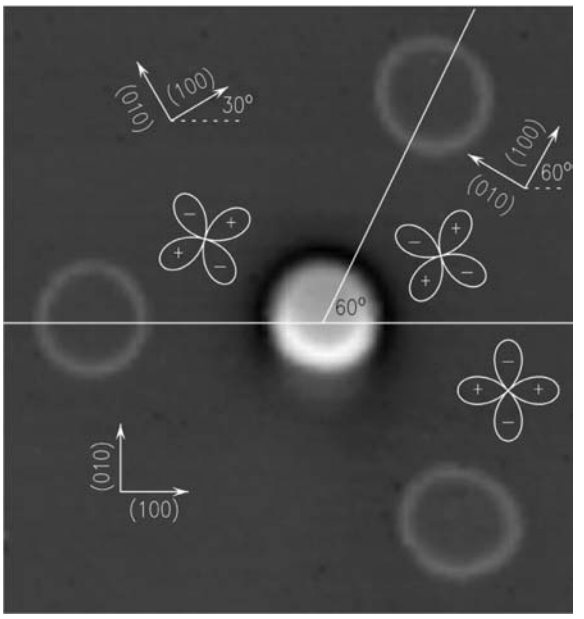

*Figure 3*
SQUID microscope image of thin-film YBCO rings. The presence of a half-flux quantum in the central ring indicates that YBCO has predominantly d-wave pairing symmetry (after Tsuei *et al*. 1994).

## SQUIDs: Nondestructive Testing

The need for inspection has been recognized ever since people began to build machines. Nondestructive evaluation (NDE) techniques that can find hidden flaws are ultrasonics, radiography, and electromagnetic techniques (see *Nondestructive Testing and Evaluation: Overview*). Commonly used magnetic field sensors in NDE are induction coils, Hall probes, and magnetoresistors. Induction coils are versatile; however, they have the inherent disadvantage of measuring only the time derivative of the magnetic field. This requires high signal frequencies for good performance. Following the development of SQUID sensors, many research groups have shown the use of SQUIDs (see *SQUIDs: The Instrument*) in conjunction with electromagnetic NDE (e.g., see reviews by Donaldson *et al.* 1996, Jenks *et al.* 1997). The advantages of SQUIDs include high field sensitivity, wide bandwidth, and, possibly most important, very broad dynamic range in conjunction with excellent linearity.

***Figure 1***
Automated wheel-testing system.

### *1. Eddy Current Inspection*

Eddy current testing by inductive sensors is an important NDE technique, especially for layered structures. The penetration depth of the electromagnetic excitation wave, the so-called skin depth, $\delta_0 = 1/\sqrt{\pi\sigma\mu f}$, restricts the depth at which flaws can be found. For a plane wave excitation with frequency $f$ of a medium with conductivity $\sigma$ and permeability $\mu$, $\delta_0$ denotes the depth of material where the amplitude is attenuated by 1/e and the phase is rotated by $\pi$. Thus, the phase lag of the response signal contains information about the flaw depth. In contrast to conventional techniques, SQUID systems offer a high sensitivity at low excitation frequencies, permitting the detection of deeper flaws, and a high linearity, allowing quantitative evaluation of magnetic field maps from the structure investigated. Several research groups have developed LTS as well as HTS SQUID systems for eddy current testing (e.g., Ma and Wikswo 1993, Podney 1995, Tavrin *et al.* 1996, Cochran *et al.* 1995).

Nondestructive testing (NDT) of new and aging aircraft structures is essential for flight safety and for keeping inspection costs low. Eddy current testing is a widely used NDT method in aircraft maintenance. The applicability of HTS SQUID magnetometers to aircraft testing has been demonstrated by Kreutzbruck *et al.* (1997). Mobile HTS SQUID planar gradiometers with orientation-independent cooling have been developed for eddy current testing of ''second layer'' cracks and corrosion in aircraft fuselages (Krause *et al.* 1997).

The detection of deep cracks in aircraft wheels is one example of the application of HTS SQUIDs to NDT (Hohmann *et al.* 1999). Figure 1 shows the main parts of a wheel-testing unit. The system consists of a rotating table, a robot, and a sensor head. A planar SQUID gradiometer has been integrated with a commercial Joule–Thomson cryocooler, providing liquid nitrogen-free SQUID cooling. For the generation of eddy currents in the sample, a double-D configuration of induction coils is used. Figure 2 shows the measurement of flaws in an aircraft wheel.

### *2. Magnetic Flux Leakage*

Surface or subsurface flaws in ferromagnetic materials are usually detected by magnetizing the test object

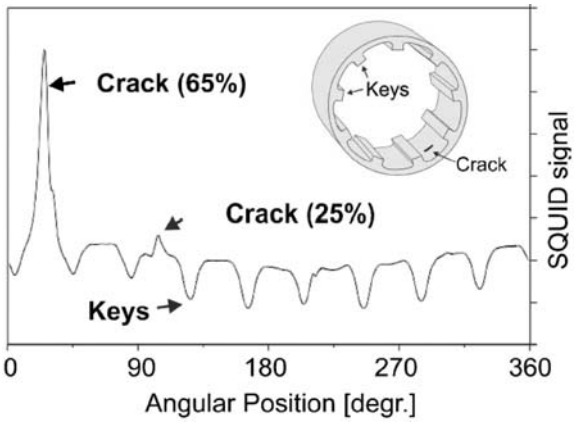

*Figure 2*
SQUID measurement of an aircraft wheel. Two inner flaws that penetrate the wall thickness by 65% and 25% are detected.

and monitoring the magnetic flux leakage (MFL) above the surface. Open voids lead to a strong enhancement of the outside stray field due to the local absence of a high permeability flux guide. Subsurface voids affect the local permeability (magnetization) of the material and, therefore, also the local stray field. These stray fields are observed either while continuously magnetizing the object or by measuring the remanent magnetization. Local changes in the stray field are mapped by means of scanning the magnetic field sensor over the metal.

The MFL technique has been used for the detection of cracks in steel reinforcement rods (rebars) in concrete structures such as bridges or roofs of buildings (Sawade *et al*. 1997). Owing to hydrogen-induced stress and corrosion, cracks and other damage to prestressed concrete members can occur. The rebars are magnetized longitudinally during a scan with a yoke magnet. In the center of the yoke, the stray field is picked up by HTS SQUIDs, having a greater linearity and dynamic range than conventional Hall

*Figure 3*
Inspection of a German highway bridge using a SQUID system.

probe magnetometers, also incorporated into the same scanner. With this system, dangerous cracks were detected in a German freeway bridge with running car traffic (see Fig. 3). Subsequent opening of the concrete at the detected location confirmed the findings, and the bridge had to be decommissioned and demolished.

## 3. Detection of Ferromagnetic Particles

The first certified commercial use of HTS SQUIDs in everyday NDE was the detection of ferrous inclusions in premagnetized aircraft gas turbine disks, fabricated from a special nonmagnetic alloy. The presence of such inclusions may cause cracks in these critical parts, and may eventually lead to engine failure. Tavrin *et al*. (1999) used a second-order unshielded axial gradiometer for determination of the mass, radial position, and depth of small ferromagnetic inclusions in the disk. The disk is slowly rotated on a turntable while the gradiometer is moved radially by a mechanically stable arm. The measurements of remanent magnetization at two different axial distances from the disk surface are used to calculate the magnetic particle depth using the dipolar $1/R^3$ scaling law. The approximate particle mass is then determined from its dipole strength. A particle mass of 1 mg is reliably measurable in the depth range up to 70 mm.

Another approach to the problem of ferromagnetic inclusion detection has been presented by Panaitov *et al*. (1999). A SQUID vector reference is used in a first-order electronic gradiometer to compensate for the disturbances of unshielded environments. Samples with small particles of different sizes and magnetic moments are placed on a scanning table and moved underneath the gradiometer sensor and the axial component of the d.c. magnetic field is recorded. By fitting the measured field profile to a dipole law, the amplitude of the magnetic moment and the distance from the sensor to the particle is determined. Figure 4 shows an example of the measured particle field profile and the dipole fit to the trace.

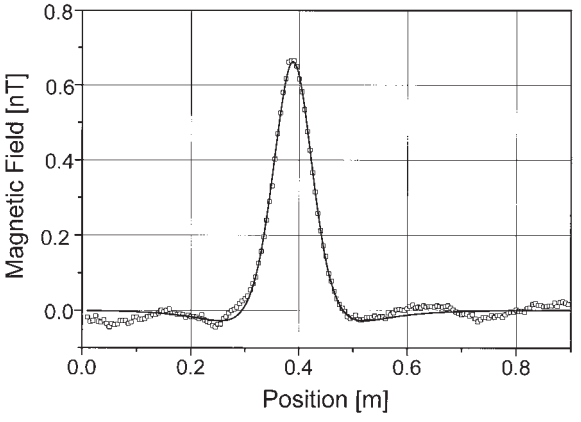

***Figure 4***
Signal of a small magnetic particle, measured with a SQUID gradiometer (squares). From the dipole fit (line) the moment of particle is found to be $2.6 \times 10^{-6}\,\mathrm{Am}^2$, with a minimum distance to the sensor of 87 mm.

## 4. Outlook

Ideally, the end user would like a tomography-like three-dimensional analysis of the material under test, an image of the sample. This requires the solution of the three-dimensional inverse problem: the determination of the source distribution inside an object by measuring the magnetic fields at a few locations outside (cf. Wikswo 1996). Practical implementation of these imaging techniques is expected to become available in the future.

## SQUIDs: The Instrument

The superconducting quantum interference device (SQUID) is exquisitely sensitive to tiny changes in magnetic flux. It can be configured as a very sensitive magnetometer or magnetic field gradiometer, but it can also be used in a wide variety of other applications, for example to measure tiny voltages, to detect very small magnetic moments, and to amplify radio-frequency (RF) signals.

There are two basic types of SQUID. The first, the d.c. SQUID—so called because it operates with a static bias current—consists of two Josephson junctions (see *Josephson Junctions: Low-$T_c$* and *Josephson Junctions: High-$T_c$*) connected in parallel on a superconducting loop. When the magnetic flux threading the loop is changed, the maximum supercurrent the device is able to sustain (the "critical current") oscillates with a period of one flux quantum, $\Phi_0 \equiv h/2e \approx 2.07 \times 10^{-15}$ Wb (see *Electrodynamics of Superconductors: Flux Properties*).

The origin of this effect lies in the flux-induced changes in the phases of the superconducting order parameter across the two junctions in a way that is analogous to the two-slit interference experiment in optics: hence the acronym SQUID. This effect was first observed by Jaklevic *et al.* (1964), and practical—if somewhat primitive—devices quickly followed. By measuring the change in voltage across the current-biased SQUID, one can detect changes in magnetic flux corresponding to a minute fraction of a flux quantum.

The second type of device, the RF SQUID, appeared in 1970, and involves a single Josephson junction incorporated into a superconducting loop (Mercereau 1970, Zimmerman *et al.* 1970). The loop is inductively coupled to the inductance of a resonant circuit that is excited at RFs. The RF voltage across the resonant circuit is periodic in the flux threading the loop with a period, $\Phi_0$, enabling one to detect changes in flux in much the same way as with the d.c. SQUID. RF SQUIDs made from machined blocks of niobium became popular in the early 1970s. However, the development of the thin-film d.c. SQUID in 1976 and the subsequent development of techniques to fabricate thin-film niobium SQUIDs on a wafer scale using microfabrication techniques borrowed from the semiconductor industry resulted in the dominance of this kind of device for low-transition-temperature ($T_c$) superconductors. These devices are mostly used at liquid helium temperatures (4.2 K) or lower.

The advent of high-$T_c$ superconductivity in 1986 led numerous research groups to adopt the SQUID as a vehicle to develop their thin-film and multilayer processing technologies. A wide variety of devices grew from this effort, based on thin films of $YBa_2Cu_3O_{7-x}$ (YBCO), resulting in a viable device technology at liquid nitrogen temperatures (77 K). Although most groups have preferred the d.c. SQUID, its advantage in sensitivity over the RF SQUID is less marked than in the case of low-$T_c$ devices.

This article first outlines the principles of the d.c. SQUID, and then describes practical low-$T_c$ devices and their operation and performance. The principle of the superconducting flux transformer is introduced, and its use in magnetometers and gradiometers is discussed. The fabrication and performance of high-$T_c$ SQUIDs, magnetometers, and gradiometers are described. The principles, fabrication, operation, and performance of high-$T_c$ RF SQUIDs are discussed, and their application as magnetometers and gradiometers is described (Barone 1992, Clarke 1996, Koelle *et al.* 1999).

### 1. Low-$T_c$ d.c. SQUIDs

Figure 1(a) shows the configuration of the d.c. SQUID. Generally, each of the two Josephson junctions is resistively shunted so that the current–voltage ($I$–$V$) characteristic is nonhysteretic, as shown in Fig. 1(b). As one changes the magnetic flux, $\Phi$, threading the loop, the critical current and the $I$–$V$

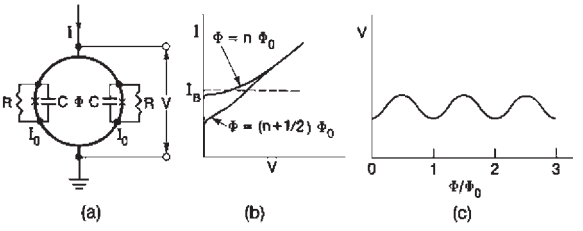

***Figure 1***
d.c. SQUID: (a) schematic; (b) $I$–$V$ characteristic; (c) $V$ vs. $\Phi/\Phi_0$ at constant bias current $I_B$.

characteristic oscillate between the two extremes shown with a period, $\Phi_0$. Thus, when the SQUID is biased with a constant current, $I_B$, the voltage across the SQUID is periodic in $\Phi$, as shown in Fig. 1(c). One operates the SQUID with the bias current adjusted to maximize the amplitude of the voltage oscillations, and the static flux is adjusted to $(n \pm \frac{1}{4})\Phi_0$ ($n$ is an integer) to obtain the maximum transfer function, $V_\Phi \equiv |\partial V/\partial \Phi|_{I_B}$. One measures a flux change $\delta\Phi \ll \Phi_0$ simply by detecting the resulting change in the voltage.

The behavior of the SQUID can be represented by a set of nonlinear equations involving the current and flux biases, the inductance, $L$, of the SQUID loop, the critical current, $I_0$, shunt resistance, $R$, and capacitance, $C$, of the two Josephson junctions, the phase difference across each junction, the voltage across the SQUID, and the Nyquist noise generated by each shunt resistor (Tesche and Clarke 1977). To avoid hysteresis in the $I$–$V$ characteristic, the junction parameters must satisfy the constraint $\beta_c = 2\pi I_0 R^2 C/\Phi_0 \lesssim 1$. There have been extensive computer simulations of these equations in order to obtain parameters that optimize the performance of the SQUID.

These simulations reveal that thermal noise causes the performance of the device to deteriorate significantly unless the magnetic energy per flux quantum, $\Phi_0^2/2L$, exceeds about $40k_BT$. At 4.2 K this constraint places an upper limit on $L$ of about 1 nH. The simulations yield values of $V_\Phi$ and the power spectral density of the voltage noise, $S_V(f)$. From $S_V(f)$ one can obtain the power spectral density of the flux noise, $S_\Phi(f) \equiv S_V(f)/V_\Phi^2$, and the so-called flux noise energy, $\varepsilon(f) = S_\Phi(f)/2L$. The value of $\varepsilon(f)$ is minimized when $\beta_L \equiv 2LI_0/\Phi_0 \approx 1$. For optimum $\beta_L$ one finds $V_\Phi \approx R/L$, $S_V(f) \approx 16k_BTR$, and

$$\varepsilon(f) \approx 16k_BT(LC/\beta_c)^{1/2}; \beta_c \lesssim 1 \qquad (1)$$

In addition, there is a current noise in the SQUID loop that often should be taken into account when the SQUID is coupled to an input circuit.

Equation (1) gives a clear prescription for reducing $\varepsilon(f)$: one should reduce $T$, $L$, and $C$. In practice, the design of SQUIDs is a compromise between these requirements and other practical considerations. For example, for photolithographically patterned tunnel junctions, $C$ will be not less than a few tenths of a picofarad, and in order to couple flux efficiently to the SQUID loop, its inductance should be greater than a few tens of picohenries. The majority of d.c. SQUIDs in use involve a niobium square washer as the loop and two resistively shunted Nb–$Al_xO_y$–Nb tunnel junctions (Fig. 2). The signal to be measured is coupled in via a niobium spiral coil deposited over the washer, with an intervening insulating layer; this arrangement provides efficient magnetic coupling between the coil and the washer (Ketchen and Jaycox 1982). In typical devices, $L$ is in the range 50–200 pH, $I_0$ in the range 5–20 μA, and $R$ in the range 3–10 Ω. There are typically $n = 10$–50 turns on the coil. The self-inductance of the coil and its mutual inductance to the loop are approximately $n^2L$ and $nL$, respectively. These devices are fabricated on silicon substrates using standard photolithographic patterning techniques. The SQUID is often enclosed in a hermetically sealed assembly, and surrounded by a niobium shield to exclude ambient magnetic field fluctuations.

Most SQUIDs are used to measure signals at frequencies up to a few kilohertz, and are invariably operated in a flux-locked loop (Fig. 3). The output current of the amplifier chain is fed into a coil coupled to the SQUID so as to maintain the flux threading it at a constant value. This feedback system produces a linear response to an input magnetic flux,

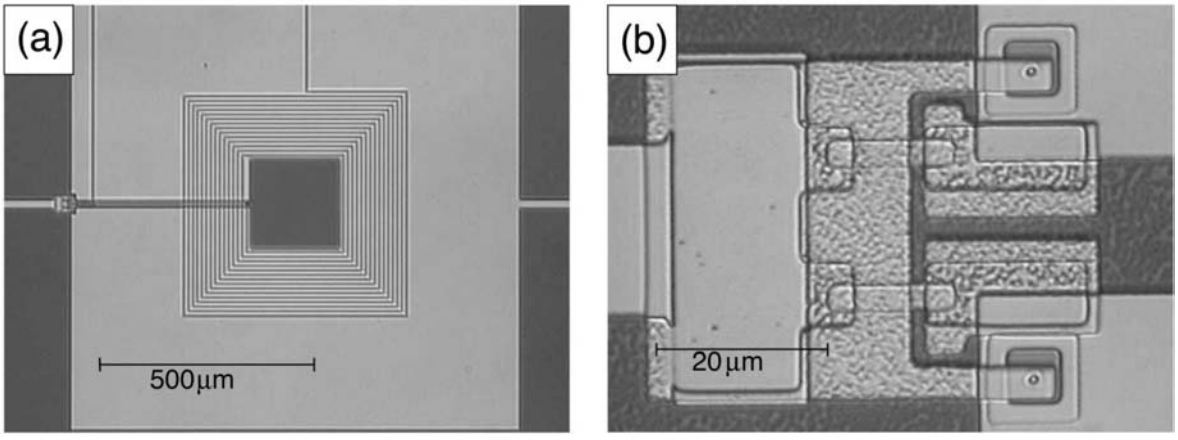

***Figure 2***
(a) d.c. SQUID with 15-turn input coil. (b) Area to left of SQUID washer showing the two junctions and shunt resistors (courtesy of Xiaofan Meng and Robert McDermott).

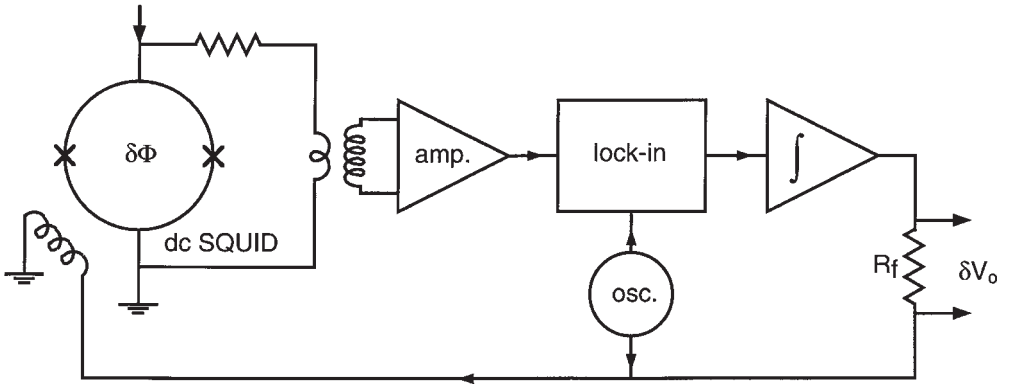

*Figure 3*
Flux-locked loop for d.c. SQUID.

even though it may correspond to many flux quanta, while enabling one to detect a flux change that is much less than one flux quantum.

There are a number of different detection and feedback systems (Drung 1996). The most widely used scheme, shown in Fig. 3, involves the application of a modulating flux, $\Phi_m \cos 2\pi f_m t$, to the SQUID, where $\Phi_m = \Phi_0/4$ and $f_m$ is typically 100 kHz. The resulting alternating voltage across the SQUID is amplified by a transformer (often cooled) and a chain of amplifiers, and is then lock-in detected at frequency $f_m$. If the applied flux in the SQUID is $n\Phi_0$, the $V$–$\Phi$ curve is symmetric about this local minimum, the voltage contains components only at $2f_m$, and the output of the lock-in is zero. When the flux is changed to $n\Phi_0 + \delta\Phi$, there will be a component at $f_m$ and an output from the lock-in. After integration, this signal is fed back to the SQUID via a resistor, $R_f$; the voltage across this resistor is proportional to $\delta\Phi$.

A second popular scheme is "direct readout," in which the SQUID is coupled directly to a low-noise amplifier. The signal from the amplifier is integrated and fed back to a coil coupled to the SQUID as in the flux modulation scheme.

Since the amplifier voltage noise is significantly higher than the intrinsic SQUID noise, the transfer function of the SQUID is enhanced by "additional positive feedback." In this technique, the terminals of the SQUID are connected across a resistor in series with a coil that, in turn, is inductively coupled to the SQUID. When the SQUID is current biased, a change in the voltage across it due to an applied flux generates a current in the shunting network and hence a flux in the SQUID that supports the applied flux. This scheme has the advantage of relatively simple electronics, and can operate at frequencies up to about 10 MHz.

The performance of the d.c. SQUID can be summarized as follows. At 4.2 K the better devices have a flux noise, $S_\Phi^{1/2}(f)$, of 1–2 $\mu\Phi_0\,\mathrm{Hz}^{-1/2}$, corresponding to a noise energy of around $100\hbar$, at frequencies down to roughly 1 Hz; at lower frequencies $S_\Phi^{1/2}(f)$ scales approximately as $1/f^{1/2}$. With properly designed electronics, the measured white noise is largely intrinsic to the SQUID, and its value is in good agreement with computer simulations. Other parameters are determined by the flux-locked loop. For flux-modulated electronics, the bandwidth is typically 0–50 kHz, the dynamic range is $10^7$, and the slew rate is up to $10^7\Phi_0\,\mathrm{s}^{-1}$.

## 2. *Flux Transformer*

Although the SQUID is very sensitive to magnetic flux, because of its small area it is not as sensitive to magnetic fields as one would like for many applications. For this reason, to make a sensitive magnetometer the input coil of the SQUID is connected to an external superconducting circuit to form a flux transformer. Figure 4(a) shows the configuration of a magnetometer. The inductance of the large area pickup loop is approximately matched to the inductance of the much smaller input coil of the SQUID. Some flux transformers involve a loop of niobium wire bonded to the input coil of the SQUID; others consist of a thin niobium film coupled to the input coil and fabricated along with the SQUID to make an integrated device. A typical flux transformer enhances the magnetic field sensitivity by 1–2 orders of magnitude, and the best devices achieve a resolution of 1–2 $\mathrm{fT\,Hz}^{-1/2}$ at frequencies above a few hertz.

To detect weak signals in a magnetically noisy environment, most notably in biomagnetic measurements, one generally uses a flux transformer configured as a gradiometer, for example the first-derivative axial gradiometer shown in Fig. 4(b). The gradiometer attenuates magnetic noise from sources at distances much greater than its baseline—the separation

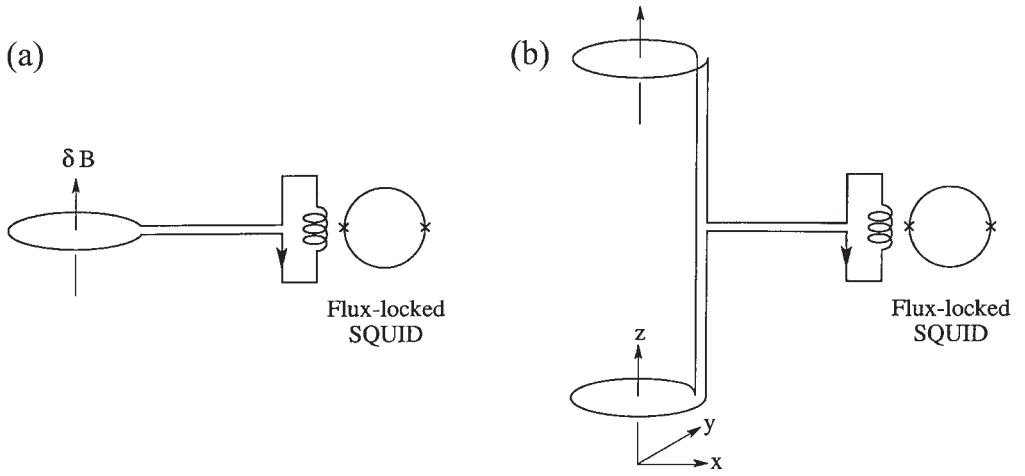

*Figure 4*
Wire-wound superconducting flux transformers: (a) magnetometer; (b) first-derivative axial gradiometer.

of its pickup loops—while leaving signals at a distance less than its baseline largely unattenuated. Second-derivative axial gradiometers are also used, as are thin-film planar gradiometers measuring off-diagonal gradients.

### 3. *Low-$T_c$ SQUIDs as High-frequency Amplifiers*

Low-$T_c$ SQUIDs can be operated at frequencies up to about 100 MHz (see *SQUIDs: Amplifiers*), and have been used as sensitive detectors of NMR and nuclear quadrupole resonance. In this application, the SQUID is operated open loop, with the static flux adjusted to optimize $V_\Phi$. At 100 MHz gains of about 20 dB and noise temperatures of about 1 K have been achieved (Hilbert and Clarke 1985).

A subsequent configuration—the so-called "microstrip SQUID amplifier"—has been realized to amplify signals up to about 1 GHz (Mück *et al*. 1998). In this device the signal is coupled between one end of the spiral input coil and the SQUID washer (Fig. 2), which form a microstrip. When the signal frequency corresponds to the half-wavelength resonance in the microstrip, gains of up to 25 dB have been achieved. Cooled to 20 mK, such amplifiers have noise temperatures close to the quantum limit.

### 4. *High-$T_c$ d.c. SQUIDs*

Most high-$T_c$ SQUIDs (Koelle *et al*. 1999) are intended for operation at 77 K. The constraint $\Phi_0^2/2L \gtrsim 40k_BT$ imposes an upper limit on $L$ of about 50 pH; at this value the constraint $\beta_L \approx 1$ implies $I_0 \approx 20\,\mu A$. All practical high-$T_c$ d.c. SQUIDs are fabricated from thin films of YBCO, deposited by laser ablation, sputtering, or co-evaporation. The major remaining difficulty in the fabrication of these devices is the lack of a reproducible junction technology that produces acceptable parameters at 77 K. The most commonly used junctions involve grain boundaries, formed by the epitaxial growth of the film either on bicrystal substrates or over a step patterned in the substrate, which is usually $SrTiO_3$. The film crossing the grain boundary is patterned to a width of 1–2 μm. Although the results are generally satisfactory, the yield of junctions with acceptable parameters is smaller than is desirable. These junctions do have the virtue of simplicity in that the entire SQUID is patterned in a single layer of YBCO, most usually by ion milling. A dozen or so devices with 500 μm × 500 μm washers can be patterned on a 10 mm × 10 mm substrate.

Compared with their low-$T_c$ counterparts, high-$T_c$ grain boundary junctions produce high levels of $1/f$ noise. Fortunately, this noise can be greatly reduced in the d.c. SQUID by a scheme in which the bias current is reversed, typically at a few kilohertz. The noise of high-$T_c$ SQUIDs varies more widely than that of low-$T_c$ SQUIDs, reflecting the variability in the junction parameters. The best devices achieve a flux noise of about $5\,\mu\Phi_0\,Hz^{-1/2}$ at frequencies down to about 1 Hz, corresponding to a noise energy of $10^{-30}\,J\,Hz^{-1}$, or a little better. For reasons that remain unclear, noise energies are typically an order of magnitude higher than the computed values. Since the flux-locked loop is similar to that used for low-$T_c$ devices, with the addition of bias reversal, comparable values of dynamic range, frequency response, and slew rate are achieved.

The small area of high-$T_c$ SQUIDs mandates the use of a flux transformer for sensitive magnetometers. One approach is to use a configuration much like that of Fig. 2. Although integrated devices of this kind

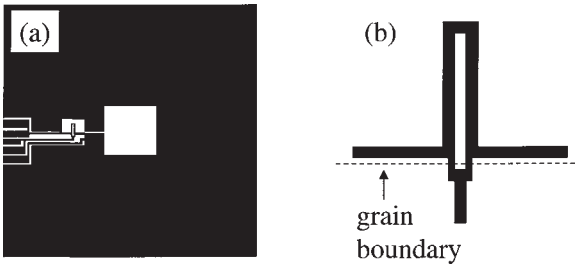

*Figure 5*
(a) Directly coupled magnetometer fabricated from a thin film of YBCO (not to scale); (b) magnified view of the d.c. SQUID showing location of the two grain boundary junctions (courtesy of Hsiao -Mei Cho).

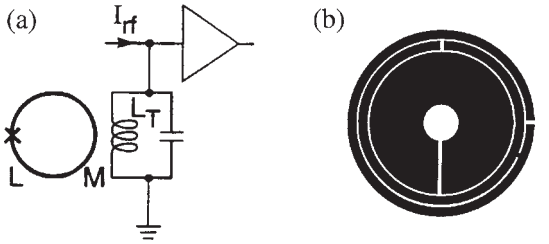

*Figure 6*
RF SQUID. (a) Schematic showing SQUID inductively coupled to a resonant circuit excited by an RF current, $I_{rf}$. (b) Coplanar microwave resonator and flux concentrator; RF SQUID is on a separate substrate, and is not shown (Zhang *et al*. 1998).

have been successfully fabricated, the difficulty of obtaining appropriate junction parameters and a fully epitaxial YBCO–$SrTiO_3$–YBCO multilayer on the same substrate has led to low yields. As a result, many groups have resorted to a flip-chip technology in which the SQUID and flux transformer are made on separate chips that are pressed together face-to-face, separated by a thin insulating layer. The best of these magnetometers achieves a white noise below $10\,\mathrm{fT\,Hz^{-1/2}}$; however, all these multilayer structures exhibit $1/f$ noise, which increases the noise to, typically, $30\,\mathrm{fT\,Hz^{-1/2}}$ at 1 Hz. An alternative approach, illustrated in Fig. 5, is the so-called "directly coupled magnetometer," which has the advantage of being patterned in a single YBCO layer. A current induced in the large area pickup loop by a magnetic field is injected directly into the body of the SQUID. The magnetic field noise of the best devices, about $30\,\mathrm{fT\,Hz^{-1/2}}$, remains constant at frequencies down to about 1 Hz.

Various configurations of gradiometers have been fabricated and tested. Given that suitable high-$T_c$ wire is not available, hardware gradiometers are invariably planar structures that measure off-diagonal gradients. The best of these has a baseline of about 50 mm, and attenuates uniform magnetic fields by roughly $10^3$. In an alternative approach one subtracts the signals from high-$T_c$ magnetometers electronically to form first or second derivatives.

An important issue with high-$T_c$ devices is their operation in an ambient magnetic field, such as that of the earth. When a high-$T_c$ film is field cooled, flux vortices may enter; thermally induced hopping of these vortices can produce large levels of $1/f$ noise. This problem is largely overcome by ensuring that the film has a narrow linewidth, formed, for example, by patterning it with holes or slots.

## 5. *High-$T_c$ RF SQUIDs*

The RF SQUID (Fig. 6(a)) consists of a single Josephson junction integrated into a superconducting loop that is inductively coupled to the inductance, $L_T$, of an $LC$ resonant (tank) circuit. The tank circuit is driven by a current at frequency $\omega_{RF}/2\pi$, and the resultant RF voltage is periodic in the flux applied to the SQUID with period $\Phi_0$. The RF can range from 20 MHz up to 10 GHz. The RF amplitude is demodulated, and this signal is amplified, integrated, and fed back to flux lock the SQUID as in Fig. 3.

Operation of the RF SQUID relies on the fact that the applied flux, $\Phi$, which induces a supercurrent around the loop, in general differs from the total flux, $\Phi_T$. There are two distinct modes of operation. For $\beta_L' \equiv 2\pi L I_0/\Phi_0 > 1$, the plot of $\Phi_T$ vs. $\Phi$ is hysteretic. Energy is dissipated each time an RF cycle traverses a hysteresis loop; the number of these traversals per unit time is periodic in $\Phi$. As a result, the quality factor of the tank circuit and hence the voltage across it at constant RF current are also periodic in $\Phi$. However, for $\beta_L' < 1$ there is no hysteresis and no dissipation. Rather, the SQUID behaves as a parametric inductance, modulating the effective inductance and hence the resonant frequency of the tank circuit as the flux is varied. Consequently, at constant drive frequency the RF voltage is again periodic in $\Phi$.

In the hysteretic regime, for an optimized RF SQUID the noise energy is given by (Chesca 1998)

$$\varepsilon(f) \approx (LI_0^2/2\omega_{RF})(2\pi k_B T/I_0\Phi_0)^{4/3} \qquad (2)$$

Note that $\varepsilon$ scales inversely with $\omega_{RF}$, implying that higher frequency operation results in lower noise. In the nonhysteretic regime, $\varepsilon$ also scales as $1/\omega_{RF}$ up to the limiting value $\omega_{RF} = R/L$, at which frequency, under optimum conditions (Chesca 1998), one obtains

$$\varepsilon(f) \approx 3k_B T/(\beta_L')^2 (R/L) \qquad (3)$$

Equations (2) and (3) show that $\varepsilon(f)$ increases with $T$. For low-$T_c$ SQUIDs, however, the noise temperature of the amplifier coupled to the tank circuit is often much higher than the bath temperature so that

the system noise is much greater than the intrinsic noise. This is one reason why the d.c. SQUID is preferred. When the temperature is raised to 77 K the intrinsic noise of the d.c. SQUID increases, while the effective system noise temperature of the RF SQUID changes little. As a result, at 77 K the noise energy of the RF SQUID, operated at gigahertz frequencies, is not very different from that of the d.c. SQUID.

The first generation of RF SQUIDs involved thin-film YBCO washers containing a central hole and a slit connected by one (or often two) grain boundary junctions. The washer was inductively coupled to a tank circuit, excited at frequencies that ranged from 20 MHz to 200 MHz. The magnetic field sensitivity could be enhanced by means of a flux concentrator, made from bulk YBCO, or a single-layer flux transformer. The most sensitive of these devices achieved a magnetic field noise below 30 fT $Hz^{-1/2}$ at frequencies down to about 1 Hz. However, the large size of these magnetometers—up to 50 mm across—limited their applicability. Subsequently, operation at higher frequencies, 1–3 GHz, was achieved by replacing the lumped tank circuit with a microwave resonator. In the design shown in Fig. 6(b) the circular RF SQUID (not shown) is flip-chip coupled to the YBCO resonator, which consists of a flux concentrator surrounded by two coplanar lines (Zhang *et al.* 1998). The relative position of the gaps in these lines and of the connection between them enables one to adjust the resonant frequency. This configuration is straightforward to fabricate, involving the fabrication of a single-layer RF SQUID on one chip and of a single-layer resonator on the other. The best white noise achieved is below 20 fT $Hz^{-1/2}$; however, the level of $1/f$ noise is high, about 100 fT $Hz^{-1/2}$ at 1 Hz. More sophisticated devices with a multiturn flux transformer integrated with the resonator have also been developed.

A detailed comparison of the measured and predicted noise of the RF SQUID has proved difficult, partly because it is difficult to determine the critical current accurately so that it is not clear whether $\beta'_L$ is greater or less than unity. It is likely that some devices are operated in a mixed mode in which the flux-dependent RF signal is produced by variations in both dissipation and inductance. RF SQUIDs have been configured as gradiometers using both thin-film structures and electronic subtraction of magnetometers.

## 6. Final Remarks

The technology of low-$T_c$ d.c. SQUIDs, based on Nb–$Al_xO_y$–Nb tunnel junctions, is highly developed, enabling one to fabricate reproducible devices in quantity on 2–4 in (5–10 cm) silicon washers. The sensitivity of these devices as magnetometers, around 1 fT $Hz^{-1/2}$, surpasses the demands of virtually all applications. Thus, there is little research on low-$T_c$ d.c. SQUIDs themselves, at least for low-frequency applications, although there are ongoing efforts to make the associated electronics less expensive, particularly for systems with large numbers of channels. The emphasis is much more on applications, most notably in biomagnetism (Hämäläinen *et al.* 1993, Vrba 1996) (see *SQUIDs: Biomedical Applications*), nondestructive evaluation (Wikswo 1995) (see *SQUIDs: Nondestructive Testing*), NMR (Greenberg 1998) (see *SQUIDs: Amplifiers*), and a vast array of basic science experiments.

In the high-$T_c$ arena, the magnetic field sensitivity achieved for d.c. SQUIDs is not vastly greater than for RF SQUIDs. However, presumably because of the complexity of the microwave system required for the RF SQUID, most groups prefer the d.c. SQUID. In contrast to the low-$T_c$ situation, there is not yet a satisfactory high-$T_c$ junction technology; most devices rely on grain boundary junctions. The white flux noise of d.c. SQUIDs is unlikely to be reduced significantly until better junctions—with a higher $I_0R$ product—are realized. The $1/f$ noise of single-layer devices is satisfactorily low, but in the case of multilayer structures—which have the lowest white noise—it remains higher than is desirable. It is to be hoped that work to improve the crystalline quality of multilayers and of film edges will reduce the $1/f$ noise. Further investment is also required to manufacture high-$T_c$ SQUIDs in reasonable quantities, and thus reduce their price. However, despite these remaining problems high-$T_c$ SQUIDs are now exploited in various applications, for example magnetocardiology (see *SQUIDs: Biomedical Applications*), nondestructive evaluation (see *SQUIDs: Nondestructive Testing*), and magnetic microscopy (see *SQUIDs: Magnetic Microscopy*).

# Steels, Silicon Iron-based: Magnetic Properties

Electrical steels are used in the cores of electromagnetic devices such as motors, generators, and transformers because of the ability of ferromagnetic materials to magnify the magnetic effects of current-carrying coils (see *Magnets Soft and Hard: Magnetic Domains*). Of the available ferromagnetic materials, iron and its alloys offer the best cost beneficial performance. The torque of a motor is proportional to $B^2$, where $B$ is the intensity of magnetization operating between its stationary and moving parts. Because of this square law relationship even small gains in $B$ lead to useful increases in torque and thus output power.

In the case of transformers, the large magnetizations available from iron enable voltage transformations to be carried out by windings of an acceptable size. The voltage appearing at a transformer winding is related to the rate of flux change $d\Phi/dt$ for the core and is normally of sine form so that operation at high peak flux levels is important.

It is clear that for steels to be of the most use for electrical machines a high working induction is desired, as close as practicable to the approximately 2 T at which iron becomes saturated.

At the same time a high permeability (ratio of $B$ to $H$) or flux magnifying property is desired. The effective permeability of iron reduces as saturation is approached leading to heavier demands on magnetizing current.

Additionally the duties of core steel must be executed without serious wastage of energy within the metal (called power loss or core loss) due to the periodic magnetic reversals involved in use.

The range of electrical steels available has arisen out of the appropriate compromises struck between these factors. Different types of steel suit different applications (see Table 1).

## 1. Reduction of Power Loss

One of the primary sources of power loss within an electrical steel is eddy current loss (see *Magnetic Losses*). If a solid iron core is placed within a magnetizing coil the iron core itself provides short-circuited current paths in which so-called induced ''eddy currents'' can flow. These waste energy as heat and also produce magnetic fields which oppose the magnetization (Lenz's law effects) so that penetration of flux to the centre of the core is inhibited. Eddy currents can be radically reduced by splitting up the core into laminae which restricts the flow of eddy currents (Fig. 1). There are limits to the degree of lamination which can be applied set by the cost of rolling steel to reduced thickness and the complexity of handling this material for core building. Inevitably as thinner steel is used the effective space occupancy of the metal reduces since a pile of plates can never have the same mass as solid metal of the same superficial dimensions.

Further the need to insulate laminae from each other by applying coatings reduces the effective space occupancy. Overall the effect is to reduce the apparent saturation induction of the core. Lamination creates much more metal surface, and surfaces produce power loss due to domain wall pinning.

A second means of restraining eddy currents is the use of alloying elements added to iron. Adding some 3% of silicon to iron raises its resistivity fourfold. Many other elements have been tried as resistivity raisers (e.g., aluminum) but silicon has proved to be the most useful. Adding silicon certainly reduces eddy currents (and so power loss) but the resulting alloys are more difficult to roll and harder to punch into laminations. Further, added silicon dilutes the iron

***Table 1***
Typical electrical steels.

| Type of steel | Thickness | Power loss | Conventional density (g cm$^{-3}$) | Relative permeability | Usage |
|---|---|---|---|---|---|
| Non-oriented motor grade requiring customer anneal | 0.65 mm | 7.0 W kg$^{-1}$ $\hat{B}$ 1.5 T, 50 Hz | 7.85 | 3000 at 1.5 T | Small |
| Non-oriented superior motor grade, requiring customer anneal | 0.5 mm | 3.8 W kg$^{-1}$ $\hat{B}$ 1.5 T, 50 Hz | 7.85 | 3000 at 1.5 T | Small/medium motors |
| Non oriented fully annealed | 0.5 mm | 5.3 W kg$^{-1}$ $\hat{B}$ 1.5 T, 50 Hz | 7.75 | 1620 at 1.5 T | Larger rotating machines small transformers |
| Non oriented fully annealed | 0.35 mm | 2.25 W kg$^{-1}$ $\hat{B}$ 1.5 T, 50 Hz | 7.60 | 660 at 1.5 T | Large rotating machines |
| Grain oriented steel (CGO) | 0.27 mm | 0.78 W kg$^{-1}$ $\hat{B}$ 1.5 T, 50 Hz | 7.65 | 1.83 T at 800 A m$^{-1}$ Rel $\mu$ 1830 at 1.83 T | Transformers |
| High permeability grain oriented steel | 0.27 mm | 0.98 W kg$^{-1}$ $\hat{B}$ 1.7 T, 50 Hz | 7.65 | 1.93 T at 800 A m$^{-1}$ Rel $\mu$ 1930 at 1.93 T | Transformers |
| Relay soft iron | 1.0 mm | – | 7.85 | Coercive field strength | 56–80 A m$^{-1}$ |

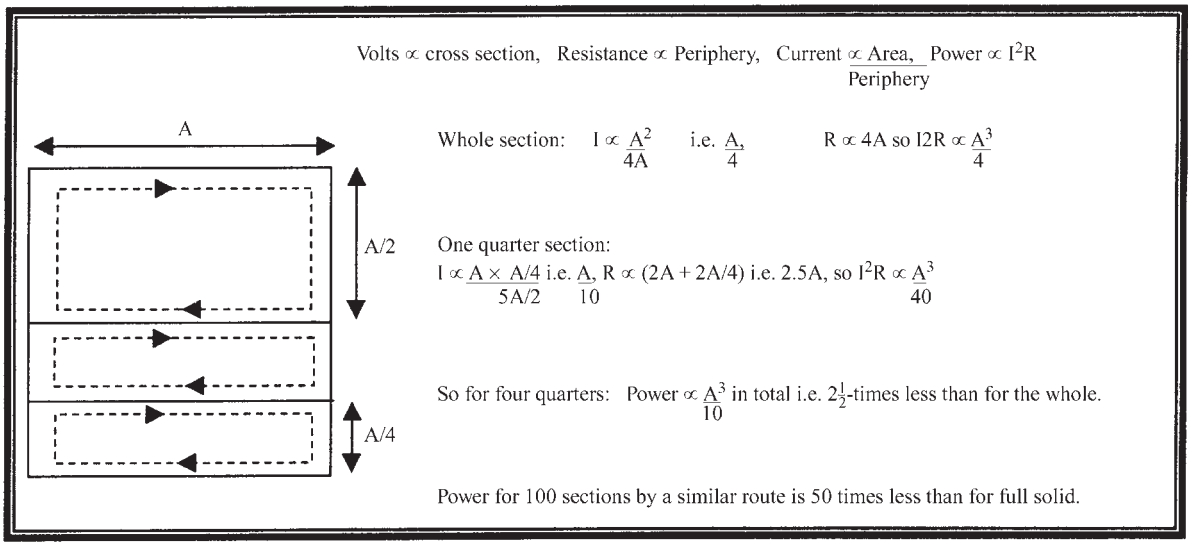

***Figure 1***
Lamination restrains eddy currents and reduces power wastage—a simplified model.

present and reduces saturation magnetization and high field permeability.

A second major component of power loss is hysteresis loss. If a plot is made of $B$ vs. $H$ over a cycle of magnetization then the area of the resulting $B$–$H$ loop represents lost energy. The mechanism of this so-called "hysteresis loss" relates to the fact that the magnetization in iron functions via ferromagnetic domain wall motion (see *Magnetic Hysteresis*). Easy domain wall motion is impeded by non-magnetic inclusions in the steel, stressed regions and unfavorable surface states. Clearly it is advantageous for the steel

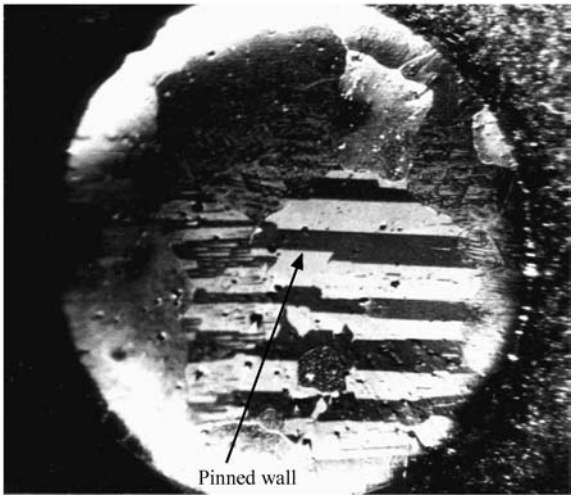

***Figure 2***
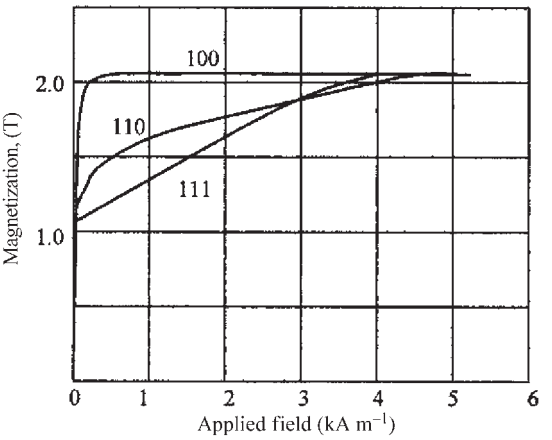
Magneto-optic image of ferromagnetic domains.



The 100 direction is the easy cube edge direction
The 110 is the hard cube face diagonal direction
The 111 is the hardest cube body body diagonal direction.

***Figure 3***
Responses to magnetizing fields of different crystal directions.

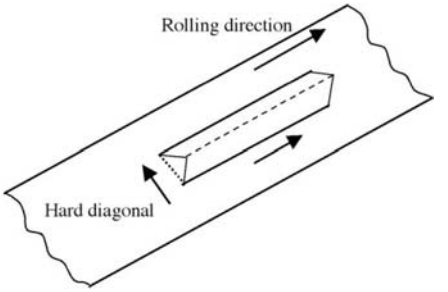


***Figure 4***
A ''Goss-oriented'' crystal's relationship to the sheet rolling direction.

to be inclusion-free (high purity) and free from stress. Domain wall pinning occurs at surfaces so that no more surface than is appropriate should be created (i.e., steel not too thin). The bonding of coatings to steel can produce effective roughness at the coating/steel interface which pins domain walls and adds to hysteresis loss. Figure 2 shows the domain structure in an electrical steel in which a domain wall is clearly shown with part of its length pinned.

A further contribution to loss reduction comes from increasing grain size of the steel. With larger grains (crystallites) there is less grain boundary per unit volume. Grain boundaries are prime domain wall pinning sites. Special rolling and heat treatment regimes are used to promote grain growth. Appropriate heat treatments also relieve stress.

Permeability (in certain directions) can be enhanced by growing grains in which the easy direction of magnetization of the iron lattice (Fig. 3) is caused to lie along the direction in which magnetization is desired. This process of ''grain orientation'' is commonly based on the creation of directionally organized impurity particles, which act to inhibit grain growth in directions other than that desired. To perform this operation, impurities are purposely added to steel at the melting stage (e.g., manganese sulfide, aluminum nitride) so that during subsequent metallurgical operations grains with easy directions of magnetic response in the rolling direction of production are grown preferentially. Figure 4 shows the orientation for the most used Goss grains system.

The statistics of grain growth require that if only certain nuclei are allowed to grow, then from a reduced population the resulting grains will be large. In so-called conventional grain oriented (CGO) steel grains are some 3–4 mm across in metal 0.27 mm thick. The easy direction of magnetization of the grains lies within a spread of a few degrees about the rolling direction.

The desire to get the very highest in-rolling-direction permeability from steel has led to the devising of better and better grain growth inhibitors so that the so-called ''improved oriented steel'' can have a directionality spread of only 1–2°. This precision has arisen from the requirement that only super-accurately oriented nuclei grow. The growth statistics now lead to grains, which may be 2–3 cm across. This sounds good as orientation is excellent and grain boundaries are few.

However, the magnetic energy considerations within a grain dictate that large grains support wide domain wall spacings. With a wide domain wall spacing walls must move more rapidly to execute the required

flux reversal. A rapidly moving domain wall is a dissipative item due to the micro eddy currents induced by its movement.

This effect can be countered to some degree by creating artificial grain boundaries and reducing the domain wall spacing. Such artificial grain boundaries can be created by lines of mechanical damage or stress, or even gross displacement of metal at the steel surface. Such domain refinement can use laser treatments, spark ablation, ball scribing, etc., to give the desired effect. Figure 5 shows the effect of domain refinement.

The addition of silicon not only restrains eddy currents but improves medium-field permeability and reduces the tendency for losses to rise over time due to the occurrence of fine precipitates within grains.

It is often suggested that eddy current losses increase with the square of frequency of excitation and hysteresis losses linearly. However, complex domain interactions produce losses in excess of this simple model. From the point of view of machine-design engineers, losses are fairly well described by the equation:

$$\text{Loss} = Af + Bf^2 \ (f = \text{frequency}).$$

Here $A$ is a coefficient linked to hysteresis, though not exclusively, and it is increased by the effects of stress and impurities. $B$ is a coefficient influenced by material thickness and resistivity, but also by domain wall spacing.

In general power loss increases with the amplitude of magnetization and the hysteresis component rises with approximately the 1.6 power of $B_{max}$. This is a useful indicator within the normal range of magnetizations.

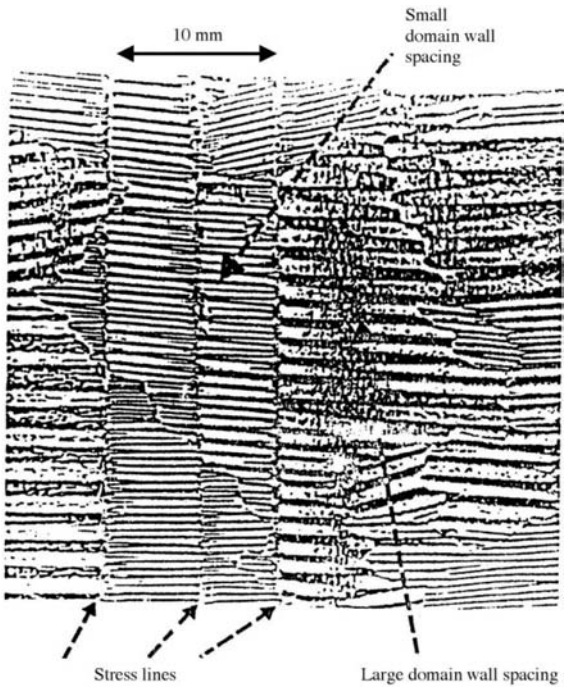

***Figure 5***
Example of domain refinement.

## 2. *Steel for Transformers*

The production of grain orientation is very valuable for materials destined for use in transformers since unidirectional flux is employed (except at joints and corners). In cores where the percentage of corner region is relatively high conventional grain oriented steel may be preferred as the less exact orientation eases flux rotation at corners. Figure 6 shows cores of differing aspect ratio. Where the long limbs and smaller percentage of corner is used the super-oriented steel can be best exploited. It is usual to employ super-oriented steel at higher working inductions ($B_{max}$ 1.7 T and above) than is usual for CGO ($B_{max} \approx 1.5$ T). However, in any system over voltage can more rapidly take steel operating at $B_{max}$ 1.7 T into technical saturation when severe unwanted magnetizing currents will flow.

## 3. *Steel for Rotating Machines*

Grain orientation of the Goss type is unsuitable for the cores of most motors and generators where properties need to be equal at all angles in the plane

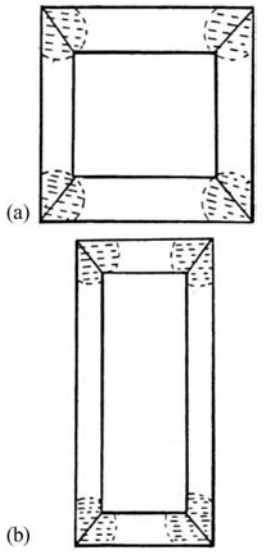

***Figure 6***
(a) A core with low aspect ratio, (b) a core with high aspect ratio.

of the sheet. Here the benefits of lamination and added silicon still apply and enhanced purity with large grains is desirable. Large grains can be produced by two main methods.

### 3.1 Long Hot Anneal

Steel strip can be annealed at about 1000 °C in a strand anneal line so that grains may grow to some tens of microns in diameter. Combined with a moderate amount of added silicon, e.g., 1–3%, a good core material is produced which is nearly isotropic. After such an anneal the steel is soft but the added silicon raises hardness to a degree where stamping into motor laminations is fairly convenient.

### 3.2 Critical Grain Growth

Here strip steel is annealed in a strand anneal line then given a small amount of cold rolling, reducing thickness by about 8%. This is just enough cold work to build in sufficient strain energy to provide "explosive" grain growth when the metal is re-heat treated at about 800 °C. This can usefully be applied after stamping of the steel which was done while still hard from cold rolling. The removal of stamping stress is combined with the beneficial effects of critical grain growth.

### 3.3 Decarburization

A strand anneal conducted in wet hydrogen, e.g., 800 °C and a dew point of 65 °C enables dissolved carbon to be removed down to some 0.003%. This practice helps reduce hysteresis loss.

Further, end users can make the final post-stamping anneal a decarburizing anneal. In recent years it has become possible to reduce carbon to very low levels at the steel making stage of production so that anneals can be conducted in a neutral gas, e.g., nitrogen. The application of a wet hydrogen anneal when carbon is already low can damage the metal by the production of sub-surface oxidation which harms permeability.

A wide range of highly developed methods exists for the management of lamination annealing for stress removal and decarburization.

## 4. Coatings

A variety of coatings are used on electrical steels. On grain oriented steel a magnesium oxide coating is applied to the steel before final anneal so that the sulfur which was introduced to control grain growth for orientation can be finally removed. This coating reacts with the silicon in the steel to yield a magnesium silicate glass, which is both insulative and able to apply tension to the steel substrate due to the low thermal expansivity of the glass A supplementary tensile coating may be applied on top of the glass. Tension in the steel refines the ferromagnetic domain structure and reduces power loss. Non-oriented steel may be given a fully organic coating which aids stamping (no further anneal used), or it may require a mixed organic/inorganic coating, part of which survives anneal.

For small machines, e.g., below kilowatt size, interlaminar insulation is not very dependent on applied coatings and provided that stamping burrs do not create unwanted current paths losses do not rise unduly.

A suitable coating can prevent sticking of laminations when these are annealed in stacks. More recently coatings have been developed which are able to survive cold rolling aimed at eventual critical grain growth so that the overall process is simplified.

## 5. Relay Steels

Electrical steels are normally classified by power loss, and further by permeability. Unalloyed iron intended for use in electromechanical relays is classified by coercive force. ($H$ needed to bring $B$ to zero after full magnetization in ampere-meters). Table 1 shows some typical properties of electrical steels.

## 6. Conclusions

Silicon–iron alloys represent the most widely used and most cost beneficial core materials for devices used in electric power handling.

# Stress Coupled Phenomena: Magnetostriction

In terms of a simple atomic description the equilibrium distances between the constituents of solid matter are mainly determined by forces between electric charges and the thermal energy. These distances can

be altered by externally applied mechanical forces resulting in deformations usually described by the tensor of strains $\varepsilon$. In substances exhibiting an ordered structure of atomic magnetic moments the magnetic interaction energy contributes to the total energy and causes additional deformations $\varepsilon_M$. For a ferromagnetic substance with spontaneous magnetization, $M_S$, these magnetically caused deformations have an isotropic part, resulting in volume changes proportional to $M_S^2$ (Néel 1937) and an anisotropic part (depending on the direction of $\mathbf{M}_S$). $\varepsilon_M$ is connected with the elastic tensor by means of so-called magneto-elastic coupling constants. If $\mathbf{M}_S$ is rotated, e.g., by an external magnetic field, the deformations $\varepsilon_M$ are changed resulting in macroscopic deformations, $\Delta l$, of a sample, often denoted as magnetostriction.

### 1. Volume Magnetostriction ($\lambda_V = \Delta V/V$)

This type of magnetostriction can be observed in cases where $M_S$ is altered either by strong magnetic fields or near the temperature of a magnetic phase transition, e.g., the Curie temperature for ferromagnets. In most cases $\lambda_V$ is proportional to the magnetic field strength $H$. In practicable magnetic fields the slope $\lambda_V/H$ is small ($\sim 10^{-13}$–$10^{-12}$ m/A$^{-1}$). Near the Curie temperature $T_C$, however, $M_S$ can be considerably enhanced by moderate fields. Recently, values of $\lambda_V/H \approx 10^{-8}$ m/A$^{-1}$ were reported for La(Fe$_{0.88}$Si$_{0.12}$)$_{13}$ at $T = 200$ K (Fujita and Fukamichi 1999). On the other hand, $M_S$ changes dramatically with temperature near $T_C$ for a constant field and may induce volume changes equal to or larger than the thermal expansion.

### 2. Joule Magnetostriction $\lambda_J = (\Delta l/l)_{anis}$

The anisotropic part of magnetic deformations was discovered by Joule more than 150 years ago and is therefore often called Joule magnetostriction. In polycrystalline materials with statistically distributed crystalline axes it depends on the angle $\theta$ between $\langle \mathbf{M}_S \rangle$ and the measuring direction where $\langle \mathbf{M}_S \rangle$ is the volume averaged spontaneous magnetization:

$$\lambda_J = (3/2)\lambda_S(\cos^2\theta - \langle \cos^2\theta_0 \rangle)$$

Here $\lambda_S$ denotes the saturation value of $\lambda$ and $\langle \cos^2\theta_0 \rangle$ is the mean value of $\cos^2\theta$ in the initial state. In a single crystal $(\Delta l/l)_{anis}$ additionally depends on the direction of $M_S$ with respect to the crystalline lattice and is, therefore, described by several anisotropy constants $\lambda_n$ depending on the lattice type as well as on the material. Cubic materials, e.g., iron, nickel, and many alloys, are described by two constants $\lambda_{100}$ and $\lambda_{111}$ measured for the cases where the direction of $\mathbf{M}_S$, and that of the measurement, are parallel to the lattice directions [100] and [111], respectively. Therefore,

$$\lambda_J = (3/2)\lambda_{100}[(\alpha_x^2\beta_x^2 + \alpha_y^2\beta_y^2 + \alpha_z^2\beta_z^2) - 1/3] + 3\lambda_{111}(\alpha_x\alpha_y\beta_x\beta_y + \alpha_y\alpha_z\beta_y\beta_z + \alpha_z\alpha_x\beta_z\beta_x)$$

where $\alpha_i$ and $\beta_i$ are the direction cosines of $\mathbf{M}_S$ and the measurement direction with respect to the crystal axes, respectively. Usually $\lambda_n$ values are of different magnitude and may even have opposite signs. A typical example is iron with $\lambda_{100} = 24 \times 10^{-6}$ and $\lambda_{111} = -22 \times 10^{-6}$. Iron often serves as illustration of the apparently complicated dependence of $\lambda_J$ as a function of the field strength. The behavior can simply be explained in terms of magnetic domains. According to the magnetocrystalline anisotropy of iron in small fields the magnetization inside each domain is essentially parallel to one of the three $\langle 100 \rangle$ axes and gets closer to the field direction by shifting the walls between differently oriented $\langle 100 \rangle$ domains, this results in a positive $\Delta l/l$. With an increasing field strength, however, $\mathbf{M}_S$ is rotated away from the $\langle 100 \rangle$ direction. Then, due to the higher probability to find one of the four $\langle 111 \rangle$ axes near the field direction, the negative contribution of $\lambda_{111}$ dominates the initial positive change.

## 3. Theory

### 3.1 Phenomenological Approaches

The simplest way to describe magnetostrictive effects is through mathematical phenomenology: to calculate the dependence of magnetization $\mathbf{M}$ and strain $\varepsilon$ on magnetic field $\mathbf{H}$ and stress $\sigma$ one introduces the so called path-dependent differentials (PDD), the integration of which over the material history should recover the correct $\mathbf{M}$ and $\varepsilon$ behavior. The goal is to construct these PDDs using as few adjustable parameters as possible and yet with enough predictive power to make this approach useful.

By a ''physical'' macroscopic treatment of magnetostriction the magnetization $\mathbf{M}$ is presented as the sum of reversible $\mathbf{M}_r$ and irreversible $\mathbf{M}_{irr}$ contributions. $\mathbf{M}_r$ can then be expressed as a function of the effective field $\mathbf{H}_{eff}$, which, in turn, depends on the magnetization state and elastic stress. The changes of $\mathbf{M}_{irr}$ can be due to various dissipative processes, e.g., domain wall motion. The theory in its simplest form (for an isotropic material) results in a system of nonlinear equations that depend on $\mathbf{M}$ and magnetostriction $\lambda(\mathbf{M})$ (which is also assumed to exhibit hysteresis). The input parameters of the theory (besides the standard material characteristics) are, e.g., the pinning constant and the initial magnetic susceptibility (Sablik and Jiles 1993).

The ''microscopic'' approach, which should be able to predict not only the average properties of

magnetostrictive materials but also their microscopic features, is based on the minimization of the magnetoelastic free energy, written as a function of the magnetization $\mathbf{M}(\mathbf{r})$ and deformation $\varepsilon(\mathbf{r})$ of a magnetic body (James and Kinderlehrer 1994). The energy minimization itself can be carried out either analytically (for simplest cases) or numerically. However, numerical methods, which would allow self-consistent computations of magnetization structures and deformation fields in a general three-dimensional case, are not yet available.

### 3.2 Ab Initio *Calculations*

First principles calculations of magnetostriction constants are now possible for two kinds of magnetic materials:

(i) In transition metals like iron, cobalt, and nickel, where itinerant electrons are responsible for magnetic order, the spin-orbit coupling which leads to the magnetostrictive effects is weak and can be treated using the perturbation theory. Due to the complicated band structure of transition metals, corresponding numerical calculations of the magnetocrystalline anisotropy energy $E_{\mathrm{MCA}}$ (its derivative, with respect to the lattice strain $\varepsilon$, provides information about the magnetostriction constant $\lambda$) are very tedious. However, due to recent methodological progress, monotonic and numerically stable dependencies of $E_{\mathrm{MCA}}(\varepsilon)$ can be obtained (Wu *et al*. 1998) leading to a reasonable quantitative agreement (within 15–30%) between the experimentally measured $\lambda$-values and theoretical results.

(ii) In most rare earth elements magnetic properties are dominated by localized *f*-electrons, and the corresponding spin-orbit coupling is so large that the opposite limit of infinite coupling is a good basis for the calculations. In this limit the charge density of the *f*-shell is assumed to follow the orientation of the atomic magnetic moment in an applied field. Due to the strong anisotropy of this charge density, a large lattice distortion occurs on rotation of these *f*-electron clouds, thus leading to huge magnetostriction. Corresponding *ab initio* calculations (Buck and Fähnle 1998) require the determination of the equilibrium lattice constants of rare earth compounds when the sample magnetic moment is oriented along various crystallographic directions. Magnetostriction $\lambda$ can then be determined from the relative difference between these constants. Unfortunately, a comparison with experimental data is difficult at present due to their relatively poor quality.

## 4. *Applications*

Volume magnetostriction can be used to adjust the thermal expansion coefficient in certain temperature regions, e.g., for invar and covar alloys. The latter is widely used for metal-glass seals and in large cooling cells for liquid hydrogen shipping. Joule magnetostriction was initially used for ultrasound generators and is, at present, applied in many other systems as well. A material composed of two compounds each consisting of a rare earth element and iron is specially designed for the generation of large elongations at room temperature in small magnetic fields. One of them ($TbFe_2$) yields a giant saturation magnetostriction. It needs, however, a high magnetic field strength. The other ($DyFe_2$) is added to $TbFe_2$ in order to make the combination magnetically soft. The optimized substance containing about 70% $DyFe_2$ yields a $\lambda_S \approx 2 \times 10^{-3}$ at room temperature in a moderate magnetic field and is, therefore, an ideal material for actuators and transducers. Recently, a plan was conceived which would achieve a high magnetostriction combined with a high saturation magnetization. This can be realized by using multilayers consisting of thin films of amorphous TbFe and films of Fe–Co alloys (Quandt and Ludwig 1999). These systems are tailored for applications in optical scanners, micro-valves, linear and rotation micro-motors and micro-pumps. It should be pointed out that this class of substances provides a conversion factor from magnetic to mechanical energy of nearly one.

## 5. *New Effects in Thin Films and Multilayers*

In ultra thin films and multilayers new effects, due to interfaces and large strains, were found. Interfaces give a remarkable contribution to the magneto-elastic coupling at film thicknesses smaller than several nm resulting, e.g., in nearly magnetostriction free $Co_{50}Fe_{50}$ films at a film thickness of about 1.6 nm. $Co_{50}Fe_{50}$ is an alloy with the high saturation magnetostriction of $80 \times 10^{-6}$ in the bulk state. In polycrystalline iron films the saturation magnetostriction changes its sign at a film thickness of 5 nm. In systems where, due to epitaxial growth, giant strains in the range of several percent can be obtained, higher order magneto-elastic coupling coefficients are observed (Sander *et al*. 1999). Their magnitude is comparable even with the usually dominating linear ones. Triggered by these new experimental findings both the scientific and the practical importance of magnetostriction effects have recently received considerable attention.

# Superconducting Machines: Energy Distribution Components

Most of the potential applications of superconductivity in power systems benefit from zero resistance and high critical current densities in the superconducting state thus reducing losses and size of components, for example the generator, transformer, cable (see *Superconducting Wires and Cables: Low-field Applications*), SMES (superconducting magnetic energy storage) and motor. But, there is also a potential application which utilizes the transition from the superconducting to the normal-conducting state in order to limit fault currents. The device is usually referred to as a superconducting fault current limiter (SCFCL).

## *1. Superconducting Transformer*

Transformers are major components of power systems. They allow generation, transmission, and distribution of electrical energy at different voltage levels, leading to economical benefits.

Replacing the copper windings in transformers by a superconductor (SC) offers several opportunities. First it offers reduction in losses, owing to the zero resistance of the conductor. Second it offers reduction of size and weight. Because of higher current densities, the mass of conductor needed can be very small. By applying more winding turns/length in the coils, the amount of iron can be reduced as well. Even iron-free transformers might become feasible. Third, large conventional power transformers are oil-cooled. A superconducting transformer would be more environmentally benign.

In a conventional transformer design the SC will be exposed to alternating magnetic fields up to about 0.3 T. In designs with increased winding turns/length (to reduce iron volume) an even higher magnetic field (B) would be reached. The main challenges for the SC material are high $j_c$ losses, low ac losses at high B, and low cost. Since transformers generate losses not only in the conductor but also in the iron core, it is advisable to leave the core of an SC transformer at room temperature, where cooling is cheaper. Such a design however, poses serious requirements on the cryostat, which would need a warm bore and should ideally be made of nonmagnetic and electrically insulating material in order to avoid additional losses.

### *1.1 Status of Research*

Several SC transformers based on LTS have been built in the past, having a rated power of a few 100 kV A. Commercially available LTS (low temperature superconductor) wires meet technical and economical needs ($j_c$ about $50\,kA\,cm^{-2}$, a.c. losses $<10^{-5}\,W\,A^{-1}\,m^{-1}$ at 0.1 T. However, commercialization of LTS transformers has so far been prohibited by the rather high cooling costs, mainly caused by thermal losses through cryostat and current leads.

HTS offers the opportunity to operate SC transformers at 77 K, which could reduce cooling costs to an acceptable level. But, HTS (high temperature superconductor) wires are not nearly as mature as the LTS wires. At present Bi2223 wire is the only HTS available of sufficient length, which could be operated at 77 K. First prototypes based on these materials have been built. A 630 kV A prototype has already been operated for one year under realistic conditions. Even though the technical feasibility has been proven, the present Bi2223 wire will hardly allow a commercial SC transformer to be built.

At present the 77 K field dependence of $j_c$ ($j_c$(B)), of the wire is too strong and the a.c. losses and wire costs are too high. $J_c$(B) can be improved by operating the transformer at a lower temperature, which of course increases cooling costs. Bi2223 conductors with reduced a.c. losses are under development. The

maximum acceptable losses are in the order of $10^{-4}\,W\,A^{-1}\,m^{-1}$ at 0.1 T; present values are about 10 times higher.

YBCO ($YBa_2Cu_3O_{7-x}$) tapes, even though only available at length of few meters, offer better $j_c(B)$ and potentially lower cost. The a.c. losses in magnetic fields parallel to the YBCO tape will be negligible. However, it will be a great challenge to reduce the losses due to perpendicular field components (occurring mainly at the end of the coils) to an acceptable value. Nevertheless, considering the status of early twenty-first century technology, the material seems to have the highest potential for transformer applications.

## 2. *Superconducting Fault Current Limiter*

In electric power systems short circuits might be caused by aged or accidentally damaged insulation or by lightning striking an overhead line. The subsequent fault current is only limited by the impedance of the system between location of fault and power sources. All components of the power system have to be designed to withstand the stresses caused by a short circuit. The higher the fault current anticipated, the higher the costs for the equipment.

Many approaches for realising fault current limiters (FCL) have been based on components with strongly nonlinear current–voltage characteristics (e.g., semiconductors, iron-core reactors, and superconductors). Among the nonlinear materials, superconductors stand out because of their unique transition from zero to finite resistance. FCLs which utilize this transition will be referred to as superconducting fault current limiters (SCFCLs). FCLs which are based on other concepts but might still use SC, e.g., in order to realize low-loss coils, will not be discussed here. There are essentially two concepts in SCFCLs, i.e., the ''resistive'' and the ''shielded core'' concepts.

### 2.1 *Resistive SCFCL*

The most straightforward concept in an SCFCL is the so called ''resistive SCFCL'' in which the SC is directly connected in series to the line to be protected. For cooling, the SC might be immersed in a coolant (e.g., liquid helium for LTS or liquid nitrogen for HTS), which is chilled by using a refrigerator.

The cross-section of the SC is determined such that, at nominal current, the SC is operated inside the superconducting state, i.e., at zero resistance, so that its interference with the network is negligible. However, the SC only has true zero impedance for direct current (d.c.)-currents. For the more common a.c. applications the finite length of the SC leads to a finite reactance and the alternating magnetic field generated by the current produces a.c. losses. They both depend very strongly on the geometry of the SC, and can be reduced by optimized conductor architecture, e.g., in the coils with windings in opposite directions or meander structures.

In case of a fault, the increase in $j$ will drive the SC out of the superconducting region into a flux–flow regime. The rapidly increasing resistance limits the current to a value below the unlimited prospective fault current. The actual limitation behavior depends very much on the length of the SC and also on the type of SC material. The three main different limitation behaviors can be realized by just varying the length of the same SC material.

First, by using a very long conductor, the electric field $E = (\text{line voltage})/(\text{conductor length})$, to which the SC is exposed during the fault will be very small. Thus, the corresponding current density will exceed the nominal value only by a little. The power density $E_{\cdot j}$ dissipated in the SC will be negligible so that the SC will essentially not warm up (curve 1 in Fig. 1). This ''constant temperature'' design gives a very good limitation. However, the long length of the conductor will be prohibitively expensive and cause rather high a.c. losses.

The other extreme design would be using a rather short conductor, leading to a relatively large $E$ during the fault. As the fault occurs, the current will increase essentially unlimited by the small resistivity of the flux–flow regime and only limited by the impedance of the power system. However, because of the very high $E_{\cdot j}$ dissipated in the SC, the material will heat up rapidly and, after a few 100 μs, will become normal conducting and limit the fault current close to or even below the nominal value (curve 3 of Fig. 1). This ''fast heating'' design needs a rather small amount of SC material. However, the height of the first peak still depends on the unlimited prospective fault current, and instantaneous recovery to normal operation is not possible, since the SC first has to cool down. Furthermore, severe over voltages may arise from the abrupt current reduction, caused by the rapid transition into the normal-conducting state. Last, but not least, the high $E_{\cdot j}$ value during the fault might lead to the SC being damaged.

Using a conductor of intermediate length will lead to an intermediate poor density dissipation in the SC. For the first 10 ms the maximum of the fault current will be limited to several times (e.g., 5–10) that of the nominal current. The SC will keep warming up and after a few tens of milliseconds will enter the normal conducting region (''slow heating'' design, curve 2 in Fig. 1).

### 2.2 *Hot Spots*

In the above discussion it is assumed that during the limitation process the voltage drop is uniform over the whole length of the conductor. In reality,

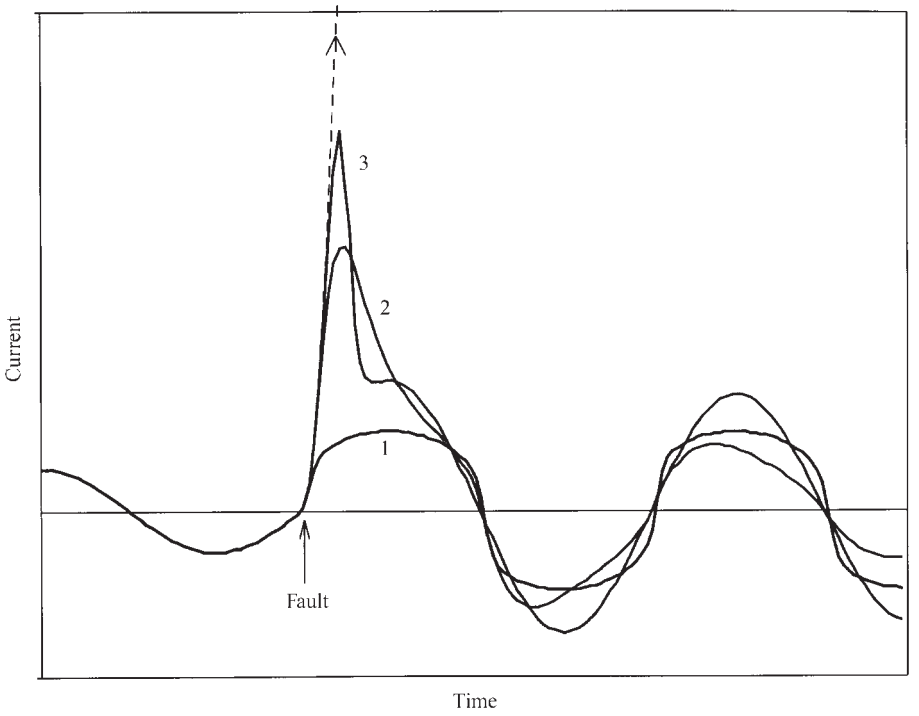

***Figure 1***
Different designs offer different current limitation behaviors. 1, Constant temperature; 2, slow heating; 3, fast heating.

however, SC tends to develop thermal instabilities called "hot spots," which are due to the strong current and temperature dependence of their resistance. The common measure for reducing the problem is to attach a normal conducting "bypass" or "shunt" in close electrical contact to the SC, which allows the current to bypass the hot spot. Of course, the bypass reduces the total normal resistance of the conductor, which might have to be compensated by increased length. It should be noted that the problem of excessive heating will also limit the maximum possible electric field to which the conductor can be exposed during the fault, i.e., it will also set a lower limit for the length of the SC.

### *2.3 Shielded Core SCFCL*

The second concept in a SCFCL is often referred to as the "shielded core." In this concept the SC is not connected galvanically in the line, but magnetically. The device is essentially a transformer, with its primary normal conducting coil connected in series to the line to be protected, while the secondary side is a superconducting tube (i.e., a one turn coil). In normal operation the iron core sees no magnetic field because it is completely shielded by the SC, thus the name "shielded core." Because of the inductive coupling between the line and the SC, the device is sometimes also referred to as an "inductive SCFCL." The voltage on the secondary is reduced by the number of the turns of the primary coil, while the current is increased by the same factor. The SC on the secondary has to be designed for these values. Assuming an ideal transformer, the SCFCL will behave exactly like a resistive SCFCL.

In order to achieve a certain limitation behavior, both types of SCFCL need the same amount of a certain SC material. Compared to the resistive SCFCL, the shielded core SCFCL shows the disadvantage of being only applicable for a.c. currents and having a much larger size and weight. On the other hand it needs no current leads, which is especially attractive for high current applications, since the losses of the leads are proportional to their current-carrying capability.

### *2.4 Status of Research*

Several SCFCL prototypes with a rated power of several MVA have been realized based on LTS following the resistive concept. Because of the high $j_c$ and low heat capacity of LTS the "fast heating" design was the "natural" choice. However, like in the

case of the transformer, commercialization has so far been prohibited by the rather high cooling costs.

To date, the largest HTS SCFCL prototype that has been built utilizes Bi-2212 bulk material. ABB has realized a three-phase 1.2 MV A prototype based on tubes of this material. For ceramic HTS, this geometry is usually more easily realized than long length conductors. The device is of the ''shielded core'' and ''slow heating'' type, it was successfully operated for one year under realistic conditions in a Swiss hydropower plant.

Because of their high critical current density ($1\,MA\,cm^{-2}$) YBCO films are especially suitable for the ''fast heating design.'' Siemens has demonstrated a resistive 300 kV A model based on this material. The films were deposited on planar ceramic substrates, covered with a gold bypass, and patterned into meander.

Bi2223 wires are at present not particularly suitable for SCFCL, because of the low normal resistivity of the Ag-matrix. However, if this resistivity could be increased, the wire would be quite suitable for resistive SCFCL and could even allow for the incorporation of ''current limitation'' functionality in other devices. Following this approach, a project led by ABB in partnership with American Superconductor and Electricité de France has been launched to develop a current limiting transformer.

## Superconducting Machines: Energy Storage

Superconducting magnetic energy storage (SMES) is an emerging technology offering tremendous benefits to the electric power industry. Many years after its conception (Ferrier 1970), SMES is still not widely implemented and its commercial viability is only slowly being established.

### *1. Principles of Operation*

Electric power has always been available on instant demand with a high degree of reliability, flexibility, and control; however, it has never been easy to store in large quantities on a cost-effective and environmentally sound basis.

In SMES, electric energy is stored by circulating a current in a superconducting coil, or inductor. Because no conversion of energy to other forms is involved (e.g., mechanical or chemical), round-trip efficiency can be very high. The energy stored in a d.c. inductor is given by

$$E = \frac{1}{2} LI^2 \qquad (1)$$

where $E$ is the stored energy, $L$ is the inductance of the coil (which depends on coil geometry), and $I$ is the circulated current.

As an energy storage device, SMES is a relatively simple concept. It stores electric energy in the magnetic field generated by d.c. current flowing through a coiled wire. If the coils were wound using a conventional wire such as copper, the magnetic energy would be dissipated as heat owing to the resistance of the wire. However, if the wire is superconducting (no resistance), then energy can be stored in a persistent mode, virtually indefinitely, until required.

The SMES coil, a d.c. device, is usually connected to its load (typically an a.c. device) via an a.c./d.c. converter, or ''power conditioning system'' (PCS).

The architecture of the PCS varies depending on the application, but in general is based on standard semiconductor power switches in arrangements to maximize reliability, efficiency, and controllability.

The only loss associated with magnetic storage is the power needed to keep the coil cryogenically cooled as required by the superconductor. Additionally, there are minor losses associated with power transfers through the a.c./d.c. converter. Overall efficiency of a SMES system is heavily dependent on size (stored energy) and power rating, as well as on duty cycle, but in general SMES units can be much more efficient than many other systems for energy storage.

## 2. *Applications*

In terms of energy storage, SMES competes with other technologies such as batteries, flywheels, and capacitors. The choice of technology is determined by economics (cost) when considering all angles: system performance, capital and operating costs of the unit, reliability and maintainability, environmental and disposal costs, insurance, etc.

SMES is particularly attractive in comparison to other options in cases where a high power/energy ratio is needed (sharp pulses), or when the power pulse repetition rate is high (e.g., tens or even hundreds of pulses per day).

Pulsed power loads such as electromagnetic launch (for military or space applications) could be enabled through the implementation of a SMES system. Buffering pulsating loads in general is a high-payoff application of SMES.

In the electric power sector SMES has two major applications: power quality enhancement, and transmission-related services. Power quality enhancement refers to the ability of SMES systems to sit idle and connected between a load and its utility supply line to ''buffer'' and ''filter'' power quality disturbances such as voltage sags and spikes, harmonic distortions, or frequency problems coming through the utility distribution network. Certain applications needing very sensitive loads (such as is required in semiconductor processing plants) can derive great benefit from access to ''clean'' power and thus pay the premium in price over other storage technologies. At the lower end of stored energy and power (a few megajoules and few megawatts) this is already a commercial application of SMES, with the prospect of capturing a larger market with the development of larger units.

The electric utility industry, being deregulated in most parts of the world, could also be major market for this technology. The applicability of SMES to the utility sector goes well beyond energy storage (daily load leveling). Some of these applications are:

- increased transmission capacity through enhanced line stability;
- spinning reserve;
- leveling of renewable energy sources;
- voltage control;
- frequency control;
- subsynchronous frequency damping;
- wide-area generation control; and
- black start.

Power and energy ratings needed for each of these application vary, from a few hundred megajoules to provide transmission line stabilization, to possibly many gigajoules in the case of spinning reserve for a large network.

In transmission stabilization, a SMES unit is strategically located within a high-voltage network to inject active and/or reactive power on demand to dampen voltage fluctuations that can cause the triggering of protective relays. These fluctuations are usually the result of large generation plants or loads tripping and creating instabilities that cause large-area blackouts. In spinning reserve a SMES unit can act as a infinitely controllable generating unit (with the added benefit of also acting as a ''sink'') to enhance flexibility of dispatch and to provide that extra cushion need to run a transmission network without the need of having ''idling'' plants with the concomitant environmental penalty.

In a fully deregulated utility industry (something not yet achieved) SMES will be an integral part of the network.

## 3. *Technology Development*

The status of SMES in terms of its development and application has been reviewed by Hassenzahl (1989) and by Luongo (1996). The early years of SMES development were mostly devoted to system studies and to determining optimum configurations. During the 1980s the technology saw an increase in activity with the implementation of programs that led to actual hardware being produced. During the 1990s there was somewhat of a retrenchment in terms of development, with relatively few full demonstration programs.

In the early 1980s a 30 MJ SMES unit was installed and tested at the Bonneville Power Authority transmission grid in the USA to demonstrate its ability to dampen subsynchronous resonant frequencies (Rogers *et al*. 1983). Also during the 1980s the US Department of Defense funded the design and development of components needed to build a large-scale SMES units that would serve as pulsed power supplies to military systems. These activities yielded a number of advances in terms of innovative designs and the actual fabrication and testing of major SMES components. Among the advances was the development of a very high-current cable-in-conduit conductor, shown in Fig. 1, rated at 200 kA (at 1.8 K and 5 T), and which was actually tested in short

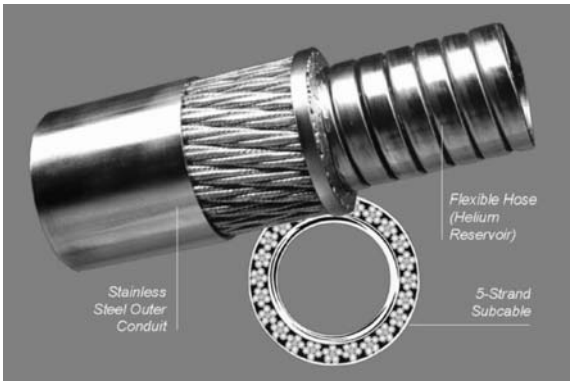

***Figure 1***
High-current cable-in-conduit conductor.

samples under operating condition to its quench current of 300 kA (Peck *et al*. 1994).

In the 1990s most of the development activity took place in Japan with a focus on transmission stability applications as well as the construction and testing of a large SMES model coil (Hamajima 1999).

Previous experience with SMES notwithstanding, it is safe to say that this technology is still in need of an integrated large-scale demonstration under actual operating conditions (e.g., utility environment) before its widespread acceptance in the market.

### *4. Outlook*

Despite its great promise and many years of development, SMES is far from being the commercial success once envisioned. Even though the technology is making some inroads into the marketplace (at the lower end of storage/power ratings), it is far from mature or being widely accepted. The main stumbling block for wider dissemination of SMES is not technical, but rather economic. The extremely high cost of superconducting devices does not justify the economic benefits that could be accrued in most applications. The advent of high-temperature superconductor (HTS) materials has done little to advance the deployment of SMES. Major reductions in the price of these superconductors would be needed before they can make an impact on the commercial viability of SMES. Operation at higher temperature alone does not justify adoption of HTS materials, as operating costs are typically a small component of lifecycle cost for SMES units of practical size.

Continued advances in SMES technology are nevertheless likely. One-of-a-kind units for specific applications will give SMES opportunities to demonstrate its benefits. Through this evolutionary chain of development SMES will some day take its promised role in the electric power industry.

## Superconducting Materials, Types of

In 1911 the Dutch physicist Heike Kamerlingh Onnes (Onnes 1911) observed during studies of the electric properties of pure metals at temperatures near absolute zero (0 K or −273.15 °C), that the resistance of a mercury wire dropped precipitously when cooled to below 4.2 K (−268.95 °C). He soon recognized this to be the manifestation of a new state of matter ''which on account of its extraordinary electrical properties may be called the superconducting state.''

For over 20 years after the discovery of superconductivity, this new state was believed to be just an ideal conductor that loses its resistance below a distinct temperature, the so-called critical temperature, $T_c$. In the year 1933, Meissner and Ochsenfeld (1933) discovered that magnetic fields are excluded from the inside of a superconductor even on cooling in a constant magnetic field that could not be explained by classical electrodynamics. This effect is known today as the Meissner–Ochsenfeld effect.

Bardeen, Cooper, and Schrieffer published their comprehensive theory of superconductivity in 1957 (Bardeen *et al*. 1957). The salient point of the so-called BCS theory is the attractive electron interaction mediated by phonons. By that virtue, two electrons couple to form so-called Cooper pairs, which act in a fundamentally different way from single electrons. Being quasi-particles with integer spin, Cooper pairs follow the Bose–Einstein statistics

which allows them to condense into a single quantum mechanical state, with all Cooper pairs having the same wave function. Thus, superconductivity is often referred to as a macroscopic quantum phenomenon. The BCS theory was very successful in predicting the critical temperature of a material and provided an explanation for the isotope effect, according to which the critical temperature shifts as a function of the isotopic mass of chemical elements.

With the discovery of materials showing transition temperatures near and above 100 K, it became evident that the BCS theory would not be adequate to describe this new class of superconductors, known as high-temperature superconductors, in contrast to the term "low-temperature superconductor" which comprises all superconductors with critical temperatures below about 30 K. Experiments gave evidence that the charge carriers of superconductivity are Cooper pairs. But, the question about the nature of the force that keeps the Cooper pairs together is still a matter of investigation.

Since the first observation of superconductivity in mercury, thousands of compounds and alloys were investigated with respect to their superconducting properties. In Fig. 1 the fever curve of superconductivity is shown, which is marked by the highest critical temperature known during that time. Since 1993, several new superconductors have been found. None of them, however, have surpassed the world champion $HgBa_2Ca_2Cu_3O_8$ exhibiting a $T_c$ of 138 K at ambient pressure, and 164 K at an isostatic pressure of 23 GPa.

## 1. Type 1 Superconductors

Type 1 superconductors—also known as the "soft" superconductors—are characterized by a very sharp transition to a superconducting state at $T_c$, and by "perfect" Meissner–Ochsenfeld effect up to the so-called critical field, $B_c$. Above $B_c$, the material becomes normal conducting. Even here, the transition is very sharp (Fig. 2). The value of $B_c$ is temperature dependent and reaches zero at $T_c$. However, the magnetic field is not repelled at the surface of the superconductor, but penetrates it within a $10^{-8}$–$10^{-7}$ m thick surface layer causing screening electric currents in the surface layer. These currents generate a magnetic field which is anti-polarized to the external field. This phenomenon is the reason for the well-known levitation effect of a permanent magnet above a superconductor, or vice versa.

The so-called penetration depth, $\lambda$, of the external magnetic field is a material property. It also is temperature dependent and increases asymptotically towards $T_c$. At the particular field $B_c$ relatively thick normal and superconducting domains running parallel to the field can coexist, known as the intermediate state.

## 2. Type 2 Superconductors

Type 2 superconductors—also known as the "hard" superconductors—differ from Type 1 in that their transition from a normal to a superconducting state is gradual across a region of "mixed state" behavior.

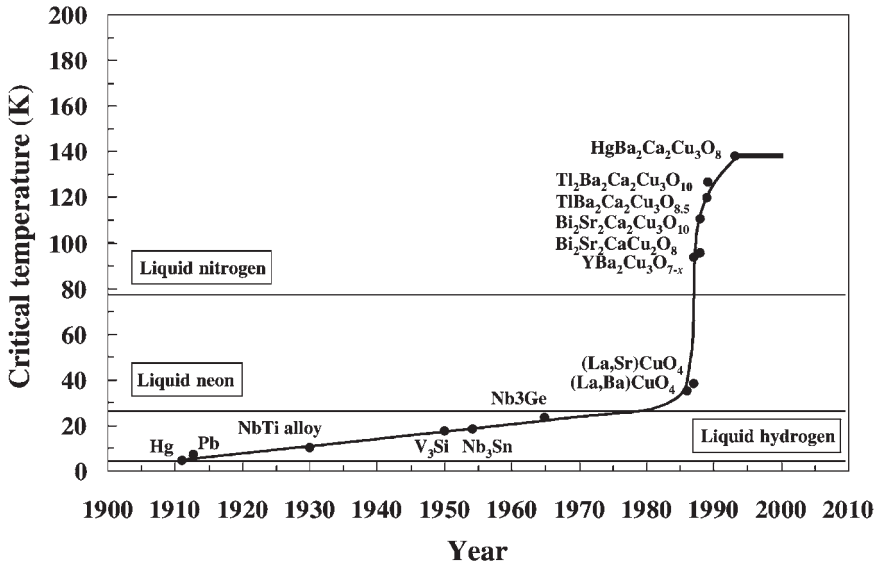

*Figure 1*
Maximum critical temperature vs. time.

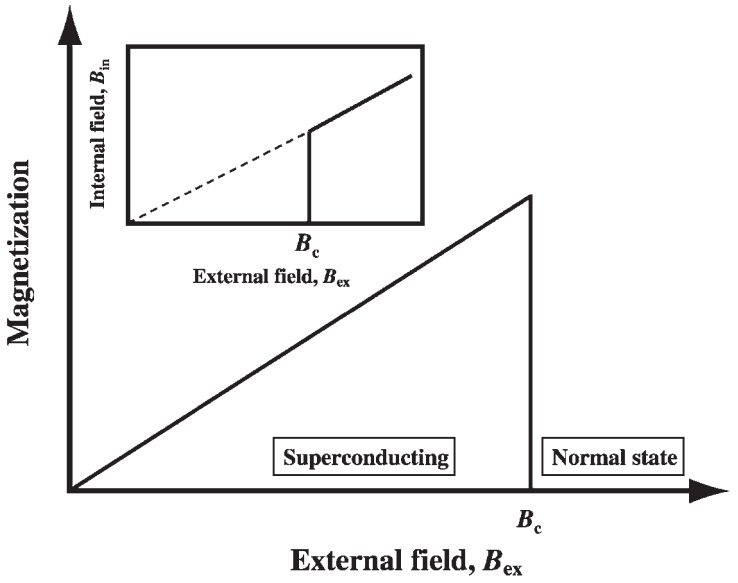

***Figure 2***
Magnetization of a Type 1 superconductor vs. the external field, $B_{ex}$. Insert: Magnetic field within a Type 1 superconductor, $B_{in}$, vs. the external field, $B_{ex}$.

A Type 2 superconductor exhibits a very different behavior in an external magnetic field compared to the Type 1 superconductors. At low external fields, like the Type 1 superconductor it repels the magnetic field up to the lower critical field, $B_{c1}$. This region is also called the "Meissner phase." Above $B_{c1}$, regularly divided quantified flux vortices or flux lines enter the material up to the so-called upper critical field, $B_{c2}$ (Fig. 3). In the region between $B_{c1}$ and $B_{c2}$, superconducting and nonsuperconducting areas with trapped magnetic flux lines are present (Fig. 4). With increasing magnetic fields, the trapped flux lines move closer together and more trapped flux lines occur, so that the superconducting volume decreases and that of the nonsuperconducting increases (see *Electrodynamics of Superconductors: Flux Properties*). The region is called the "Shubnikov phase" or the mixed state. The values of $B_{c1}$ and $B_{c2}$ are also temperature dependent and decrease with increasing temperature. At $T_c$ both values, $B_{c1}$ and $B_{c2}$, are zero (Fig. 5).

## 3. Critical Current Density

Both categories of superconductors, Types 1 and 2, can carry large electric currents up to a certain value which is called the critical current density, $J_c$ ($A\,cm^{-2}$). Above $J_c$, the superconductor becomes normal conducting. $J_c$ is dependent on both the temperature and the external magnetic field. At $T_c$ or $B_c$ (Type 1) or $B_{c2}$ (Type 2) the value of $J_c$ is zero and the superconductor becomes normal conducting (Fig. 6). Superconductors show characteristic current vs. voltage behavior. At a current below $J_c$ the voltage is zero. Above $J_c$, as in a metal, the voltage increases with the current (Fig. 7).

In the mixed state, when an electric current is transported through the superconductor due to the Lorenz force, the trapped flux lines can move through the superconductor causing dissipation of the current and a warming of the superconductor. This phenomenon can result in a rapid transition into the normal conducting state. Therefore, the value of $J_c$ is significantly lower in the Shubnikov phase compared to the Meissner phase. However, the flux lines can be pinned by so-called pinning centers, which are defects with different dimensions within the superconductor. For example, point defects (zero dimension), dislocation lines (one dimension), twin planes (two dimensions), and second phases (three dimensions). The flux lines remain pinned until the Lorenz force surpasses the pinning force of the defect.

## 4. Superconducting Materials

Except for the elements vanadium, technetium, and niobium, the Type 2 category of superconductors includes compounds and alloys. Niobium ($T_c = 9.2\,K$), especially when alloyed with titanium (Nb0.7Ti0.3: $T_c = 9.8\,K$), exhibits the highest critical temperature of all elements. Although superconductors with higher

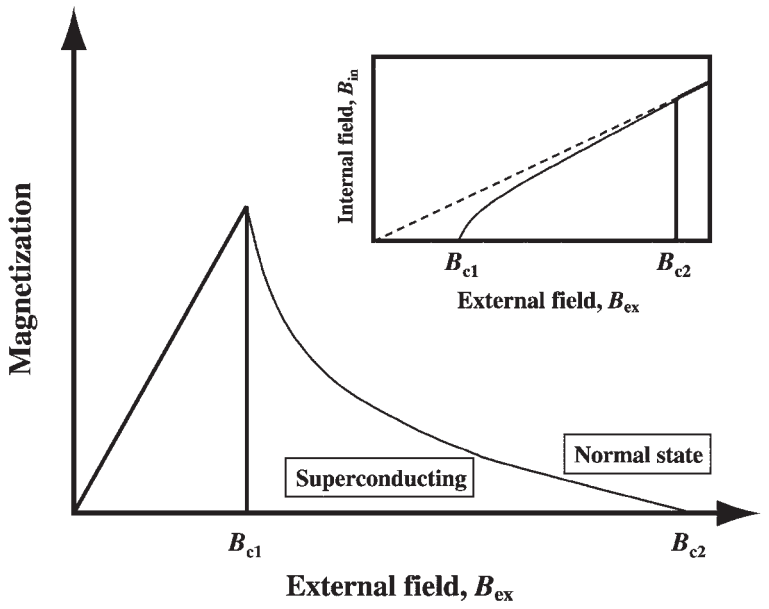

***Figure 3***
Magnetization of a Type 2 superconductor vs. the external field, $B_{ex}$. Insert: Magnetic field within a Type 2 superconductor, $B_{in}$, vs. the external field, $B_{ex}$.

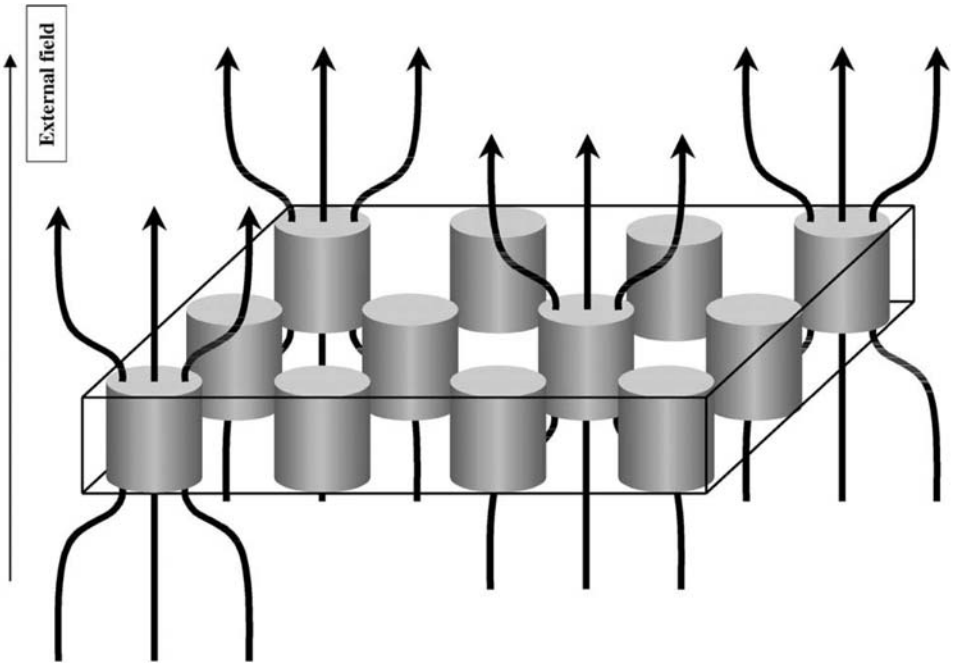

***Figure 4***
Type 2 superconductor with trapped flux lines vortex.

$T_c$ are available, until now, most commercially available superconducting magnets operating below about 5 T are based on NbTi wires, due to its comparably low price and excellent manufacturing qualities. During the late 1940s and early 1950s, compounds were found with $T_c$ values in the range of 10–20 K. These compounds belong to the $\beta$-tungsten structure family, also named A15 phases or $A_3B$ structure. The unit cell of the structure consists of a cube with the B atoms entering each corner of the cube. The A atoms

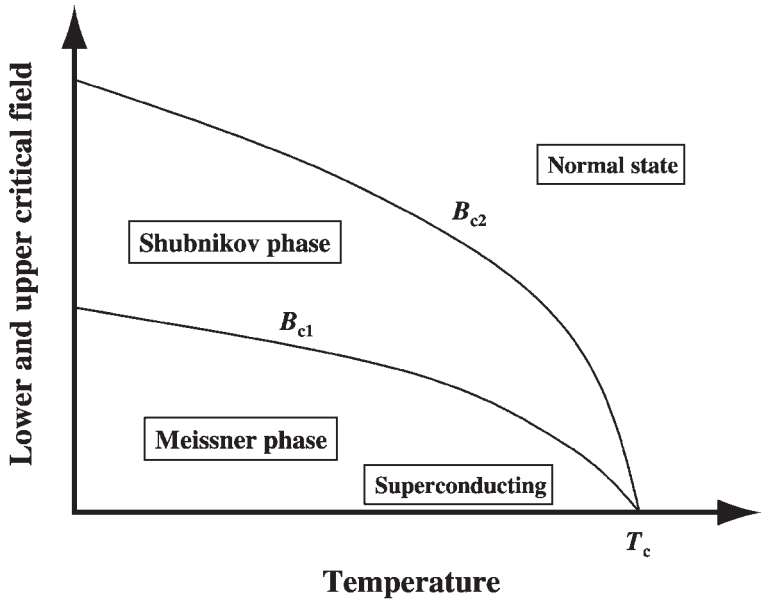

***Figure 5***
Lower and upper critical field of a Type 2 superconductor vs. the temperature.

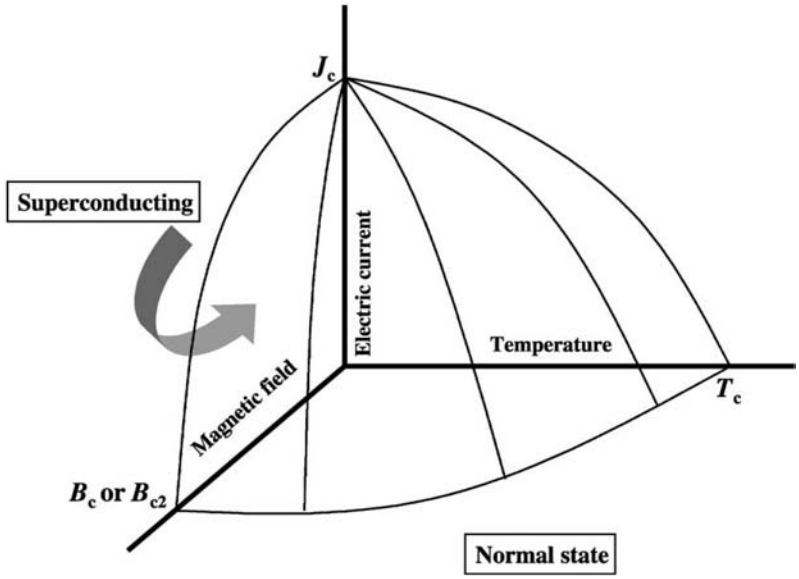

***Figure 6***
Critical current density, $J_c$, vs. the temperature and the external magnetic field.

enter the planes of the cube, and so form lines parallel to each crystallographic direction of the crystal (Fig. 8). It is believed that this extraordinary structural feature is mainly responsible for the relatively high $T_c$s of the compounds. Due to technological considerations with respect to processing and fabrication, only $Nb_3Sn$ ($T_c = 18.1$ K) is used for the manufacturing of wires for high field ($>5$ T) superconducting magnets.

$MgB_2$ has been found to be superconducting at a $T_c$ of 39 K and a $B_{c2}$ at about 11 T. This new Type 2 superconductor has a hexagonal structure ($AB_2$) with $a = 3.086$ Å and $c = 3.524$ Å. Although the compound has quite low $T_c$ and $B_{c2}$ values (about 15 T at 4.2 K and 10 T at 20 K), it is of considerable interest for the processing of wires used for the construction of superconducting magnets operating at 1–2 T and 20 K, due to its comparably low price and excellent workability. In addition, it is hoped that besides $MgB_2$ other superconducting compounds of this new class of superconductors with $T_c$s much higher than 39 K will be found.

Superconductivity has been found in different materials (Table 1), which indicates that superconductivity is not only related to one or two structural types, but may occur everywhere.

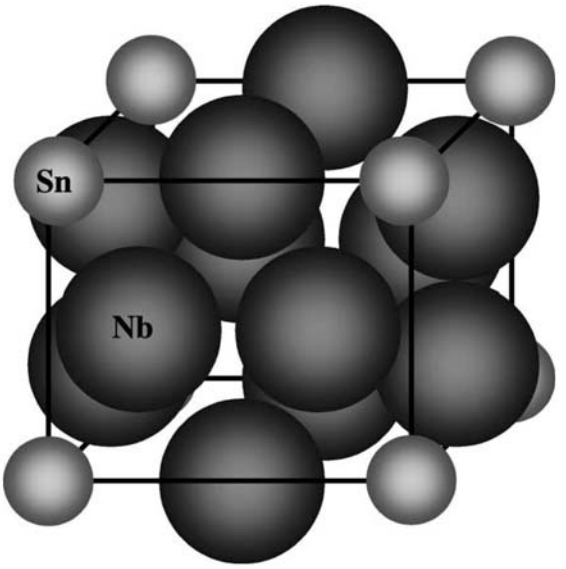

***Figure 8***
Crystal structure of A15 phases ($Nb_3Sn$).

### *4.1 High-temperature Superconducting Cuprates*

Since the first high temperature superconductor (HTSC) based on copper oxide with the composition $La_{0.85}Ba_{0.115}CuO_3$ was found, a variety of high-temperature superconductors have been synthesized. They all share a single structural feature, namely superconducting two-dimensional sheets of $CuO_2$ consisting of corner-shared $CuO_4$ units. The sheets are separated by a nonsuperconducting layer which supplies the sheets with charge carriers. The HTSCs can be divided into three major groups: (i) $REEBa_2Cu_3O_{7-x}$ (123 type);

(ii) $AB_2Ca_{n-1}Cu_nO_{2n+2.5}$ (1223 type); (iii) $A_2B_2Ca_{n-1}Cu_nO_{2n+4}$ (2223 type) with REE = rare earth elements; A = Bi, Tl, Hg; B = Sr, Ba. The phases have a pronounced layered structure which is visible both microscopically (Fig. 9) and macroscopically (Fig. 10). Due to the significantly different parameters of the a, b, and c axis, the crystallization rate in direction of the a,b plane is about $10^2$–$10^3$ times faster than in c direction.

Compared with low-temperature superconductors of Type 2, the cuprates behave very differently with respect to their superconducting properties vs. the temperature. Their resistivity transition is broader and the breadth increases rapidly with the applied field. This means that there is a region below $B_{c2}$ where the material shows a substantial electrical resistance, although the material is superconducting with respect to quantum mechanical considerations. This region is shown in Fig. 11 between $B_{c2}$ and the irreversibility line, $B_{irr}$. Below $B_{irr}$ the resistance of the material is zero. The substantial resistance above $B_{irr}$ corresponds to very easy flux flow.

The layered structure also implies a pronounced anisotropy of the properties, causing the so-called

"two-dimensional superconductivity" parallel to the a,b plane. For example, the critical current density as well as the $B_{c1}$ and $B_{c2}$ values of the compounds, are significantly greater parallel to the a,b plane than parallel to the c axis (Fig. 12). In addition, due to the almost complete decoupling of the $CuO_2$ sheets by the nonsuperconducting (Bi, Tl, Hg)O sheets, the HTSCs behave very differently within an applied magnetic field. At temperatures below about 30 K flux lines are formed above $B_{c1}$ like in the Type 2 low-temperature superconductors. Above that temperature, the flux lines disappear and separated, almost two-dimensional, flux disks, the so-called pancake vortices, are formed within the $CuO_2$ sheets (Fig. 13). The coupling between the pancakes is very weak, especially at high temperatures, for example 77 K (boiling point of liquid nitrogen), so that the pancakes are moving independently from the neighboring pancake of the next $CuO_2$ sheet when a Lorenz force is applied. Pinning of these pancakes is almost impossible and therefore, the $J_c$ decreases significantly in an applied magnetic field (Fig. 14).

### *4.2 The Compound $YBa_2Cu_3O_{7-x}$*

One of the main important high temperature superconducting cuprates is the compound $YBa_2Cu_3O_{7-x}$, better known as the "123 phase" ($T_c = 93$ K). The 123 phase is characterized by a Cu–O sublattice consisting of the $CuO_2$ sheets parallel to the crystallographic a–b plane, and Cu–O chains parallel to the crystallographic a axis (Fig. 15). The yttrium atom enters the center of the unit cell, and separates the Cu–O sheets. At temperatures of above 700 °C the compound is tetragonal with $a = 3.857$ Å and $c = 11.839$ Å. Below that temperature, the phase becomes orthorhombic with $a = 3.885$ Å, $b = 3.818$ Å, and $c = 11.680$ Å due to the introduction of excess oxygen into the Cu–O chains.

The phase transformation is combined with a formation of elastic twins parallel to the crystallographic [110] plane. This phenomenon makes it easy to distinguish between the tetragonal and orthorhombic 123 phase using a microscope and polarized light (Fig. 16). Tetragonal $YBa_2Cu_3O_6$ is nonsuperconducting. With increasing oxygen content the compound becomes superconducting at about $YBa_2Cu_3O_{6.3}$. Maximum $T_c$ is reached at $YBa_2Cu_3O_{6.93}$. A further increase of the oxygen content decreases $T_c$.

### *4.3 The 1223 and 2223 Type Compounds*

The compounds have layered structures parallel to the crystallographic a,b plane, consisting of (Bi,Tl, Hg)O-layers which alternate with perovskite-like $B_2Ca_{n-1}Cu_nO_{1+2n}$ units as illustrated in Fig. 17. The $Sr_2Ca_{n-1}Cu_nO_{1+2n}$ units contain the $CuO_2$ sheets which are oriented parallel to the a,b plane. The $n = 2$ phase (1212 or 2212 phase) is characterized by two $CuO_2$ sheets and the $n = 3$ phase (1223 and 2223 phase) by three $CuO_2$ sheets, respectively. Thus, the general structure of all members of the series consist of $CuO_2$ sheets, that are separated by calcium (for $n > 1$) and covered in the c direction by (Ba,Sr)O

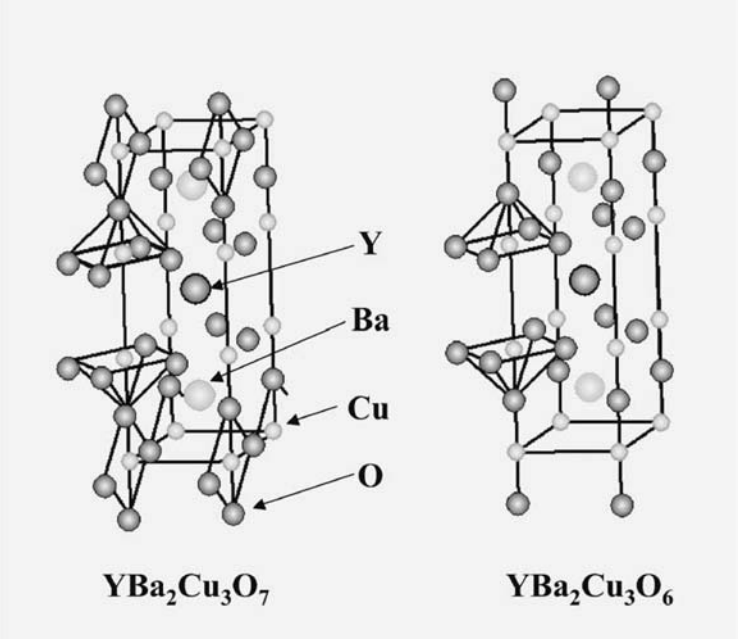

***Figure 15***

sheets. These perovskite-like units alternate in c direction with the (Bi, Tl, Hg)O-layers.

The $T_c$s of the compounds are dependent on the oxygen content and, like the 123 phase, they exhibit a maximum $T_c$ at a certain oxygen content. However, none of them become nonsuperconducting at low oxygen contents, and the dependence of $T_c$ is very different from compound to compound.

## Superconducting Materials: BCS and Phenomenological Theories

At very low temperatures many metals and alloys undergo a second-order phase transition to a superconducting state in which there is no resistance to flow of electricity. Superconductors exhibit other remarkable phenomena such as exclusion of magnetic flux from the interior (the Meissner effect) and flux quantization. Phenomenological theories were developed to describe semiquantitatively different aspects of superconductivity, including the Gorter–Casimir

two-fluid model for thermal properties and the London theory for electromagnetic properties. In spite of many attempts, it was nearly 50 years from the discovery of superconductivity in 1911 before a microscopic theory based on pairing of electrons was derived from quantum mechanics. The theory has been able to account quantitatively for most properties of superconductors as well as to predict new unexpected phenomena. Transition temperatures can be derived essentially from first principles for the simpler metals, but the theory has been less successful in predicting new compounds with high transition temperatures.

## 1. Outline of Phenomenological Theories

Superconductivity was discovered by Kamerlingh Onnes, only three years after he had liquefied helium. He found that the resistance of a rod of frozen mercury drops suddenly to zero when cooled to near the boiling point of helium (4.2 K). It was soon found that superconductivity is a common phenomena, exhibited by many metals, alloys, and intermetallic compounds when cooled below a critical temperature $T_c$. To show that the resistance really vanishes, Onnes showed that a persistent current flows indefinitely in a ring or solenoid with no voltage applied. In steady state, the electric field in a superconductor vanishes ($E=0$).

It was not until 1933 that Meissner discovered a property that is even more basic; a superconductor excludes a magnetic field ($B=0$). If a sphere or other simply connected body is placed in a magnetic field and cooled below $T_c$, the flux in the interior is expelled. If the field were applied when the sphere is in the superconducting state, currents would be set up near the surface to keep the flux inside from changing. They would flow indefinitely, so that $B$ would remain zero in the interior. What Meissner showed is that the state with the flux excluded is the unique thermodynamically stable state of a superconductor. Thus the currents flowing near the surface that counteract the external field are stable, not metastable.

Early attempts to account for the vanishing resistance were aimed at trying to understand why the electrons making up the supercurrent flow are not scattered as they are in the normal state. After the discovery of the Meissner effect, the focus shifted to the nature of the phase transition in the electronic structure that could lead to such remarkable properties.

Superconductivity can be understood only in terms of quantum theory; superconductors are quantum systems on a macroscopic scale. The current flowing around a superconducting ring is quantized such that the total magnetic flux threading the ring is an integral multiple of a flux unit, $\Phi_0 = h/2e = 2.07\times 10^{-15}$ Wb.

There is a critical magnetic field as well as a critical temperature. Because flux is excluded from the interior, there is an increase in magnetic energy of $\frac{1}{2}\mu_0 H^2$ per unit volume, where $H$ is the applied field. When this magnetic energy more than makes up for the free energy differences $G_s(0)$–$G_n$ between superconducting and normal phases in the absence of a field, the system reverts to normal. Thus the critical magnetic field $H_c$ is given by

$$\tfrac{1}{2}\mu_0 H_c^2 = G_n - G_s(0) \tag{1}$$

The free energy difference and critical fields decrease with increasing temperature and vanish at the critical temperature $T_c$. There is an approximate law of corresponding states:

$$H_c = H_0(1-(T/T_c)^2) \tag{2}$$

where $H_0$ is the critical field at $T=0$ K. Equation (1) gives a relation between $H_c(T)$ and the thermodynamic quantities, such as heat capacity, that can be derived from the free energy. Experiments in the early 1930s by Keesom and co-workers at Leiden verified these relations experimentally.

In 1934, Gorter and Casimir showed that Eqn. (2) and other properties could be accounted for by a phenomenological two-fluid model in which there is an electron charge density $\rho_s(\rho_s = n_s e)$ associated with the superfluid condensate and a density $\rho_n$ associated with electrons excited out of the condensate and subject to the usual scattering processes, with the total density $\rho = \rho_s + \rho_n$. The total current is then $\boldsymbol{J} = \rho_s v_s + \rho_n v_n$, where $v_s$ and $v_n$ are the velocities of the two components. In the absence of an electric field, $v_n = 0$ and $\boldsymbol{J}_s = \rho_s v_s$. There is no entropy associated with $\rho_s$, so a supercurrent carries no entropy.

A little later, in 1935, F. London and H. London proposed their famous phenomenological equations to describe the electrodynamics of superconductors. To account for infinite conductivity and the Meissner effect, they added to Maxwell's equations an equation relating the current to magnetic field:

$$\boldsymbol{J}_s(r) = -A(r)/\Lambda \tag{3}$$

where $\Lambda = m/n_s e^2\mu_0$ and $A$ is the vector potential expressed in a gauge such that $\nabla.A = 0$. The time derivative gives the usual equation for acceleration of the electron in an electric field in the absence of dissipation. Equation (3) leads in addition to the Meissner effect.

F. London suggested that superconductivity is a quantum phenomenon associated with the rigidity of the wave function describing the response of the system to changes of the momentum $\boldsymbol{p}$ of electrons in a magnetic field. The current is given by a sum over all electrons of $e\langle \boldsymbol{p} - eA\rangle/m$ averaged over the wave function of the superconducting condensate.

Equation (3) follows if $\langle \boldsymbol{p} \rangle = 0$ even in the presence of a magnetic field (described in the London gauge). In a normal metal $\langle \boldsymbol{p} \rangle$ changes in such a way that $\langle \boldsymbol{p} - eA \rangle$ is very small, giving just the small Landau diamagnetism. Particularly in his book, published in 1950, London emphasized that the rigidity of the wave functions in a magnetic field could arise from a long-range order in the momentum distribution of the electrons.

According to the London theory, the shielding currents near the surface of a superconductor in a magnetic field flow in a layer of average thickness determined by a penetration depth $\lambda = \lambda_L = \Lambda^{1/2}$, determined by $n_s$, the density of superconducting electrons. In the late 1940s, Pippard, working at Cambridge, found that the penetration depth increases markedly with added impurities. Impurities decrease the scattering mean free path of electrons in the normal state but have little effect on their density. For this and other reasons, he proposed a nonlocal form of the London relation in Eqn. (3) in which $\boldsymbol{J}_s(r)$ is given by an integral of $A(r)$ over a region surrounding the point $r$ of size determined by a coherence distance $\xi$. If $l$ is the electron mean free path,

$$\xi^{-1} = \xi_0^{-1} + l^{-1} \tag{4}$$

where $\xi_0$ is the coherence distance in the pure metal, typically of order $10^{-7}$ m.

About the same time (1950), Ginzburg and Landau proposed a different sort of modification of the London equations. They were interested in trying to understand the energy of the boundary between superconducting and normal domains in the intermediate state. The intermediate state consists of a series of normal and superconducting domains in the form of slabs parallel to the applied field. The field $\boldsymbol{B}$ is equal to the critical field in the normal domains and vanishes in the interior of the superconducting domains. The change from $n_s = 0$ in the normal domains to the equilibrium value in the superconducting domains occurs gradually across the boundary over a distance determined by the two lengths in the problem, $\xi$ and $\lambda$.

Thus they needed to have a theory that describes changes of $n_s(r)$ in space. Further, in accord with Landau's theory of second-order phase transitions, they described the ordered low-temperature phase by an order parameter that vanishes as $T \to T_c$. Ginzburg and Landau showed remarkable insight in proposing on phenomenological grounds that the order parameter be a complex function $\Psi(r) = |\Psi(r)| \exp[i\varphi(r)]$ with amplitude and phase. The order parameter describes both the density $n_s$ and the velocity $v_s$ of superconducting condensate:

$$\left.\begin{aligned} n_s^* &= |\Psi(r)|^2 \\ m^* v_s &= \hbar \nabla \varphi(r) - e^* A(r) \end{aligned}\right\} \tag{5}$$

Because of pairing, it is now known that $m^* = 2m$, $e^* = 2e$ and $n_s^* = n_s/2$.

Since $\Psi(r)$ must be single valued, the line integral of $\nabla\varphi$ around a closed loop must be a multiple of $2\pi$. If the loop is in the interior of a superconductor where $v_s = 0$ (such as around the interior of a torus containing a persistent current), the enclosed flux $\Phi = \oint A.dl = (h/e^*) \oint \nabla\varphi dl$ must be a multiple of a flux unit $\Phi_0 = h/e^*$.

By expanding the free energy in powers of $\Psi(r)$, they derived a nonlinear Schrödinger-like equation to determine $\Psi(r)$. This equation was coupled with Maxwell's equations to determine $\Psi(r)$ and thus the supercurrent flow subject to appropriate boundary conditions. The expansion is presumed to be valid just below $T_c$ where $\Psi(r)$ is small. They used the equations to determine the boundary energy as well as other properties of superconductors.

To have a Meissner effect, the boundary energy must be larger than a critical value. Otherwise the superconductor could break up into a structure with very thin normal regions that would allow the flux to penetrate a distance $\lambda$ on either side. The decrease in magnetic energy from the flux penetration would more than compensate for the higher free energy of the normal regions. Ginzburg and Landau found that the criterion could be described by a parameter $\kappa = \lambda/\xi$. If $\kappa < 1/\sqrt{2}$, the superconductor is stable against normal domain formation for all fields less than $H_c$ and there is a perfect Meissner effect. If $\kappa > 1/\sqrt{2}$, the flux begins to penetrate when the field is greater than a lower critical field $H_{c1} < H_c$, but the metal remains superconducting up to a higher critical field, $H_{c2} > H_c$. Since magnetic flux can penetrate for $H_{c1} < H < H_{c2}$, the increase in magnetic energy is less than that for a complete Meissner effect, so that the transition to the normal state does not occur until the higher critical field is reached. The upper critical field $H_{c2}$ may be as large as 20 T or greater for some intermetallic compounds. High-field superconducting magnet wire is made with such materials.

Superconductors with $\kappa < 1/\sqrt{2}$ that exhibit a perfect Meissner effect are called type I, those with $\kappa > 1/\sqrt{2}$ are called type II. Type-II superconductors were first investigated by Shubnikov at Kharkov in the Soviet Union in 1937 and 1938. His work stopped when he fell victim to a purge.

It was first thought that flux penetrates type-II superconductors through thin layers of normal domains as it does in the intermediate state. Then Abrikosov derived another solution, published in 1957, of the Ginzburg–Landau equations that he interpreted as a periodic array of quantized vortex lines. The order parameter $\Psi(r)$ goes to zero on the axis of the lines. Supercurrent circulating around the axis gives rise to one unit of flux $\Phi_0$. With this theory, Abrikosov was able to account in a quantitative way for the magnetization curves observed by Shubnikov.

In addition to the Ginzburg–Landau theory, the year 1950 was notable for the experimental discovery that $T_c$ depends on isotopic mass (indicating that the motion of the ions in the metal must be involved) and H. Fröhlich's independent suggestion that interactions between electrons and lattice vibrations (or their quanta, phonons) are responsible for superconductivity. Results of the experiments could be accounted for if $T_c$ varies inversely with the square root of the isotopic mass.

Onnes just missed discovering the isotope effect 30 years earlier. He attempted to detect a difference in critical temperature between ordinary lead and lead that came from radioactive decay of uranium. However, his measurements were not sufficiently precise to find the small difference in $T_c$ arising from the slight difference in mass of the lead nuclei from the two sources.

Attempts by Fröhlich and by Bardeen in 1950 to explain superconductivity in terms of changes in the energy of individual electrons from interaction with the phonons failed. Pines and Bardeen showed that the electron–phonon interaction leads to an effective attractive interaction for electrons which have energies within a phonon energy of the Fermi energy $E_F$. It was thought that it would be necessary to take this attractive interaction into account in a successful theory.

## 2. *Pairing Theory of Superconductivity*

In 1957, Bardeen, Cooper and Schrieffer gave a theory of superconductivity based on pairing of electrons in the superconducting ground state. Pairing occurs in such a way as to take advantage of the attractive phonon-induced interaction between electrons. An energy gap for quasiparticle excitations appears at the Fermi surface, in confirmation of experiments in the early 1950s of heat capacity and of thermal conductivity. The theory, known as the BCS theory from the initials of the authors, has been successful in accounting in quantitative detail for a wide variety of properties of superconductors, including the isotope effect, the Meissner effect, persistent currents, a second-order phase transition, an expression for the supercurrent in the form suggested by Pippard, penetration depths and their temperature dependence, and other electromagnetic and thermal properties.

Normal metals are well described by a Fermi sea of electrons and quasiparticle excitations of electrons from the sea. Each quasiparticle state is defined by a wave vector $\boldsymbol{k}$ and spin $\sigma$. At $T=0\,\mathrm{K}$, all states with energies less than the Fermi energy $E_F$ are occupied; those above are unoccupied. Low-lying excited configurations can be described by the wave vectors of the occupied states above $E_F$ and unoccupied states or holes below $E_F$. If the energy $\xi_k$ is measured from the Fermi energy, the total excitation energy is given by

$$W_{\mathrm{exc}} = \sum_{\substack{\mathrm{occ}\\ k>k_F}} \xi_k + \sum_{\substack{\mathrm{occ}\\ k<k_F}} |\xi_k| \tag{6}$$

Self-energies from effects of coulomb and phonon interactions are included in the quasiparticle energies $\xi_k$.

According to BCS, the ground-state wave function of the superconducting condensate is a linear combination of a selected set of wave functions $\Psi_i$ of low-lying excited configurations of the normal metal:

$$\Psi_s = \sum a_i \Psi_i \tag{7}$$

The configurations $\Psi_i$ which enter the sum are restricted to those in which the normal quasiparticle states are occupied in pairs of opposite spin and momentum $(\boldsymbol{k}\uparrow, -\boldsymbol{k}\downarrow)$, such that if in a given configuration one of the two states is occupied, the other is also. An interaction between electrons gives matrix elements between two configurations in which a pair $\boldsymbol{k} \equiv (\boldsymbol{k}\uparrow, -\boldsymbol{k}\downarrow)$ is occupied and the pair $\boldsymbol{k}'$ unoccupied in one configuration and $\boldsymbol{k}'$ occupied and $\boldsymbol{k}$ unoccupied in the other. With paired configurations, the phases of the wave functions can be chosen so that all matrix elements between such configurations are negative for an attractive interaction $V$. If the coefficients $a_i$ have the same sign or phase, the matrix elements $V_{ij}$ add coherently to give a negative contribution to the energy:

$$\int \Psi_s^* V \Psi_s d\tau = \sum a_i^* a_j V_{ij} \tag{8}$$

The wave function in Eqn. (7) was written by BCS in terms of creation operators, $c_{k\sigma}^*$ for putting a particle in the state $\boldsymbol{k}$, $\sigma$:

$$\Psi_s = \prod_k (u_k + v_k c_{k\uparrow}^* c_{-k\downarrow}^*)\Psi_0 = \sum_N a_N \psi_N \tag{9}$$

Here $v_k^2$ is the probability that the pair $(\boldsymbol{k}\uparrow, -\boldsymbol{k}\downarrow)$ is occupied and $u_k^2 = 1 - v_k^2$ is the probability that it is unoccupied. The wave function is not an eigenstate of the number of pairs $N$, but the coefficients $u_k$ and $v_k$ can be chosen so that the distribution is sharply peaked about the number in the normal ground state below $E_F$.

For a simple model in which it is assumed that $V_{ij} = -V$ for $|\xi_k| < \hbar\omega_{\mathrm{ph}}$ and zero otherwise, where $\hbar\omega_{\mathrm{ph}}$ is an average phonon energy, the following results are obtained by a variational method:

$$u_k^2 = 1 - v_k^2 = \frac{1}{2}\left(1 + \frac{\xi_k}{E_k}\right) \tag{10a}$$

$$E_k = (\xi_k^2 + \Delta^2)^{1/2} \quad \text{for} \quad |\xi_k| < \hbar\omega_{\mathrm{ph}} \tag{10b}$$

$$\Delta = 2\hbar\omega_{\mathrm{ph}} \exp[-1/N(0)V] \tag{10c}$$

$$G_s - G_N = -\tfrac{1}{2} N(0)\Delta^2 \tag{10d}$$

where $N(0)$ is the normal state density of states at the Fermi level.

A superconductor has a set of quasiparticle excitations in one-to-one correspondence with those of the normal metal. The energy of such an excitation is $E_k$, corresponding to that of a particle above the Fermi sea or a hole below. Since excitations are formed in pairs from the ground state, the minimum energy required for creating a pair of excitations at the Fermi surface is the energy gap $2\Delta$.

The probability that a state $k$ is occupied at finite temperatures is given by the Fermi function

$$f_k = \frac{1}{1+\exp(\beta E_k)} \tag{11}$$

where $\beta^{-1} = k_B T$. The gap parameter $\Delta$ decreases with increasing temperature and goes to zero at the critical temperature $T_c$. The value of $\Delta(T)$ can be found from the equation

$$1 = N(0)V \int_0^{\hbar\omega_{ph}} \frac{(1-2f_k)d\xi_k}{E_k} \tag{12}$$

This equation is commonly referred to as the BCS gap equation. Near $T_c$, $\Delta(T)/\Delta(0) \simeq 1.74[1-(T/T_c)^2]^{1/2}$. The gap goes to zero as $T \to T_c$ and there are no solutions for $T > T_c$. The value of $T_c$ is given by

$$k_B T_c = 1.13\hbar\omega_{ph} \exp[-1/N(0)V] \tag{13}$$

The energy gap at $T = 0$ is proportional to $T_c$:

$$E_g = 2\Delta(0) = 3.52 k_B T_c \tag{14}$$

In this weak coupling approximation there is only one parameter, $\Delta(0)$ or $k_B T_c$, rather than two, $\hbar\omega_{ph}$ and $N(0)V$. Weak coupling means that $k_B T_c$ is very small compared with the phonon energies so that the phonon spectrum is not important. In this limit there is a law of corresponding states since everything scales with $T_c$. Strong coupling and effects of coulomb interactions will be discussed later.

With a ground state and set of quasiparticle excitations it is possible to calculate transition probabilities and various response functions without much more difficulty than for normal metals. The main complications arise from coherence factors that are a result of the pairing. In normal metals scattering from $\boldsymbol{k}\sigma$ to $\boldsymbol{k}'\sigma'$ is independent in first approximation from all other scattering. In a superconductor it is possible to go from $\boldsymbol{k}\uparrow$ to $\boldsymbol{k}'\uparrow$ either directly or by scattering from $-\boldsymbol{k}'\downarrow$ to $-\boldsymbol{k}\uparrow$ and these two contributions must be added coherently. Depending on the nature of the scattering, they add constructively or destructively.

The coherence factors can be calculated most easily by a reformulation of the BCS theory given independently by Valatin and by Bogoliubov. They define quasiparticle operators for a superconductor as linear combinations of creation and destruction operators for normal quasiparticles:

$$\gamma^*_{k\uparrow} = u_k c^*_{k\uparrow} - v_k c_{-k\downarrow} \tag{15a}$$

$$\gamma^*_{-k\downarrow} = u_k c^*_{-k\downarrow} + v_k c_{k\uparrow} \tag{15b}$$

These operators do not conserve particle number and are designed to operate on wave functions of the type of Eqn. (9) that are not eigenstates of the number of pairs $N$. The ground state $\Psi_s$ is the vacuum state for quasiparticle excitations:

$$\gamma_{k\uparrow}\Psi_s = \gamma_{-k\downarrow}\Psi_s = 0 \tag{16}$$

When there is current flow, the paired states $(\boldsymbol{k}_1\uparrow, \boldsymbol{k}_2\downarrow)$ all have precisely the same momentum $\boldsymbol{p}_s = \hbar(\boldsymbol{k}_1 + \boldsymbol{k}_2)$ so that any pair can be scattered into another pair. There is thus a long-range order of the momentum distribution as envisaged by London. Individual electrons can be scattered, but such scattering does not change the common momentum of the paired states.

As in the Ginzburg–Landau theory, the canonical momentum $\boldsymbol{p}_s$ can be expressed as the gradient of a phase $\varphi$ (see *Josephson Effects in Weak Links*). There is an arbitrary phase factor in the ground-state wave function since $v_k$ can be replaced by $v_k \exp(i\varphi)$ without changing the energy. The degenerate wave function is an eigenstate of phase

$$\begin{aligned}\Psi_s(\varphi) &= \prod_k (u_k + v_k \exp(i\varphi) c^*_{k\uparrow} c^*_{-k\downarrow})\Psi_0 \\ &= \sum_N a_N \exp(iN\varphi)\Psi_N\end{aligned} \tag{17}$$

The phase and the number of pairs $N$ are conjugate variables, with $N_{op} = -i\partial/\partial\varphi$. If the number of pairs is fixed, the phase is undetermined. The phase corresponds to that of the Ginzburg–Landau theory, with $\boldsymbol{p}_s = \hbar\nabla\varphi$ the momentum of a pair.

It was trying to understand whether phase differences between two superconductors connected by a weak link could be observed that led Josephson to predict that a supercurrent should flow through a tunnel junction separating two superconductors differing in phase. The importance of phase as a variable describing the superconducting state had been stressed by Anderson. The Josephson effect was first observed by Anderson and Rowell. It has led to many practical applications.

## 3. Gor'kov–Eliashberg Formulation

Not long after the first publications of the BCS theory, Gor'kov used the method of thermal Green's functions to treat problems in which there is a space variation of the order parameter $\Delta(r)$ as well as

problems in which there is strong coupling so that it is necessary to include the energy dependence of $\Delta$. One of his first applications was to show that the theory reduces to the Ginzburg–Landau theory near $T_c$, with $\Delta(r)$ playing the role of the order parameter $\Psi(r)$. An important difference is that the charge of a pair, $2e$, replaces the electronic charge $e$.

Eliashberg used the Gor'kov formulation to derive a gap equation sufficiently general to include strong coupling. The electron–phonon interaction enters the integral equation in the form $\alpha^2(\omega)F(\omega)$, where $F(\omega)d\omega$ gives the number of phonons with energies in the interval $\hbar d\omega$ and $\alpha(\omega)$ is the electron–phonon coupling constant averaged over all directions in space. There are two coupled integral equations for $\Delta(\omega)$ and for the mass renormalization factor $Z_s(\omega)$ from the electron–phonon interaction, both of which are in general complex.

For weak coupling, $Z_s$ is the same as $Z_n$ and is the factor by which the density of states in energy is enhanced by the electron–phonon interaction. Expressed in terms of an interaction parameter $\lambda$, $Z_s = Z_n = 1 + \lambda$ where

$$\lambda = 2\int_0^\infty \alpha^2(\omega)F(\omega)d\omega/\omega \tag{18}$$

The parameter $\lambda$ corresponds to $N(0)V_{ph}$ of the BCS theory, with the phonon energy $\hbar\omega_{ph}$, defined by

$$\hbar\omega_{ph} = 2\int_0^\infty \alpha^2(\omega)F(\omega)d\omega/\lambda \tag{19}$$

The repulsive Coulomb interaction between electrons can be included by renormalizing the screened interaction $V_c$ to the same energy range as the phonons. The interaction constant $\mu = N(0)\langle V_c\rangle$ for scattering between states extending over an energy of the order of $E_F$ from the Fermi surface is replaced by a renormalized constant

$$\mu^* = \mu/[1 + \mu\ln(E_F/\hbar\omega_{ph})] \tag{20}$$

for scattering within an energy $\hbar\omega_{ph}$ of $E_F$. Virtual scattering to states outside of this range is included in the renormalized interaction. The expression for $T_c$ for weak coupling is then

$$k_B T_c = 1.13\hbar\omega_{ph}\exp[-1/(\lambda - \mu^*)] \tag{21}$$

Normally, $\mu^*$ varies only slowly with electron density and is typically in the range 0.10–0.15. It may, however, change the exponent $\alpha$ in the isotope effect $T_c \sim M^{-\alpha}$ from the value $\frac{1}{2}$ because $\mu^*$ can vary with isotopic mass through its dependence on $\hbar\omega_{ph}$.

McMillan used the Eliashberg equations to calculate $T_c$ for a series of transition metals and found that the results could be fitted approximately by the semiempirical expression

$$k_B T_c = \left(\frac{\Theta_D}{1.45}\right)\exp\left[-\frac{1.04(1+\lambda)}{[\lambda - \mu^*(1+0.62\lambda)]}\right] \tag{22}$$

where $\Theta_D$ is the Debye temperature. Values of $\lambda$ range from about 0.25 for metals with low $T_c$ to above 1.25 for strongly coupled superconductors with high $T_c$.

Metals and compounds with high $T_c$ are those with a reasonably large $\lambda$ and high phonon energies as defined by Eqn. (19). It is difficult to find materials that satisfy both criteria because a large $\lambda$ is usually associated with a soft lattice and consequently low phonon frequencies. Examples of soft metals are mercury ($T_c \simeq 4.2\,K$) and lead ($T_c \simeq 7.2\,K$). A high density of states $N(0)$ such as is found with transition metals is helpful, but within a range of alloys it is often found that $\lambda$ increases inversely with the density of states. The matrix elements of the electron–phonon coupling go in the opposite direction and more than compensate for the decrease in $N(0)$. Materials with high $T_c$ have been discovered by empirical methods rather than by suggestions from theory.

The Gor'kov–Eliashberg theory has been used to calculate $T_c$ essentially from first principles for simple metals and alloys such as aluminum (weak coupling), tin (moderate coupling) and lead (strong coupling). The phonon spectra are derived from neutron scattering data and a pseudopotential method is used to calculate $\alpha^2(\omega)$. The good agreement with experimental values leaves little doubt about the basic validity of the theory.

Of even greater interest is the application of equations to derive $\alpha^2(\omega)F(\omega)$ empirically from the current–voltage characteristics of a tunnel junction between a normal metal (N) and the superconductor (S) separated by a thin insulating layer. At low temperatures $(dI/dV)_{NS}$ is portional to the density of states in the superconductor. The ratio to the conductance measured when both sides are normal is for a voltage $V$ corresponding to $eV = E = \hbar\omega$

$$\left(\frac{dI}{dV}\right)_{NS}\Big/\left(\frac{dI}{dV}\right)_{NN} = \frac{N_S(E)}{N(0)} = \frac{E}{(E^2 - \Delta^2)^{1/2}} \tag{23}$$

where $N(0)$ is the uniform density of states in the normal metal and the expression on the right is for weak coupling. The current vanishes when $E < \Delta$.

For strong coupling, when $\Delta(E)$ is complex, Schrieffer and co-workers showed that

$$\frac{N_S(E)}{N(0)} = \mathrm{Re}\left\{\frac{E}{[E^2 - \Delta(E)^2]^{1/2}}\right\} \tag{24}$$

If the conductance is measured over a broad energy range, Kramers–Krönig relations can be used to determine both the real and imaginary parts of $\Delta(E)$ and thus the complete Green's functions required to

calculate equilibrium and transport properties. This procedure has given excellent agreement between theory and experiment, even when there is strong coupling.

McMillan devised a computer program to determine $\alpha^2(\omega)F(\omega)$ directly from tunnelling data with use of the Eliashberg integral equations. This method has been used for a large number of superconducting elements and compounds to obtain detailed information about $\alpha^2(\omega)F(\omega)$ and its variation with energy. It is necessary to estimate $\mu^*$ from the electron density; the only other variable in the equations is then $\alpha^2(\omega)F(\omega)$. Generally, the peaks of $\alpha^2(\omega)F(\omega)$ coincide with the peaks of the phonon density of states $F(\omega)$ measured by neutron scattering.

### *4. Basic Features and Extensions of the Pairing Theory*

At low temperatures, the normal state is described as a weakly interacting gas of quasiparticles and phonons. The quasiparticles correspond to electrons above or holes below the Fermi surface.

The fully renormalized quasiparticles are in one-to-one correspondence with those of a gas of non-interacting particles. Because of interactions, the quasiparticle excitations are not exact eigenstates of the normal metal but have a finite lifetime. According to the Landau Fermi liquid theory, the lifetime varies at low temperature as $\omega^{-2}$, where $\omega$ is the quasiparticle energy relative to that of the Fermi surface. Thus the approximation treating the quasiparticles as independent becomes better and better as the temperature is decreased.

The wave functions of the superconducting state are described by linear combinations of low-lying normal-state configurations. If the energies of the normal-state configurations are derived empirically, the free energy difference between normal and superconducting states may be derived with far greater precision than would be possible by a first-principles calculation of either phase by itself.

What is needed is the matrix element for scattering of a pair of quasiparticles in state $(\boldsymbol{k}_1, \boldsymbol{k}_2)$ to $(\boldsymbol{k}_1', \boldsymbol{k}_2')$ with conservation of wave vector:

$$\boldsymbol{k}_1 + \boldsymbol{k}_2 \rightarrow \boldsymbol{k}_1' + \boldsymbol{k}_2' \tag{25}$$

When the interaction is mediated by the electron–phonon interaction it may be regarded as occurring in two steps:

$$\boldsymbol{k}_1 \rightarrow \boldsymbol{k}_1' + \boldsymbol{q}_{\mathrm{ph}} \tag{26a}$$

$$\boldsymbol{k}_2 + \boldsymbol{q}_{\mathrm{ph}} \rightarrow \boldsymbol{k}_2' \tag{26b}$$

where $\boldsymbol{q}_{\mathrm{ph}}$ is the wave vector of the phonon. An alternative process is the same as in Eqn. (26) with $\boldsymbol{k}_1$ and $\boldsymbol{k}_2$ interchanged. Energy is conserved only in the final step. The superconducting phase is formed from a subset of low-lying normal configurations between which the matrix elements are predominantly negative, corresponding to an attractive interaction.

The quasiparticles in the subset are associated in pairs each of which has exactly the same momentum as every other pair. When there is no current flow the paired states have opposite spin and momentum.

One of the earliest extensions of the original BCS theory, by Mattis and Bardeen, was to include effects of a scattering mean free path $l$. In this case, the momentum $\boldsymbol{k}$ is not a good quantum number to describe the quasiparticles. A quasiparticle state $\psi\uparrow$ is paired with the time-reversed state $\psi^*\downarrow$. The main effect is to replace the inverse of the Pippard distance, $\xi_0^{-1}$, with $\xi^{-1} + l^{-1}$, as in Eqn. (4).

Not long after the microscopic theory was published suggestions were made to get an attractive interaction between quasiparticles other than that mediated by phonons. These are not necessarily alternatives to the phonon mechanism but may supplement it so as to enhance the transition temperature. Although none has been firmly established, it is likely that something besides phonons is required to account for the high transition temperature of compounds with copper oxide layers, first discovered by Bednorz and Müller.

Other low-lying excitations that have been suggested are, like phonons, defined by a wave vector. They include excitons (creation of electron–hole pairs), acoustic plasmons (in a ground state with equal numbers of conduction electrons and holes in overlapping bands) and spin and charge-density wave excitations (where there is nesting of opposite faces of the Fermi surface).

Little and, independently, Ginzburg suggested an exciton mechanism in which there is physical separation of the excited electron–hole pair and the carriers that give the current flow. Little suggested conduction in linear chains surrounded by polarizable side chains. Ginzburg suggested layer structures with conductive layers alternating with polarizable layers in which the electron–hole excitations take place.

Both may have found realizations in two classes of compounds with abnormally high superconducting transition temperatures, although it is still far from certain that it is the exciton mechanism that is responsible. Ginzburg's suggested geometry is similar to that of the high-$T_c$ copper oxide layer structures. Little's is similar to that of organic linear-chain compounds that have been found by Williams and coworkers to have transition temperatures as high as 13 K. However it has been found that in both systems the normal metal is not described by a simple Fermi liquid. More radical departures from the usual BCS theory than getting enhanced attractive interactions may be required. In both systems, experiments indicate that in the normal state the reciprocal of the quasiparticle lifetime varies as $\omega$ rather than as $\omega^2$.

The energy gap in planar directions in the high-$T_c$ oxides is about $8k_BT_c$, much larger than the BCS value of $3.52\,k_BT_c$ for weak coupling. Some extensions and changes of the BCS theory are required to account for the high-$T_c$ oxides and organic linear-chain superconductors. It is uncertain whether or not these changes are minor or require a major restructuring of the theory.

### 5. *Applications to Other Areas of Physics*

The concepts and mathematical methods of the theory of superconductivity have been applied successfully to the superfluid phase of liquid helium of isotopic mass three, to the structure of nuclei, to pulsars and neutron stars and to the elementary particles of high-energy physics. Liquid $^3$He, like electrons in metals, obeys Fermi–Dirac statistics. The liquid undergoes a pairing transition to a superfluid phase below 3 mK. The pairing is of parallel spins in a triplet state ($S=1$) rather than the singlet spin pairing ($S=0$) that occurs with electrons in superconducting metals. Extensions of superconductivity theory have been applied with great success to account for the pairing energy of neutrons and protons in nuclei. The pairing energy gap decreases with increasing atomic number. The biggest superfluid objects in the universe are pulsars and neutron stars in which there is evidence that both neutrons and protons undergo pairing transitions.

To define the state of a superconductor it is necessary to specify the superfluid velocity $v_s$ in addition to the other macroscopic variables, such as temperature and pressure. This is associated with what is called broken-gauge symmetry. Analogous concepts are now being used widely to better understand the structure of the particles (elementary excitations) of high-energy physics.

## Superconducting Materials: Irradiation Effects

Irradiating superconducting materials changes their physical properties, such as critical temperature, $T_c$, critical current, $J_c$, and critical magnetic field, $H_c$ (Brown 1981). Therefore, irradiation effects on superconducting materials are important to the technological applications and basic understanding of superconductivity. These effects depend on the material and the nature of the radiation itself. The radiation source can be x- or $\gamma$-rays, electrons, fast or thermal neutrons, or light or heavy ions. The irradiation effects depend on the type of radiation source, radiation energy, flux density, and accumulated dosage. From a technological point of view, fast neutrons and $\gamma$-rays are the principal radiation sources. Both $\gamma$-rays and neutrons interact with materials through electrically charged particles—electrons, light or heavy recoil ions, or charged reaction products in transmutations. Ion irradiation can be well controlled for energy, dose, damage type and density, irradiation temperature, and damage orientation, etc., to provide an understanding of the physical processes occurring in a material. Therefore, the emphasis of this article is placed on irradiation effects caused by ions.

### 1. *Energy Loss and Defect Formation*

Energy loss is the most important factor in ion–solid interactions, because it is a measure of the capacity of a particle to deposit energy within a material. Energy loss is a material property, which is a function of the mass, atomic number, and energy of the particle. Figure 1 shows the energy dependence of electronic and nuclear energy loss of various ions in a typical high-temperature superconductor (HTS), namely $YBa_2Cu_3O_7$. Ions of hydrogen, helium, bromine, tin, and gold are used for illustration.

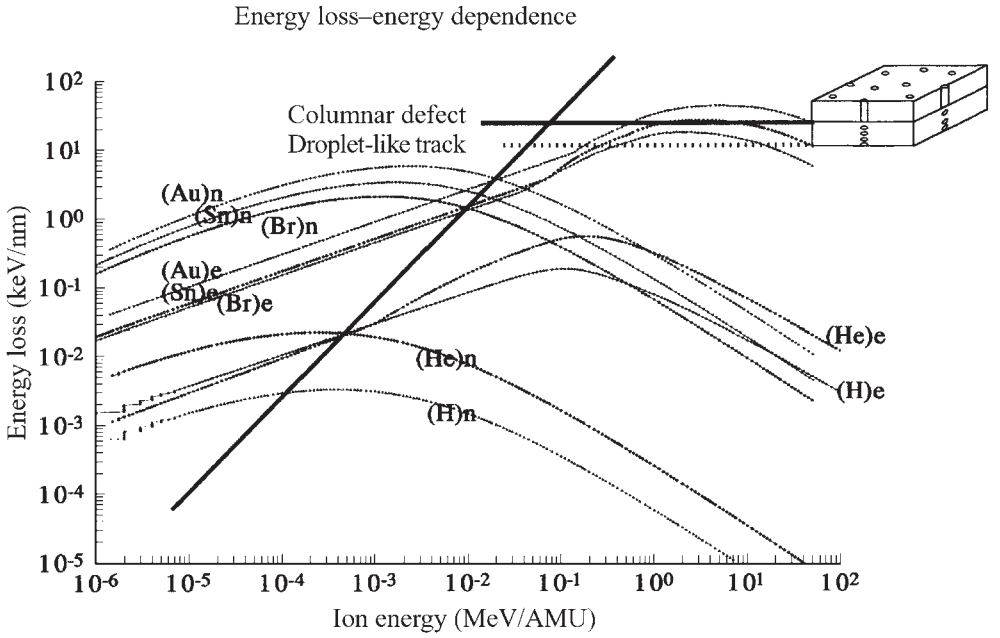

***Figure 1***
Defect formation in different energy loss regions and its dependence on incident particle energy. See text for details.

Energy loss is expressed in units of $\mathrm{keV\,nm^{-1}}$ and the ion energy is normalized by the mass number of the projectile. Subscripts "n" and "e" label the nuclear and electronic energy loss, respectively, for a given ion in the HTS. Figure 1 has three straight lines that mark the approximate boundary of different regions of significance. The upper left area of the inclined line is a region where nuclear energy loss is greater than electronic energy loss. In this region, the energy of the projectile is transferred to the material via collisions that displace the target atoms, creating point defects. When the energy of the recoiled atoms is high enough, these recoiled atoms will subsequently strike others, creating a collision cascade.

At higher ion energy (across the inclined straight line in Fig. 1), the energy loss is dominated by the ionization and excitation of the electrons of the target material with consequential diluded defect formation, which has very little effect on the properties of superconductors. However, for heavy ions of GeV energies, when the electronic energy loss is close to the maximum, the highly striped multicharged heavy ions can interact with and set in motion a large number of target electrons. This dense ionization in a small area will leave a high density of atomic disorders owing to a thermal spike (Szenes 1996). At electronic energy losses higher than $11\,\mathrm{keV\,nm^{-1}}$ in YBCO (marked as a horizontal dotted straight line in Fig. 1), local defects with high densities of atom disorders may form droplet-like and discontinuous columnar defects along the fast ion track. Above a critical electronic energy loss between $28\,\mathrm{keV\,nm^{-1}}$ and $35\,\mathrm{keV\,nm^{-1}}$ (marked as a horizontal straight line in Fig. 1), entirely continuous amorphous tracks with diameters of a few nanometers are produced along the ion path (Wheeler *et al*. 1993). Different effects on superconductivity will result from these defects. Before we correlate the defect structure with the superconductor properties, we need to understand the magnetic properties of type II superconductors.

## 2. *Defects and Pinning Centers in Type II Superconductors*

HTSs and all the technologically relevant conventional superconductors are type II superconductors. In these materials, the magnetic field penetrates in the form of an array of flux lines called superconducting vortices (Blatter *et al*. 1994). These vortices are string-like objects consisting of a central core (whose radius is approximately the coherence length, $\xi$), where the order parameter, $\psi(r)$, is depressed, surrounded by supercurrents extending over a larger distance. In a defect-free superconductor, the ground state of the vortex array is a triangular Abrikosov lattice. As electric currents exert force on the vortices, any transport current density, $J$, results in a dissipative vortex motion (i.e., finite resistance) and the most relevant property for application is lost.

Crystallographic defects may locally depress $\psi(r)$. If a core sits on one of these defects, the energy of the vortex decreases. This position-dependent energy distorts the lattice and produces vortex pinning, i.e., flux line motion is prevented until $J$ surpasses $J_c$.

Controlling the structure of defects in the material is thus the key for the optimization of vortex pinning. The relationship between the elementary pinning force, $f_p$, of one defect and $J_c$ is rather complex, but several basic rules exist (Ullmaier 1975). First, the best pinners are those defects that are just large enough to accommodate a vortex core, of transverse size $\sim\xi$. Second, to increase the total pinning force the density of defects should be large. Finally, defects elongated along the $H$ direction (columnar defects) are particularly appropriate, as they are able to confine large portions of a core.

## 3. Irradiation Effects in Superconductors

The methods of optimizing pinning in conventional superconductors have improved (Brown 1981). The inclusion of nonsuperconducting particles (as in Nb–Ti wires) or the introduction of dislocations by metallurgical techniques are well-known procedures. Amorphous superconductors are less sensitive to radiation damage, owing to the absence of pre-irradiation crystalline order. Irradiation of clean materials with very low initial $J_c$ has been used as a tool to investigate vortex pinning in samples with a well-characterized structure of defects.

The very small $\xi$ of HTSs ($\sim$1–2 nm) suggests that irradiation may be a very appropriate tool for pinning enhancement. The small $\xi$ and the lack of ductility prevent the use of many metallurgical techniques to create defects. The controlled generation of defects by irradiation is a powerful tool in exploring the novel properties of the vortex matter.

Irradiation of HTSs with light particles, which produce a random distribution of localized defects (Civale 1993), reduces $T_c$ and increases the normal state resistivity. The initial $dT_c/d\Phi$ for different ions and energies is proportional to the nuclear energy loss rate, confirming that damage is only due to atomic collisions. For higher $\Phi$ the defective regions start to merge, and $T_c$ decreases faster.

Vortex pinning effects of irradiation in HTSs are best explored in high-quality single crystals, where weak links are absent and $J_c$ before irradiation is low. The introduction of random defects in HTS crystals enhances $J_c$, and cascade defects generated by fast neutrons are very effective. In YBCO, for instance, $J_c$ may increase by an order of magnitude (up to $\sim 10^7\,A\,cm^{-2}$) at 5 K and $H$ of a few tesla, and by two orders of magnitude (up to $\sim 10^5\,A\,cm^{-2}$) at 77 K and low $H$. Protons of 2–3 MeV produce similar results. $J_c$ increases with $\Phi$ at low doses, reaches a broad maximum, and eventually drops abruptly at the $\Phi$ range where $T_c$ also starts to collapse. As expected, optimum $J_c$ occurs when the distance between defects is a few times the value of $\xi$. The damage produced by electrons in the 1–3 MeV energy range, which consists mostly of point defects (Frenkel pairs), also produces a small, but still considerable increase in $J_c$ in YBCO and Bi-2212.

Aligned columnar defects (CD) produced by heavy-ion irradiation are the strongest pinning centers in HTSs, because of simple geometrical reasons (Civale 1993). First, they can confine the whole length of the core, gaining a large pinning energy without the energy cost of an elastic distortion. Second, their diameter (5–10 nm) is appropriate to exert a very large pinning force (Wheeler *et al*. 1993). The advantage with respect to random defects is dramatic at high $T$ and $H$. For instance, for YBCO at 77 K and 5 T, $J_c > 10^5\,A\,cm^{-2}$ can be obtained. The density of CD can be expressed in terms of the equivalent *matching field*, the field at which the CD and vortex densities are the same.

CD generate uniaxial pinning, i.e., the $J_c$ increase is anisotropic, being largest when $H$ is parallel to the tracks. Uniaxial pinning gives rise to the lock-in effect (Blatter *et al*. 1994): in the solid phase, $H$ can be tilted away from the direction of the tracks by a finite angle and the vortices will still remain trapped in the CD. Irradiation of Bi-2212 and Bi-2223 with $\sim$1 GeV protons has been used to produce fission of the bismuth nuclei (Civale 1993). The damage created by the fission fragments consists of amorphous tracks similar to the aligned CD, but randomly oriented. These isotropic distributions of CD also produce large increases in $J_c$, with the technological advantage that the penetration range of the protons is large ($\sim$50 cm), in contrast to the few micrometers of heavy ions. Similar fission damage has been introduced in uranium-doped YBCO by irradiation with thermal neutrons.

# Superconducting Microwave Applications: Filters

## 1. Fundamentals of Microwave Absorption of High-temperature Superconductors

The microwave response of a superconductor can be understood by two physical phenomena. First, by the Meissner effect (see any textbook on superconductivity, e.g. Waldram 1996), which causes any magnetic field applied to the surface of a superconductor to decrease exponentially inside the superconductor on the length scale of the London penetration depth $\lambda_L$, which is about 160 nm for the most relevant high-temperature superconductor (HTS) compound $YBa_2Cu_3O_7$ (called "YBCO") at $T \to 0$. The London penetration depth increases with temperature according to $[\lambda_L(0)/\lambda_L(T)]^{-2} \approx 1 - (T/T_c)^2$ ($T_c$ = transition temperature, with $T_c = 92$ K for YBCO). As $T$ approaches $T_c$, $\lambda_L(T)$ converges to the normal metal skin depth. Below about $0.8T_c$, $\lambda_L(T)$ is nearly frequency independent up to several hundred gigahertz.

The second fact is that at finite temperatures below $T_c$, Cooper pairs (corresponding to "ballistic" charge carriers without dissipation) and quasi-particles (corresponding to normal conducting charge carriers obeying Ohm's law with a temperature dependent conductivity $\sigma_1(T)$) coexist (see, e.g., Klein 1997). According to this simple physical picture, the electrodynamic response of a superconductor can be described by a complex valued conductivity:

$$\sigma = \sigma_1(T) - i\sigma_2(T) = \sigma_1(T) - \frac{i}{\omega\mu_0\lambda_L^2(T)} \qquad (1)$$

The imaginary part of the conductivity corresponds to the inductive response of the Cooper pairs. The explicit relationship between $\sigma_2$ and $\lambda_L$ follows from the London equations. It should be emphasized that the rigorous treatment of the electrodynamic response of a superconductor requires a quantum mechanical treatment based on BCS theory including some peculiarities of high-temperature superconducting oxides (Klein 1997, Hein 1999). In the context of this article, only a basic understanding of the microwave response being necessary for the understanding of superconducting filters can be provided. At microwave frequencies $\sigma_1 \ll \sigma_2$ holds true resulting in a simple expression for the surface resistance and reactance of a superconductor (by a Taylor expansion of Eqn. (1)):

$$R_s = \frac{1}{2}\omega^2\mu_2^0\sigma_1(T)\lambda_L^3(T); \quad X_s(T) = \omega\mu_0\lambda_L(T) \quad (2)$$

In contrast to normal metals, the surface resistance exhibits a quadratic frequency dependence. The absolute values for thin films of YBCO at a temperature of 77 K are shown in Fig. 1. According to this data, there is a clear advantage by orders of magnitude for using HTS for the whole range of microwave communications bands. Above 77 K, $R_s$ increases strongly towards the critical temperature due to the strong increase of the London penetration depth. Below 77 K, $R_s$ decreases gradually towards zero temperature by less than one order of magnitude.

The surface resistance data discussed so far correspond to the linear regime corresponding to low levels of microwave magnetic fields. For higher field levels corresponding to higher values of the stored field energy, nonlinearities occur resulting either in an increase of $R_s$ and/or intermodulation distortion (Hein 1999). This is of particular importance, because—as a result of magnetic field displacement—planar conductors possess a strongly peaked edge current

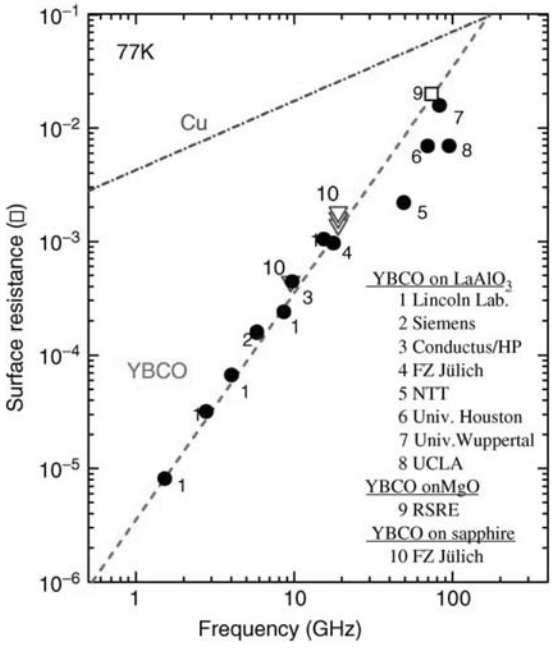

***Figure 1***
Measured surface resistance of epitaxially grown YBCO films grown at different laboratories at $T = 77$ K in comparison to that of copper.

density (enhanced by about one order of magnitude). This effect can only be avoided by employing "edge current free" modes in circular disk or ring resonators. Typically, intermodulation distortion as well as a field dependent surface resistance occurs at field levels, which depend strongly on the film quality. As an example, misoriented grains in the strongly anisotropic materials and grain boundaries give rise to strong nonlinearities.

The nonlinear effects in HTS films are strongly temperature dependent, in particular close to $T_c$ (Klein 1997, Hein 1999). Therefore, operation temperatures of 50–65 K are more favourable than 77 K. As discussed in Sect. 5, temperatures in this range can be attained by low-power closed-cycle cryocoolers.

## 2. Technology of High-temperature Superconducting Thin Film Devices

In most cases, HTS planar microwave devices rely on epitaxially grown films of YBCO grown by vacuum deposition techniques. Nonvacuum techniques like spraying or sol–gel (Alford *et al*. 1997) represent very challenging developments with the focus on low-cost production. However, the properties of such films are still behind that of epitaxial film. However, for some applications like coating of large area microwave cavities for base-station filters, HTS thick films are in use (Remilliard *et al*. 2001). For a review about the growth of YBCO films see Wördenweber (1999).

Apart from YBCO, thin films with reasonable microwave properties have been prepared from the thallium-based compounds $Tl_2Ba_2CaCu_2O_8$ ($T_c \approx 105$ K) and $Tl_2Ba_2Ca_2Cu_3O_{10}$ ($T_c \approx 115$ K) (Klein 1997, Wördenweber 1999). For the thallium-based and the more recently discovered mercury-based compounds with $T_c$ values up to 140 K, epitaxial growth is very difficult because of the volatility of thallium and mercury, respectively.

HTS films with reasonable and qualified microwave properties can be grown on wafers up to a diameter greater than 4 in; the most common sizes are 2 in and 3 in for microwave applications (Wördenweber 1999). A very important step was the preparation of double-sided coatings, which have turned out to be essential for planar microwave devices, where the ground plane needs to be superconducting in order to achieve high quality factors.

Substrates for planar HTS microwave devices need to fulfil the criteria for expitaxial growth plus moderated values of the dielectric constant ($\varepsilon_r \leqslant 25$) and a low level of dielectric losses ($\tan\delta \leqslant 10^{-5}$). The most commonly used substrate materials are lanthanum aluminate ($LaAlO_3$, $\varepsilon_r \approx 23$), magnesium oxide (MgO, $\varepsilon_r \approx 10$) and sapphire ($Al_2O_3$, $\varepsilon_r \approx 10$) (see Krupka *et al*. 1994, Zuccaro *et al*. 1997).

The fabrication of a planar microwave device is based on a patterning process. As a first step, masks are prepared according to the layout of the structure. A conventional photolithographic procedure based on a photoresist layer followed by chemical or ion beam etching is applied for patterning of the HTS wafers. In order to provide electrical contacts to microstrip connectors and to the housing, the HTS films are often covered with an *in situ* gold layer prior to patterning. The feature sizes are typically not smaller than 10 μm, but due to RF current crowding at the edges, the performance of planar microwave devices becomes quite sensitive to the quality of the patterning process. After process optimization no significant degradation of the microwave properties remains.

## 3. Planar HTS Resonators

Typically, the building blocks of HTS filters are planar HTS resonators. In general, a microwave resonator is characterized by its resonant frequency $f_0$, its unloaded quality factor $Q_0$ of the selected resonant mode(s), and its spectrum of spurious modes.

The unloaded quality factor of a resonator is determined by the stored energy $W$ and the dissipated power $P_{diss}$

$$Q_0 = \frac{2\pi f_0 W}{P_{diss}} \tag{3}$$

$P_{diss}$ contains loss contribution from the circuit layer and the unpatterned ground plane, dielectric losses from the substrate materials in use, and radiation losses (or metal losses from the housing). The dielectric losses are characterized by the loss tangent $\tan\delta$ of the substrate material. Neglecting radiation losses, the unloaded quality factor is given by

$$\frac{1}{Q_0} = \kappa \tan\delta + \frac{R_s}{G}; \quad \kappa = \frac{\varepsilon_r \int_S \boldsymbol{E}^2 \mathrm{d}V}{\int_{V-S} \boldsymbol{E}^2 \mathrm{d}V + \varepsilon_r \int_S \boldsymbol{E}^2 \mathrm{d}V};$$
$$G = \frac{\omega\mu_0 \int_V \boldsymbol{H}^2 \mathrm{d}V}{\int_C \boldsymbol{H}^2 \mathrm{d}A} \tag{4}$$

with $\kappa$ representing the filling factor indicating the normalized fraction of electric field energy stored in the dielectric substrate ($S$). Typically, $\kappa$ values are slightly smaller than 1. The quantity $G$ is a geometric factor (in Ω) representing the surface integral of the squared RF magnetic field over the conducting parts ($C$). In case of planar resonators $G$ is roughly proportional to the substrate thickness. For conventional metals, the dielectric losses are small in comparison to metal losses. For HTS resonators, substrate losses can play a significant role. The integrals in Eqn. (4) with subscript "$V$" are volume integrals over the entire volume of the resonator, i.e., substrate plus housing.

Figure 2 shows typical examples of HTS planar resonators which have been used as building blocks of multipole filter structures. Planar HTS resonators

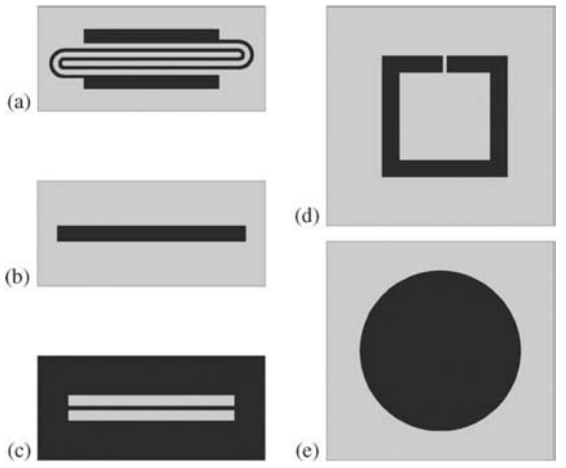

***Figure 2***
Typical planar resonators being used as building blocks for planar HTS filters: quasi-lumped element (a), (design by Superconductor Technologies Inc.), microstrip (b), coplanar waveguide (c), folded microstrip with integrated capacitors (d), and two-dimensional disk resonator (e). Omitting the capacitive gap in the folded microstrip design (d) leads to a ring resonator (if circular shaped), which also represents a quite commonly used microstrip resonator design.

are either formed by segments of quasi-TEM (transverse electromagnetic) transmission lines defining the resonances to be at frequencies where the length $L$ equals a multiple of half a guided wavelength (b,c) or lumped element resonators each composed of a discrete inductor $L$ and capacitor $C$ (see (a) and (Hieng *et al*. 2001)) with its resonance at a frequency $f = 1/[2\pi(LC)^{1/2}]$. In many cases hybrids of lumped elements and microstrip lines are used, e.g., folded microstrip lines disrupted by a capacitive gap (d) (Hong *et al*. 1999). In order to obtain a high value of $Q$ for microstrip and lumped element structures, the ground plane needs to be formed by a HTS film, e.g., in general double-sided films are required in order to achieve ultimate performance. As an alternative, coplanar resonators have been used (c) with some compromise on $Q$ in comparison to microstrip lines of the same size but with the advantage of single sided coating. However, until now no high performance multipole filters based on coplanar resonators have been built. For the highest $Q$ and ultimate power handling capability circular two-dimensional disk resonators excited in the $TM_{010}$-mode have been used (e), also requiring double sided coating (Kolesov *et al*. 1997).

The structures shown in Fig. 2 are generally not restricted to superconductors, but only here the achievable quality factors are comparable or higher than the ones of bulky cavities or dielectric resonators at room temperature. Therefore, there is strong potential in high-temperature superconductor technology for the miniaturization of high-performance microwave devices and circuits.

## *4. Planar Multipole Filter Topologies*

The class of microwave filters which can mostly benefit from HTS technology is characterized by some common structural features (“topologies”).

Filters of this class are passive and reciprocal two-ports, where the incident power is transmitted within certain frequency intervals (passbands) and reflected within the stopbands. Rejection in the stopbands is achieved by reflection. Unavoidable dissipation causes a degradation of the filter performance. For a given amount of dissipation, the degree of degradation depends on the filter parameters. In turn, this determines whether an HTS realization is beneficial or not.

In the most common filter topology all resonators are identical, possessing the same resonant frequency $f_0$ in the uncoupled state. A structure where input and output ports are coupled via one resonator only, represent a one-pole filter with a Lorentzian shaped transmission characteristic. If losses can be neglected, the frequency bandwidth (frequency interval where the transmission factor is higher than a prescribed value) of a one-pole filter is controlled by the strength of the coupling between resonator and ports. In order to achieve a frequency response closer to the rectangular frequency response of an ideal filter, a multiple-resonant (multipole) filter structure needs to be employed. In the most common filter topology, multiple-resonant structures are realized by a set of identical resonators of unperturbed resonant frequency $f_0$, which are mutually coupled. Mutual coupling of $N$ resonators results in a splitting into $N$ (in general) different frequencies. In the case that each resonator supports two orthogonal resonant modes (dual-mode resonator), $N$ represents the number of operational modes.

Each coupling path (direct connection between resonator $i$ and $j$) is characterized by its coupling coefficient $k_{ij}$, which is related to the frequency splitting of $f_0$ into $f_e$ and $f_o$ for the even and odd mode, respectively, by $k_{ij} = (f_e - f_o)/f_0$. In the special case of pure adjacent resonator coupling ($k_{i,j} = 0$ for $i \neq j \pm 1$), a single chain between input and output port is formed. This allows one to approximate a rectangular bandpass response with transition width $\delta f$ decreasing with increasing order $N$ (see Fig. 3). Different approximations for the insertion loss response are possible. The most popular is the Chebyshev response with equal-ripple response of the (reflective) passband insertion loss (Matthaei *et al*. 1980). The required order (number of resonators or operational modes) increases with increasing ratio between the passband width $\Delta f$ and the transition

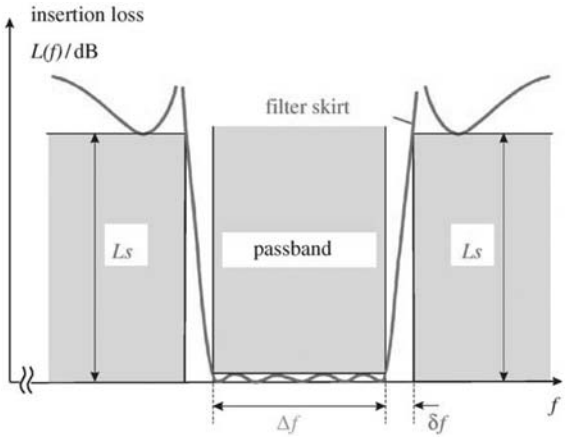

***Figure 3***
Typical frequency response of a passband filter with 2 transmission zeros in the stopbands
($\Delta f$ = passband width, $\delta f$ = transition width).

width $\delta f$. For a given order $N$ the transition width $\delta f$ can be further reduced by introducing transmission zeros in the stopband close to the band-edge. These transmission zeros cannot be realized if the coupling topology is restricted to adjacent resonator coupling. Additional coupling between non-adjacent resonators (''crosscouplings'') with appropriate coupling sign and strength is required. Filters with cross-couplings are characterized by the ratio between the number of transmission zeros at finite frequencies and the filter order and referred to as quasi-elliptic or elliptic filters (Fig. 4) (Klauda *et al*. 2000).

In analogy to spectral-analysis where frequency resolution increases with integration time, the skirt steepness (in dB $MHz^{-1}$) of a filter determines the minimum time duration in which the signal has to be stored in the filter structure. This time duration $\tau$ can be described by means of the frequency-dependent group delay which is the frequency derivative of the transmission phase and corresponds to the delay of a narrowband (bandwidth approaching zero) pulse passing through the filter. The group delay time $\tau$ allows for a simple relationship between the field energy $W$ stored in the resonators to the incident power $P_{\text{inc}}$.

$$W = \tau P_{\text{inc}} \tag{5}$$

Up to now, degradations of the filter response caused by losses were ignored. The in-band insertion loss $L_{\text{diss}}$

$$\frac{L_{\text{diss}}}{\text{dB}} = 10\log\left(\frac{P_{\text{in}}}{P_{\text{out}}}\right) = 10\log\left(1+\frac{\omega\tau}{Q}\right) \tag{6}$$

is increased due to the finite unloaded quality factor $Q$ by an amount which is proportional to the group delay. The insertion loss is associated with an unwanted power reduction of in-band signals as well as with an unwanted amplitude distortion caused by the frequency dependence of $\tau$. The latter effect leads to a rounding of the insertion loss response at frequencies close to the band edge where the group delay has a maximum.

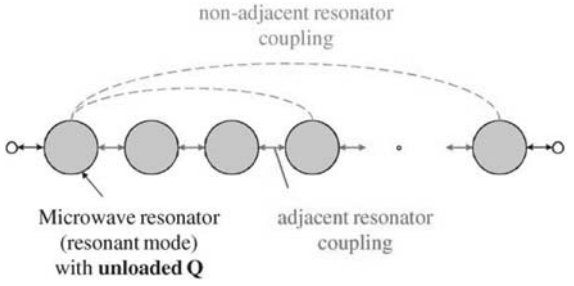

***Figure 4***
Filter topology with resonators, adjacent resonator coupling, and non-adjacent resonator coupling (cross-coupling).

Therefore, the achievable skirt steepness for a bandpass filter depends on the unloaded quality factor and on the filter topology (Klauda *et al*. 2000):

$$S < 4\times 10^{-3}\frac{Q_0\xi}{f} \tag{7}$$

The dimensionless quantity $\xi$ has a value of 0.33 for Chebyshev and 1 for elliptic filters (the values for quasi-elliptic filters are in between) (where $S$ is measured in dB $MHz^{-1}$ and $f$ in GHz).

## *5. Planar High-temperature Superconducting Filters and Subsystems*

### *5.1 Filters*

Since the late 1990s, tremendous progress has been achieved in the development of HTS planar filters and their integration in subsystems, mostly for base stations in mobile communication (Willemsen 2001). For HTS planar filters the resonator types shown in Fig. 2 and others have been used. The main emphasis was to develop filters for base stations with steep skirts coming as close as possible to the $Q$-requirements discussed in the previous section. In most cases, these are (quasi) elliptic filters with 8–17 poles or Chebyshev filters with up to 30 poles.

Figure 5 shows an example of an eight-pole quasi-elliptic filter based on folded microstrip resonators similar to ''c'' in Fig. 2. In this case of monomode resonators, coupling coefficients of different signs were achieved by changing between electric and magnetic field coupling of the resonators. For a 17-pole elliptic filter at 1.8 GHz with 5% relative bandwidth (resonator $Q_0 = 50.000$ at 65 K) a steepness of skirts of 85 dB $MHz^{-1}$ was demonstrated (Fig. 6). Such a

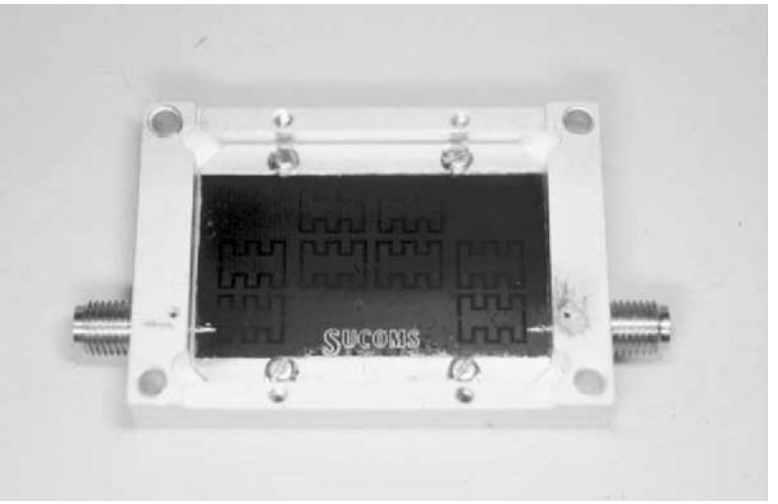

***Figure 5***
Example of an HTS-planar filter with 8 poles and quasi-elliptic characteristic (from Hong *et al*. 1999).

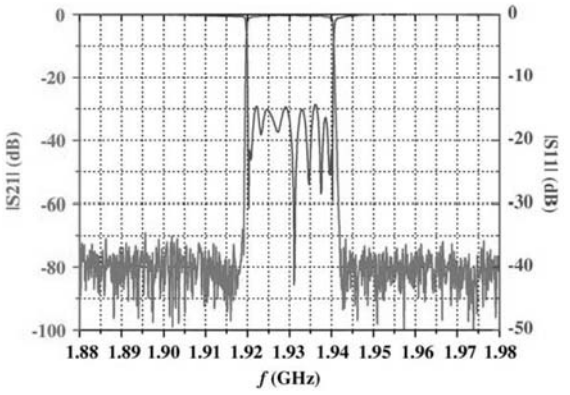

***Figure 6***
Measured characteristic of a HTS planar 17-pole elliptic filter (from Kolesov *et al*. 2000).

high performance cannot be achieved with any other filter technology.

In addition, high quality filters based on microstrip resonators have been developed for C-band satellite transponders. Figure 7 shows a three channel IMUX test module developed at Bosch SatCom GmbH in Germany. This test module, which is considered to be part of a space experiment, consists of three HTS quasi-elliptic eight-pole channel filters, cryogenic circulators, a cryogenic preamplifier, and a wide band HTS input filter (Klauda *et al*. 2000).

Due to the nonlinear surface resistance of HTS films (see Sect. 1) power handling of HTS filters is limited. In general, one can claim that planar HTS filters with edge-parallel currents in their resonators can handle power levels in the mW range without significant intermodulation distortions. Applications to transmit circuits with typical power levels of several 10 W can only be handled by employing the edge-current free disk resonator.

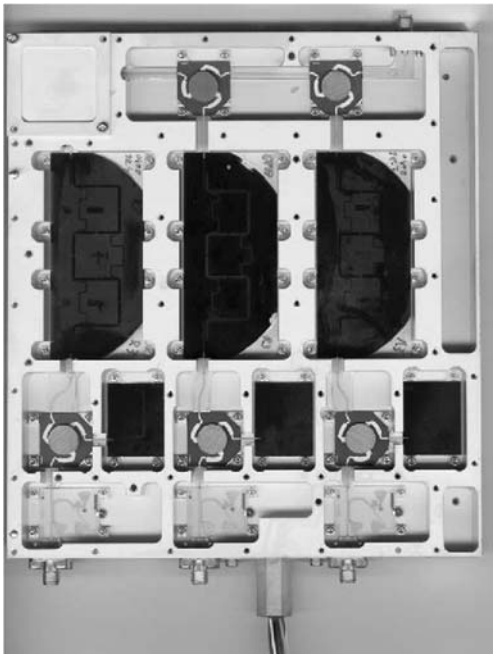

***Figure 7***
Photograph of a three-channel IMUX module based on HTS planar filters as part of a cryogenic C-band satellite transponder. The HTS filters are indicated as large black squares (from Klauda *et al*. 2000).

### *5.2 Subsystems*

The most important "enabling technology" for applications of HTS in telecommunications is cryotechnology. Cooling by liquid nitrogen is unacceptable, because the amount of maintenance for each base station should be as small as possible. The situation for satellite communications is even more severe, because the lifetime of a geostationary satellite is at least 10 yr.

The most convenient way of cooling is to use Stirling-type closed-cycle refrigerators consisting of a small stainless steel compressor with helium gas pressure of a few bar and a cold finger with a displacer inside, both connected by a thin stainless steel tube. Typically, a compressor with an a.c. 50 Hz power consumption of 100–200 W with the size of one or two beer cans provides a cooling power of 3–10 W at 77 K, which is the typical amount of cooling power needed for a HTS subsystem, consisting of about three filters and one cryogenic LNA (low-noise amplifier). For the sake of filter performance the base station subsystems are operating between 60 K and 70 K, and the satellite systems at 77 K because cooler efficiency is a crucial parameter with respect to system mass reduction (Klauda *et al.* 2000, Willemsen 2001).

Figure 8 shows a commercial system for potential use in wireless base stations (Kolesov *et al.* 2000). The filters are assembled inside a Dewar vacuum (left side), the metal cylinder in the right part of the assembly is the compressor of the Stirling-type refrigerator.

In 2002, companies are focussing on improving the coolers with respect to lifetime (currently about 3–5 yr for continuous operation) and cost reduction.

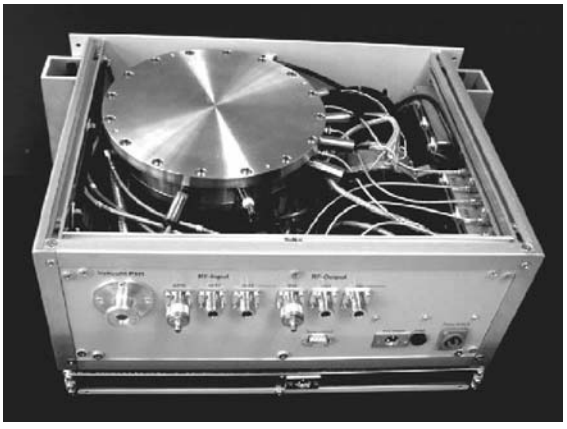

***Figure 8***

## *6. Tuneable and Switchable Filters*

Tuneable and switchable filters are supposed to have a strong potential for future receiver front-ends. First, for military communications systems, most flexible interference suppression is an important issue. Second, for future mobile communication systems beyond the currently installed third-generation systems, most flexible allocation of bandwidth may require high-performance reconfigurable filters (see also Sect. 7).

In general, the figure-of-merit (FOM) of a tuneable resonator is given by

$$\mathrm{FOM} = \frac{\Delta f}{f} Q \tag{8}$$

with $\Delta f/f$ being the relative frequency tuning range and $Q$ the unloaded quality factor of the resonator.

The most commonly investigated techniques which can be used for HTS tuneable devices are based on ferroelectrics and ferrites. For the future also micromechanical switches (MEMS) are considered to be relevant for planar HTS circuits (see, e.g., Rebeiz *et al.* 2001).

### *6.1 Ferroelectric Varactors*

These are very attractive for the integration with passive HTS microwave circuits because of the agile dielectric materials which can be grown as epitaxial heterostructures with YBCO. The current efforts are concentrated on thin films of $SrTiO_3$ ($SrTiO_3$ does not exhibit a ferroelectric phase transition but the temperature dependence of the permittivity exhibits a Curie–Weiss law similar to ferroelectric above its Curie temperature). Thin films exhibit lower $\varepsilon_r$ values in comparison to the bulk single crystals, but a stronger tuneability above about 60 K. Similarly, the dielectric losses at microwave frequencies are in the range of $10^{-2}$ (see, e.g., Petrov *et al.* 1998) in comparison to several $10^{-4}$ for bulk single crystals (Vendik *et al.* 1998).

The FOMs achieved at microwave frequencies for single varactors or tuneable resonators are in the range of about 100. Figure 9(a) shows an example of a planar HTS resonator incorporating a ferroelectric varactor based on a YBCO/$SrTiO_3$ multilayer structure. With such resonators a tuneability by about 10% was achieved (Marcilhac *et al.* 2001, B Marcilhac, private communication). Such resonators can be used to construct multipole bandpass filters (Fig. 9(b)).

### *6.2 Ferrites*

These represent a very common way of frequency tuning utilizing the magnetic field and magnetization dependence of a permeability tensor. In general, the microwave properties of a ferrite biased by a d.c. magnetic field $H_0$ in $z$-direction are defined by the

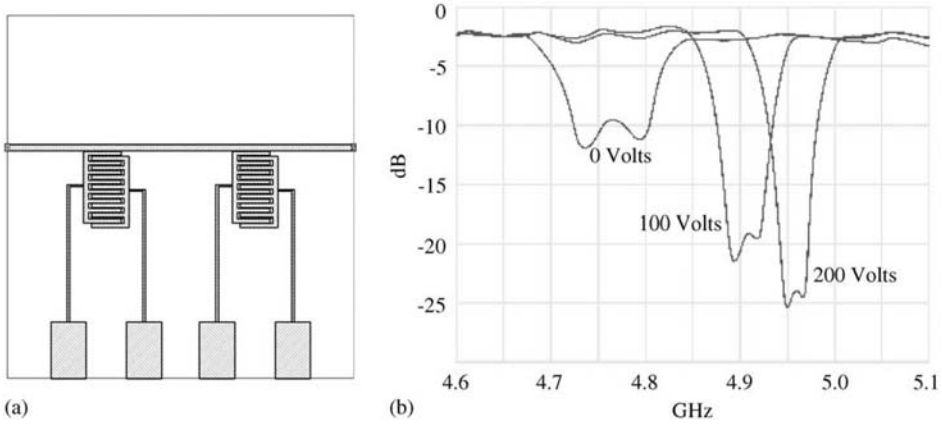

***Figure 9***
Tuneable lumped element 2-pole bandpass filter based on a $SrTiO_3$ loaded interdigited capacitor (a) and experimental result for measured filter response (b) (from Marcilhac *et al*. 2001).

permeability tensor which is in the lossless case (see, e.g., Pozar 1998)

$$[\mu] = \begin{bmatrix} \mu & i\kappa & 0 \\ -i\kappa & \mu & 0 \\ 0 & 0 & \mu_0 \end{bmatrix}$$

$$\text{with } \mu = \mu_0\left(1 + \frac{\omega_0\omega_m}{\omega_0^2 - \omega_m^2}\right) \text{ and } \kappa = \mu_0 \frac{\omega\omega_m}{\omega_0^2 - \omega_m^2} \qquad (9)$$

The angular frequencies $\omega_0 = \mu_0\gamma H_0$ and $\omega_s = \mu_0\gamma M_s$ are proportional to the external magnetic field $H_0$ and the saturation magnetization $M_s$ with $\gamma = 1.759 \times 10^{11}$ C kg$^{-1}$ being the gyromagnetic ratio. This proportionality corresponds to a ratio of 2.8 MHz G$^{-1}$ between the value of frequency $f = \omega/2\pi$ and magnetic field.

Large tuning ranges can be achieved by exploiting the ferrimagnetic resonance ($\omega = \omega_0$) in a YIG sphere. However, the losses are quite high and therefore combinations with HTS are not worth considering. In addition, high magnetic fields applied during operation may result in a significant degradation of the surface resistance of the employed HTS film. One attractive possibility is to use latching devices, where the magnetization of the ferrite can be switched between the remanent magnetization values $-M_r$ and $+M_r$ (usually slightly lower than $M_s$) employing short current pulses applied through a coil. This principle has been employed successfully for the realization of planar HTS phase shifters (Oates *et al*. 1997). Tuneable resonators and simple Chebyshev filters with a small number of poles have been demonstrated, the FOM values are about several hundred.

However, there are several drawbacks associated with ferrimagnetic tuning:

(i) The growth of HTS on ceramic YIG or other ferrites is difficult because no epitaxial growth can be achieved; epitaxial growth of single crystal YIG substrates has been achieved, but the substrates are very expensive and only available in small dimensions. Therefore, the working solutions rely on flip-chip assemblies.

(ii) The particular form of the $\mu$-tensor sets strong limits on possible tuning and phase shifting topologies.

(iii) Experimentally, the losses below about 5 GHz increase dramatically due to ferrimagnetic resonance losses of partially magnetized segments of the ferrite material in use ($M_s$ of YIG corresponds to 4.9 GHz). As an alternative to YIG, Ga- or Al-doped YIG with lower values of $M_s$ have been used (Yeo and Lancaster 2001). One of the challenges is the development and optimization of ferrites with tailored properties at cryogenic temperatures.

## *7. Impact of High-temperature Superconducting Subsystems for Future Microwave Systems*

The superior performance of HTS filters, namely high selectivity combined with a very low passband insertion loss can be used to enhance the performance of receiver front ends with respect to both interference resistivity as well as a reduced receiver noise figure.

Receiver front-ends are analogue subsystems, placed in between the antenna ports and the analogue-to-digital converters (ADCs). Their function comprises pre-amplification, down-conversion and some filter functions. It is important to distinguish between the different filter functions. Channel (carrier) selection and/or separation in principle can be performed by analogue filters in the microwave or the intermediate frequency (IF) section, or by software-controlled digital filters in the digital part. In 2002, analogue channel selection in the IF represents the best choice. Future receivers are expected to utilize

more and more digital channel selection (''software defined radio''). Transparent transponders with signal processing exclusively in the microwave regime represent an exception from this trend. In contrast to channel selection, other filter functions need to be performed in the microwave regime. These functions are the suppression of image reception in superheterodyne receivers and the rejection of strong out-of-band interferers. The second function stems from the necessity to prevent strong interfering signals from entering the LNAs and mixers, where they would cause saturation, desensitisation, and intermodulation effects due to the nonlinear response of these active devices.

Cryogenic units for base-transceiver stations (BTS) of wireless communication networks became commercially available in the late 1990s. These units comprise HTS bandpass filters followed by cryogenic LNAs, both integrated in an enclosed vacuum which incorporates the cryocooler. In order to meet the different requirements associated with frequency allocation in a first-generation analogue and second- and third-generation digital systems, these systems are available for different center frequencies and bandwidths, as well as with multiple passbands and with narrowband stopbands embedded in wider passbands. The number of filter-LNA chains in one cryogenic unit equals the number of antenna ports (sector antennas and diversity antennas) implemented in a one BTS.

For the evaluation of system benefits offered by cryogenic front-ends, the issue of a significantly improved interference suppression due to steeper filter skirts and the issue of an improved sensitivity due to the reduced receiver noise figure should be clearly distinguished. The first feature becomes significant in the case of wireless systems which have to operate in areas with strongly interfering systems with unwanted signals at frequencies closely spaced to the edge frequencies of the desired signal. Here, the improved selectivity is transformed into a lower intermodulation noise level and hence into improving the quality of service.

Alternatively, this advantage can be transformed into reduced guard-band widths and hence in an enhanced spectral efficiency and capacity.

In case of spread-spectrum systems, like the third-generation W-CDMA standard, HTS stopband filters with extremely narrow bandwidths can be used to reject narrowband interferers falling into the wideband operational frequency band.

The reduced receiver noise figure of cryogenic filter-LNA configurations originates from three different effects, namely the reduced noise temperature of the cooled LNA, the reduced thermal noise of the filter due to the lower physical temperature, and the reduced contribution of the amplifier noise due to the decreased passband insertion loss of the filter. Reduced receiver noise becomes important in noise-limited situations (e.g., rural areas), where it transforms into a lower number of required BTSs or an improved coverage for a fixed number of BTSs. Typically, the noise figure of a BTS with the cryogenic front end at the ground (noise figure degeneration due to lossy cable between antenna and front-end) resembles the noise figure of a conventional, but mast-mounted front-end.

# Superconducting Permanent Magnets: Potential Applications

When high-temperature superconductivity (HTS) was discovered, it became possible to construct electrical machines without high cryotechnic expenditure which was necessary with classical superconductors. Bulk superconductors (see *Superconducting Permanent Magnets: Principles and Results*) could be used for different types of electrical motors, e.g., hysteresis motors, reluctance motors, and trapped field motors (Kovalev *et al.* 2000, Oswald *et al.* 1998, Barnes *et al.* 2000).

While the hysteresis motor is an asynchronous motor type, the others are synchronous motors. For those drives the rotors move synchronously with the rotating field. The superconductors arranged in the rotors of synchronous motors are exposed to a d.c. field, if only the fundamental wave is considered. However, the rotating field has no pure sine-wave form, it contains higher harmonics, causing hysteresis losses and perhaps also eddy current losses in the penetration depth of the magnetic field.

With reluctance motors, the solid superconductor is used as a diamagnet which has to exclude the quadrature axis field, if possible, totally. In case of the trapped field motor, the solid superconductor works as a permanent magnet; here the strength of the trapped field is decisive and important for the power density of the motor. These principal considerations are not only true for rotating, but also for linear, drives where there is a linear moving field instead of a rotating field.

## 1. Theoretical Considerations

The intrinsic moment $M_i$ of a rotating field machine is normally dominated by the air gap field $B$ and the ampere turns per meter $A_s$ in the stator. Additionally, the phase angle $\varepsilon$ between the phasor of the main field and the ampere turns per length plays an important role:

$$M_i = CBA \cos\varepsilon \tag{1}$$

Here, $C$ is a machine constant including the motor geometry and the winding parameters. The phasor of the main field consists of the vector addition of the rotor field $B_r$ and the stator field $B_s$. For rotors with permanent magnets $B_r$ is essentially larger than $B_s$ and $\varepsilon < 20^\circ$. Consequently:

$$M_i \sim CB_rA_s \tag{2}$$

Therefore, high values for $B_r$ result in the case of equivalent motor dimensions in relatively high torques. The advantage of trapped field motors must depend on improved values of the rotor field according to Eqn. (2).

## 2. Comparison with Conventional Motors

The possible advantages of superconductive permanent magnets being used in electrical machines become obvious in a comparison with conventional motors. Here, especially the comparison with permanent magnet motors with rare-earth elements has to be discussed. Permanent magnets of the composition Nd–Fe–B have remanence field strengths of approximately 1.2–1.5 T, coercive field strengths of 800–900 $kAm^{-1}$, and maximum energy densities of 400 $kWsm^{-3}$. In the air gap of such permanent magnet motors, we obtain mean operating field strengths of 0.7–0.8 T. The strength of the air gap field determines according to Eqn. (2) the power density of a motor.

Permanent magnet motors have also a high power factor compared with other motor types, e.g., asynchronous motors, and principally no losses in the field-generating part. Both advantages allow a small motor size and an appropriately high dynamic of the motors. Superconductive permanent magnet motors certainly become interesting when their power density is significantly higher than that of normal permanent magnet motors. If it is possible to trap very high fields in the superconductors, motors could be designed

without magnetic yoke in the stator and, therefore, avoid hysteresis and eddy current losses in the iron. Consequently the size and the weight of the motor could be reduced significantly.

If superconductive permanent magnets are used, the field geometry which results from the local current density in the form of a Bean cone (see *Superconducting Permanent Magnets: Principles and Results*) differs from the rectangular field shape of conventional permanent magnets. Comparing these different motor types, this difference must be taken into account and yields a possible disadvantage of superconductive permanent magnets.

## 3. Further Developments

The present developments on bulk superconductors concentrate on the improvement of the current densities at possibly high operating temperatures, and on the manufacturing of large single domain structures. Large geometries are absolutely necessary for the construction of medium- and large-size motors. Superconductive connections across grain boundaries can perhaps become useful with a view to larger structures.

The current density in the superconductor and its geometry determine the achievable magnetic induction. The current density can be increased in bulk superconductors by decreasing the operating temperature. But, consequently the effort for the cooling system will increase significantly. Trapped field motors need a magnetizing facility that has to be integrated in the motor. Superconductive permanent magnets must be recharged in the superconductive state, i.e., at a low temperature after every period of heating up. This certainly creates a technical problem that requires an appropriate effort.

## 4. Possible Fields of Application

### 4.1 Motors

Electrical machines with superconductive permanent magnets are certainly of advantage if they offer a higher power density and simultaneously a high degree of efficiency in comparison with conventional solutions. Here all those applications are of special interest where the volume of the motor and its weight play a decisive role, e.g., in case of high-accelerated vehicles or in airplanes and rockets. Apart from that, fields of application exist where the cryotechnique is already available, e.g., in case of liquid gas pumps. The power density is also important with linear motors as servo drives, because the rotor mass directly influences the power need of these drives. This is particularly true for positioning drives, the moving cycle of which is essentially composed of only quick positive and negative accelerations.

At the present level of technique, the necessary cryotechnique is certainly still a serious obstacle for many possible applications. In future, however, the advantages of superconductive drives will lead step-by-step to industrial applications.

### 4.2 Magnetic Bearings, Fly Wheels, and Maglevs

The combination of HTS and permanent magnets, e.g., rare-earth magnets, can be used in magnet bearings, fly wheels, and magnetically levitated transport systems (Maglevs, Proceedings of ASC 1998, Proceedings of EUCAS 1999). The forces achieved depend on the superconducting currents and the field of the permanent magnet as discussed before. The higher the current density in the superconductor the higher are the levitating forces for fly wheels and for Maglev, and the restoring force in the case of bearings. For ideal conditions, i.e., an infinite current density in the superconductor, the area of which is large compared to the area of the permanent magnet, the force density is given by

$$f_x = \frac{B_s^2}{2\mu_0} \tag{3}$$

where $B_s$ is the field produced by the permanent magnet on the surface of the superconductor.

In the case of $B_s = 0.5\,\mathrm{T}$ the force density is about $10\,\mathrm{Ncm}^{-2}$.

Superconductive magnetic bearings are advantageous for very high rotating speeds, as they are nearly absolutely friction-free. However, the stiffness of such bearings, measured as force per deflection, must still be distinctly improved before their application in electric drives.

As Eqn. (3) shows, much higher force densities can be achieved using superconducting permanent magnets with trapped fields significantly higher than 1 T.

# Superconducting Permanent Magnets: Principles and Results

Bulk type II superconductors are able to trap magnetic fields and to act as permanent magnets. The trapped fields are generated by superconducting persistent currents circulating macroscopically within the superconductor. The main feature of the resulting field distribution is a maximum trapped field $B_o$ in the center of the superconducting domain. High trapped fields $B_o$ in bulk superconductors require a high critical current density of the supercurrents and large superconducting domains. Several melt-processing techniques were developed in the last years of the twentieth century to produce superconducting permanent magnets from bulk high temperature superconductors (HTS) as $YBa_2Cu_3O_{7-x}$ (YBCO), $SmBa_2Cu_3O_{7-x}$ (Sm-123), and $GdBa_2Cu_3O_{7-x}$ (Gd-123).

Trapped fields $B_o$ up to 2.1 T can be obtained at the temperature of liquid nitrogen on the surface of HTS disks several centimeters in diameter. Higher trapped fields were observed at lower temperatures due to the increasing critical current density. However, the trapped field is limited by the mechanical properties of the material, because Lorentz forces cause considerable tensile stresses during the magnetization procedure and can cause cracking of the material. To avoid cracking, HTS disks can be reinforced by steel tubes which produce a compressive stress on the superconductor after cooling from 300 K to the measuring temperature. Mechanical properties are also improved by the addition of silver. Very high trapped fields beyond 10 T have been achieved in this way in bulk YBCO material at temperatures between about 20 and 40 K.

The influence of flux creep on the properties of superconducting permanent magnets will be discussed. Furthermore, levitation forces between superconductors and permanent magnets will be considered.

## 1. Type II Superconductors and Trapped Fields

### 1.1 Field Profile

The magnetization vs. field dependence of a type II superconductor is shown in Fig. 1. In the Meissner state ($B_a < B_{c1}$ with $B_{c1}$ as the lower critical field), a superconducting surface current screens off the external magnetic field $B_a$ so that the magnetic induction $B$ in the bulk superconductor vanishes. In the mixed state between $B_{c1}$ and the upper critical field $B_{c2}$, magnetic flux penetrates the superconductor in the form of flux lines, each containing one quantum of magnetic flux $\phi_o = 2.1 \times 10^{-15}\,\mathrm{T\,m^2}$. A flux line is composed of a normal conducting core of radius $\xi$ (coherence length) and a surrounding circulating supercurrent region where the magnetic field and the supercurrents fall off within a distance $\lambda$ (London penetration depth). In the absence of defects, the flux lines form a triangular lattice. As the external field $B_a$ increases towards $B_{c2}$, the size of the superconducting region between the cores of the flux lines shrinks to zero, and the sample shows a continuous transition to the normal state. The $M(B_a)$ dependence of a defect-free type II superconductor is reversible and after switching off the external field no magnetic flux is trapped within the superconductor.

The $M(B_a)$ dependence becomes highly irreversible if the superconductor contains defects like dislocations, precipitates, etc., which interact with the flux lines. The interaction force between the defects in the material and the flux line lattice, the volume pinning force $F_p$, balances the driving force $F_L = j_c \times B = 1/\mu_o(\mathrm{rot}\ B \times B)$ acting on the flux lines due to the density gradient of flux lines. According to the concept of the critical state (Bean 1962), the gradient of the magnetic field has its maximum value $1/\mu_o\ \mathrm{d}B/\mathrm{d}r = j_c$ within regions of the superconductor penetrated by the field, or $\mathrm{d}B/\mathrm{d}r = 0$ for those regions that never felt the magnetic field.

The resulting field distribution for increasing external field is shown in the lower inset of Fig. 1. Neglecting the field dependence of the critical current density, the field within the superconductor decreases linearly with increasing distance from the sample edge. As the external field is reduced, the gradient of the local field near to the sample edge changes its sign, but has the same absolute value as before. The resulting field profile for decreasing external field is shown in the upper inset of Fig. 1. The magnetization becomes positive because a field is trapped in the superconductor by the pinning effect.

The field profile after switching off the external field is shown in Fig. 2. The trapped field decreases linearly from its maximum value $B_o$ at the center of the sample to zero at the edge of the sample. The gradient of this field profile is determined by the pinning force of the defects acting on the flux lines. Therefore, the maximum trapped field $B_o$ of a superconducting permanent

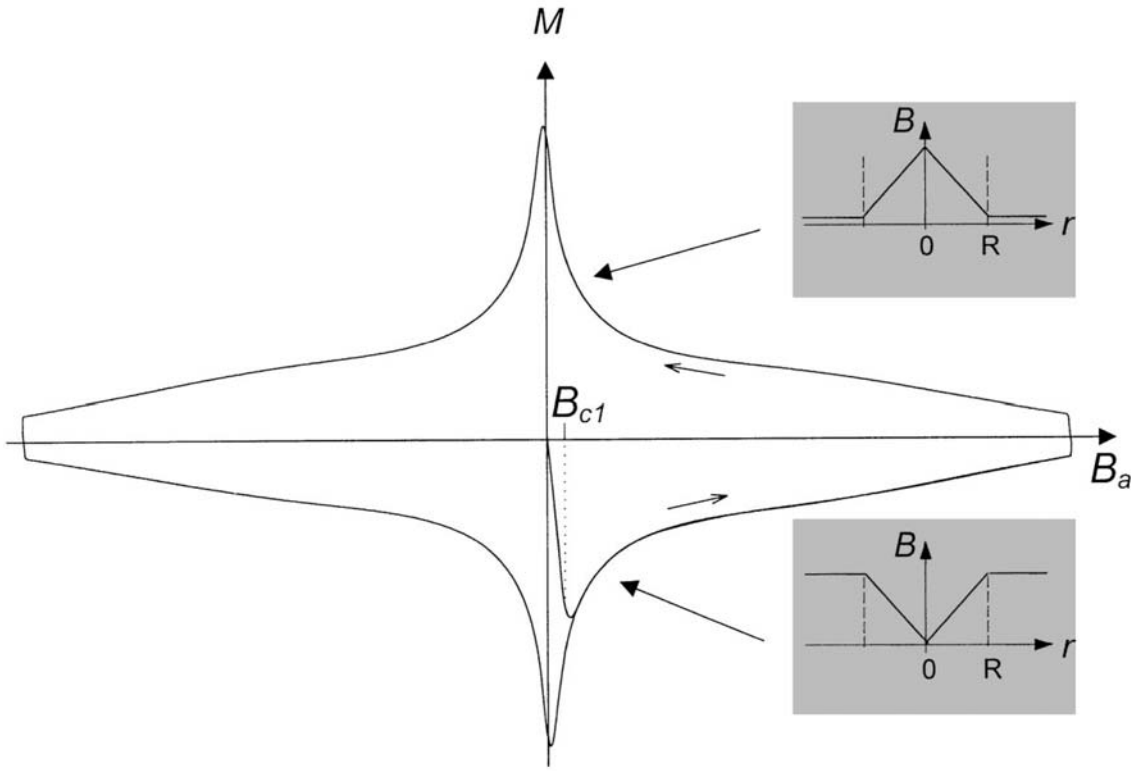

***Figure 1***
Magnetization vs. applied magnetic field of a type II superconductor. In the two insets the typical field distribution within the superconductor (radius $R$) is shown for increasing (lower inset) and decreasing (upper inset) magnetic field assuming a field-independent critical current density.

magnet depends on the critical current density $j_c$ of the supercurrents and the radius $R$ of the current loops. For a cylindrical sample of infinite length, $B_o$ is given by

$$B_o/\mu_o = j_c R \tag{1}$$

Using $j_c = 10^4\,\mathrm{A\,cm^{-2}}$ and $R = 1\,\mathrm{cm}$, Eqn. (1) gives a maximum trapped field $B_o = 12.6\,\mathrm{T}$ within the superconductor or in the gap between two long superconducting samples. The trapped field on the surface of a long superconducting sample is half as large as this value, hence $B_o = 6.3\,\mathrm{T}$. It should be noted that the results obtained from Eqn. (1) overestimate the trapped field, because a field-independent critical current density is assumed, whereas in real superconductors, the critical current density decreases with increasing magnetic field. Nevertheless, this approximation gives an idea about the relation between the critical current density and the trapped field in superconducting permanent magnets.

The field profile of a YBCO disk (Fig. 3) is shown in Fig. 4. The curved shape of the distribution of the trapped field in bulk YBCO superconductors can be calculated taking into account the field dependence of the critical current density of the supercurrents as was demonstrated by Klupsch *et al.* (1997).

### *1.2 Trapped Fields in Low- and High-temperature Superconductors*

Trapped fields in low-temperature superconductors have been investigated at the temperature of liquid helium. In a niobium hollow cylinder, magnetic fields up to 0.26 T have been trapped (Garwin *et al.* 1973). Higher magnetic fields up to 2.2 T were permanently trapped at 4.2 K in a hollow cylinder consisting of copper-clad $Nb_3Sn$ ribbons (Rabinowitz *et al.* 1977). However, the trapped field in bulk superconductors at low temperatures was found to be strongly limited by thermomagnetic instabilities resulting in flux jumps. An initial thermal disturbance in the critical state caused, for example, by the motion of magnetic flux during increasing external field, reduces the critical current. The released magnetic energy changes unstably into thermal energy as the external field

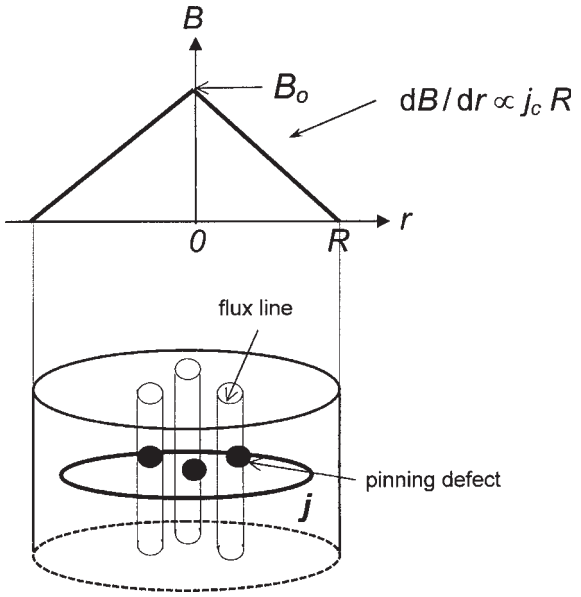

***Figure 2***
Field profile of a type II superconductor for a constant critical current density after switching of the external magnetic field and schematic view showing the circulating supercurrent (current density $j$) and pinned flux lines within the superconductor.

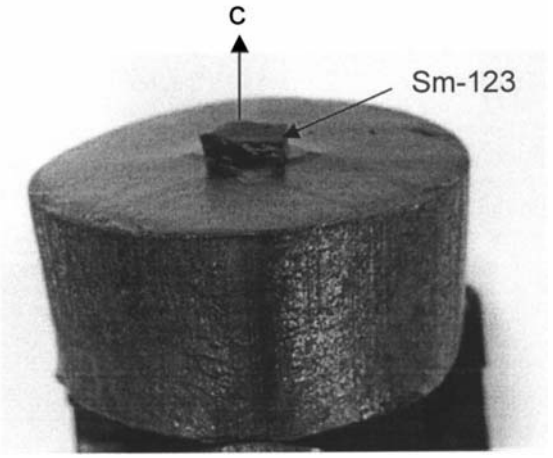

***Figure 3***
Melt-textured YBCO disk with a Sm-123 seed crystal in the centre of the disk.

exceeds a certain value $B_j$ which depends on the specific heat of the superconductor. The low specific heat of superconductors at helium temperatures reduces their instability field $B_j$ to very low values, limiting the trappable field in the bulk superconductor.

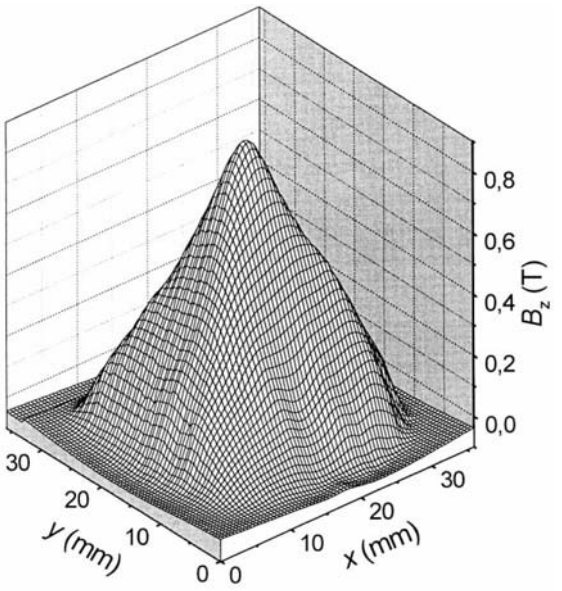

***Figure 4***
Typical field profile of a YBCO disk measured at 77 K (after Fuchs *et al*. 2000).

The discovery of high-temperature superconductors (HTS) stimulated new activities in the field of superconducting permanent magnets in bulk material. Because of the large specific heat of HTS at liquid nitrogen temperature, the instability field $B_j$ becomes much larger than at 4.2 K. A second advantage of HTS is that the use of liquid nitrogen instead of helium as coolant of the superconductor makes the handling of superconducting permanent magnets much easier. However, HTS have several peculiarities that make the preparation of bulk material with high critical current densities rather difficult. The primary problems with these materials are their extremely small coherence length, their large anisotropy, and their brittleness.

A key parameter for the performance of superconductors for applications is the coherence length which determines the size of the normally conducting core of the flux lines. In order to control the motion of flux lines one needs a microstructure with defects as small as the coherence length. The extremely small coherence length of HTS, which for YBCO is only 1.8 nm, is the reason that defects as grain boundaries—which are very beneficial in low temperature superconductors because they act as pinning defects—serve now as weak links and limit the critical current, especially in the presence of an external magnetic field.

The crystal structure of HTS is highly anisotropic, which has implications for both the physical and mechanical properties. The electrical conductivity is highly anisotropic with much higher conductivity

within the $CuO_2$ planes than perpendicular to the planes. Therefore, supercurrents can flow only within the $CuO_2$ planes, i.e., the trapped field generated by these supercurrents is directed along the c-axis.

The brittleness of HTS is mainly caused by the anisotropy of the mechanical properties. For YBCO in particular, the anisotropic expansion coefficient results in large stresses causing microcracking because, by cooling from the crystal formation temperature to the superconducting transition temperature, the lattice contracts far more along the a, b planes than perpendicular to the planes. Microcracking is a central issue to be solved for any application of YBCO and especially for superconducting permanent magnets in which large Lorentz forces arise by the interaction between magnetic fields and supercurrents.

## 2. Trapped Fields in Bulk HTS at $T = 77\,K$

YBCO has a superconducting transition temperature $T_c$ of about 91 K. The critical current density of bulk, polycrystalline YBCO material with randomly oriented grains is strongly limited by its pronounced weak link behavior. Only very small currents are able to flow across the grain boundaries, especially if a magnetic field is applied. Weak links can be avoided by growing large grains using melt-processing techniques. Several techniques have been found to be suitable for the growth of large single-domain YBCO material without high-angle grain boundaries (Murakami 1993, McGuinn 1995, Krabbes *et al.* 1997).

In most cases, seed crystals (Sm-123 or MgO) are used in order to orientate the c-axis of the YBCO sample perpendicular to the plane surface of the sample. Large superconducting domains with a c-axis texture can be produced in this way. A single-domain YBCO sample 35 mm in diameter with a Sm-123 crystal on top of the sample is shown in Fig. 3. In the present state of the art, the upper limit of bulk, single-domain YBCO samples is about 10 cm in diameter.

The simplest way to control the grain structure is to investigate the distribution of the trapped field at 77 K. By applying a magnetic field in the c-direction, flux lines penetrate the material and supercurrents are induced in the a, b plane of the YBCO sample which is cooled by liquid nitrogen. After switching off the applied field, the distribution of the trapped field in the superconductor is scanned by means of a Hall sensor with a small active area. An example for the field profile obtained for a single-domain YBCO sample is shown in Fig. 4.

It was mentioned above that the main problem in obtaining high critical current densities in YBCO is to create a defined microstructure with defects as small as the coherence length. But also the identification of the relevant defects in bulk YBCO which are responsible for pinning is difficult. Usually, different kinds of pinning defects of different size as normal conducting $Y_2BaCuO_5$ (Y-211) precipitates, arrays of stacking faults, dislocations and twin boundaries are present in the material.

The role of the different defects for the pinning effect in melt-texured YBCO material has been investigated very extensively and several review articles of the subject are available (Murakami 1992, McGuinn 1995). The Y-211 precipitates which can be observed by light microscopy have rather large extensions between about 0.5 and 20 μm compared with the diameter $2\xi = 3.6$ nm of flux lines in YBCO at 77 K. However, pinning at the interface between the superconducting matrix and the large Y-123 precipitates due to the abrupt change of the order parameter over a short distance can explain many $j_c$ results found for melt-textured YBCO, as was pointed out by Murakami (1992).

Flux pinning can be improved by radiation-induced columnar defects using heavy ions of high energy. However, these defects are limited to a relatively thin layer of a few tens of microns near to the surface of the sample. In order to introduce strong pinning defects into bulk superconductors, $^{235}$U-doped YBCO material was irradiated with thermal neutrons (Weinstein *et al.* 1994). Columnar defects were produced by fission in the bulk material and these defects were almost of optimum size with a diameter of about 5 nm. High critical current densities up to $8.5 \times 10^4\,A\,cm^{-2}$ and trapped fields up to 2.1 T were obtained on the surface of a single YBCO sample 20 mm in diameter at 77 K (Weinstein *et al.* 1996). For comparison, the best trapped field results at 77 K for nonirradiated bulk YBCO are in the range slightly above 1 T (Walter *et al.* 2000, Krabbes *et al.* 2000). Very promising results have recently been reported for bulk Nd-123 and Sm-123 material. Trapped fields up to 2.1 T (Ikuta *et al.* 1999) were achieved at 77 K for Sm-123 disks.

## 3. Relaxation Effects in Bulk YBCO

As was mentioned in Sect. 1.1, a large gradient of the field profile in superconductors requires pinned flux lines. However, pinned flux lines can also be thermally activated at a finite temperature and hop from one pinning defect to the other driven by the Lorentz force. Thermally activated flux motion or flux creep tends to reduce the field gradient and, therefore, the maximum trapped field $B_o$ in the superconductor.

Flux creep effects are small at low temperatures and for high pinning energies. For HTS, flux creep becomes extremely large at 77 K, since $kT$ is about 20 times larger than at 4.2 K. Therefore, in HTS the flux lattice is much more mobile than in low-temperature superconductors and there are large portions of the $H$–$T$ plane where extremely large flux creep effects are observed.

For 77 K, typical relaxation rates of $d(B/B_o)/d(\ln t/t_o) \approx -0.05$ were reported for melt-textured

YBCO (Weinstein *et al.* 1996), i.e., the trapped field $B_o$ reduces by about 5% per time decade. Hence, flux creep seems to be a serious problem for superconducting permanent magnets. However, successful reduction of the relaxation rate was achieved by cooling the YBCO sample by several degrees during or after activation. Investigating a YBCO mini-magnet with $B_o = 4.3$ T at 65 K, the creep rate was found to lower by factors of 6, 197, or $\geqslant 1000$ by decreasing the temperature for $\Delta T = 2$ K, 4 K, and 6 K, respectively, after activation (Weinstein *et al.* 1996).

## 4. *Limiting Factors for Superconducting Permanent Magnets in Different Temperature Ranges*

The simplest way to enhance trapped fields in YBCO is to work at temperatures below 77 K using the higher critical current density and pinning force at lower temperatures. As the trapped field increases, the mechanical properties of the material also become important, because large forces act on the superconductor during the magnetizing procedure. Since the flux lines are pinned on defects within the superconductor, a force is transferred to the crystal lattice where the pinning defects are embedded. As a result of these body forces, the material undergoes macroscopic mechanical deformations during the magnetizing procedure. Magnetoelastic effects in HTS have been reviewed by Johansen (2000).

A trapped field in the superconductor is connected to a tensile stress, which causes cracking of the disk if the tensile strength of the material is reached. The different limitations of the trapped field of a melt-textured YBCO sample are illustrated in Fig. 5. In the temperature range between about 50 K and $T_c$, the trapped field is determined by the pinning properties of the material and the size of the superconducting domains. At temperatures around and below about 50 K, the trapped field is limited by the mechanical properties of the superconductor. Thermomagnetic instabilities become predominant at temperatures below 20 K. In this region the trapped field is strongly reduced by flux jumps (Wenger 2000).

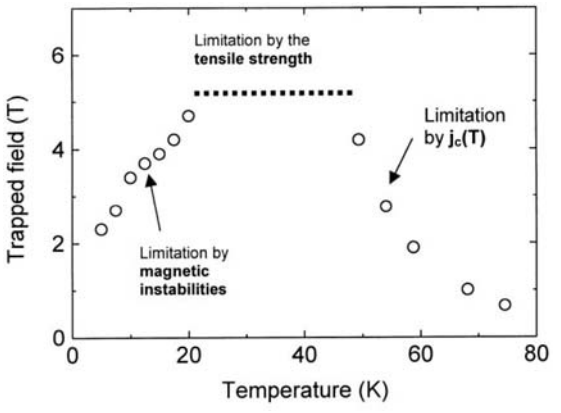

*Figure 5*
Schematic representation of the temperature dependence of the maximum trapped field $B_o$ of a YBCO disk showing the limitations of $B_o$ in different temperature ranges.

The limitations of the trapped field in the ranges of high and low temperatures have been discussed in the previous chapters. In the following, the limitation of the trapped field by mechanical properties and several possibilities to overcome this problem will be considered in more detail.

## 5. *Very High Trapped Fields in Bulk YBCO Below 77 K*

The temperature dependence of the maximum trapped field is usually measured in superconducting magnets. For magnetizing the bulk YBCO sample, a magnetic field is applied at a temperature above $T_c$ and the sample is cooled to the measuring temperature. Then, the magnetic field is reduced to zero and $B_o$ is recorded by means of a Hall probe. However, at high trapped fields, large magnetic tensile stresses act on the superconductor during this procedure resulting in cracking of the material which is indicated by a sudden decrease of the signal of the Hall probe during the magnetizing procedure. A visual inspection of damaged samples shows in some cases one crack on the surface of the sample, but sometimes no crack is visible.

The crack within the superconductor can be easily detected by a field profile measurement at 77 K (Fuchs *et al.* 1997). A typical example is shown in Fig. 6. The crack divides the disk into two superconducting domains. Currents can flow only within the superconducting domains, but not across the boundary between the two domains.

The distribution of the tensile stress within a bulk superconductor during the activation process was calculated by Ren *et al.* (1995) for long cylindrical samples. Later, this model was extended to arbitrary lengths of cylindrical samples (Johansen 1999). According to these models, the maximum tensile stress $\sigma_m$ occurs at the center of the sample and increases with the square of the trapped field $B_o$.

The tensile strength $\sigma_{max}$ of a damaged sample can be estimated from the applied magnetic field at which cracking was observed using the theoretical $\sigma_m(B_a)$ dependence predicted by the stress model. A typical value for the tensile strength of melt-textured YBCO is $\sigma_{max} \sim 40$ MPa (Ren *et al.* 1995), which is more than one order of magnitude lower than the tensile strength of metallic low-temperature superconductors originating from small cracks in melt-textured

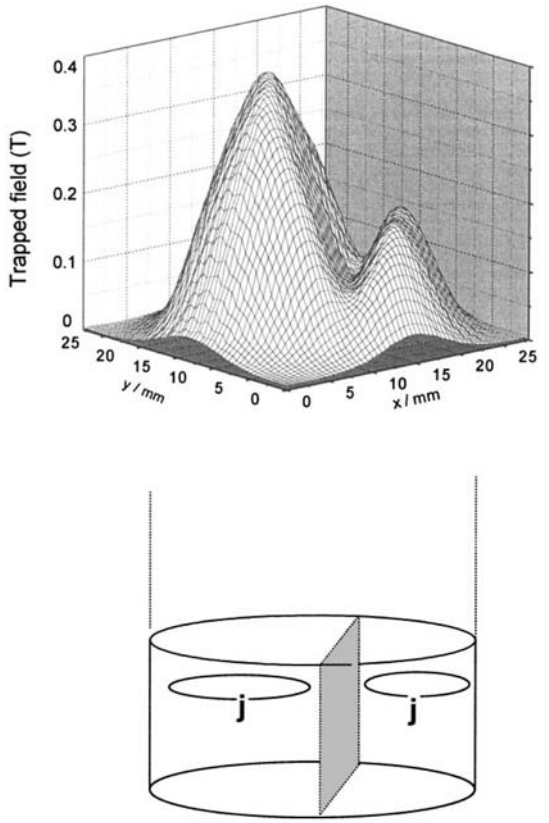

*Figure 6*
Typical field profile of a damaged YBCO disk after cracking (top panel) and schematic view of the corresponding two superconducting domains and the circulating supercurrents (bottom panel).

YBCO, limiting the tensile strength of the material. The cracks start to propagate when the external stress reaches the fracture toughness $K_c$ of the material. The tensile strength depends in this case on $K_c$ and the initial size $a$ of the largest crack according to the relation (Paker 1981)

$$K_c \sim \sigma_{max}(\pi a)^{0.5} \qquad (2)$$

Typical values of the fracture toughness of melt-textured YBCO are in the range of $K_c \sim$ (1–2) MPa m$^{1/2}$ (Schätzle *et al.* 1999). The fracture toughness was found to increase by the incorporation of ductile particles impeding the propagation of the cracks. In YBCO containing ductile silver precipitates, an enhancement up to $K_c \sim 2.4$ MPa m$^{1/2}$ was reported compared with $K_c \sim 1.9$ MPa m$^{1/2}$ in samples without silver inclusions (Schätzle *et al.* 1999). It was also reported that YBCO samples can be reinforced against the tensile stress by placing them into steel tubes. Steel has a larger coefficient of thermal

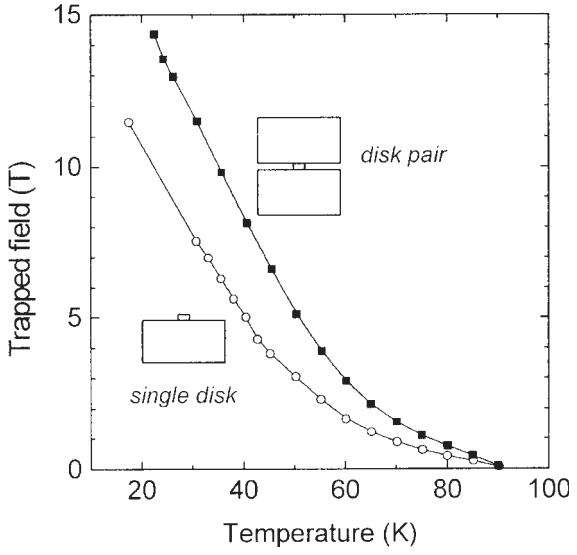

*Figure 7*
Temperature dependence of the maximum trapped field $B_o$ for YBCO disks containing 10 wt.% Ag: ○, single YBCO disk, ■, YBCO disk-pair. In both cases a bandage made of a steel tube filled with epoxy was used (after Fuchs *et al.* 2000).

expansion than YBCO in the a, b plane resulting in a compressive stress after cooling the sample from 300 K to the measuring temperature $\leqslant$77 K. Using a steel tube, the trapped field of YBCO disks with silver inclusions could be enhanced to values of $B_o = 11.4$ T (at 17 K) and of $B_o = 14.3$ T (at 22 K) on the surface of a single YBCO sample, and in the gap between two YBCO samples, respectively (Fig. 7) (Fuchs *et al.* 2000). In both cases, the YBCO disks had a diameter of 25 mm.

For comparison, trapped fields up to 10.1 T at 42 K have been reported by Weinstein *et al.* (1996) for a YBCO mini-magnet without silver additions and without mechanical reinforcement. This mini-magnet consisted of stacked irradiated YBCO tiles.

## 6. *Levitation Forces*

One of the most fascinating features associated with HTS is the stable levitation of a permanent magnet over a bulk HTS. This levitation is completely passive, because the magnetic flux surrounding the permanent magnet is pinned by defects within the superconductor. On the other hand, stable levitation is not possible for two permanent magnets and, therefore, conventional magnetic bearings require an active feedback control in order to stabilize the levitation. Passive superconducting bearings consisting of a superconductor and a permanent magnet are one of the most promising applications of bulk

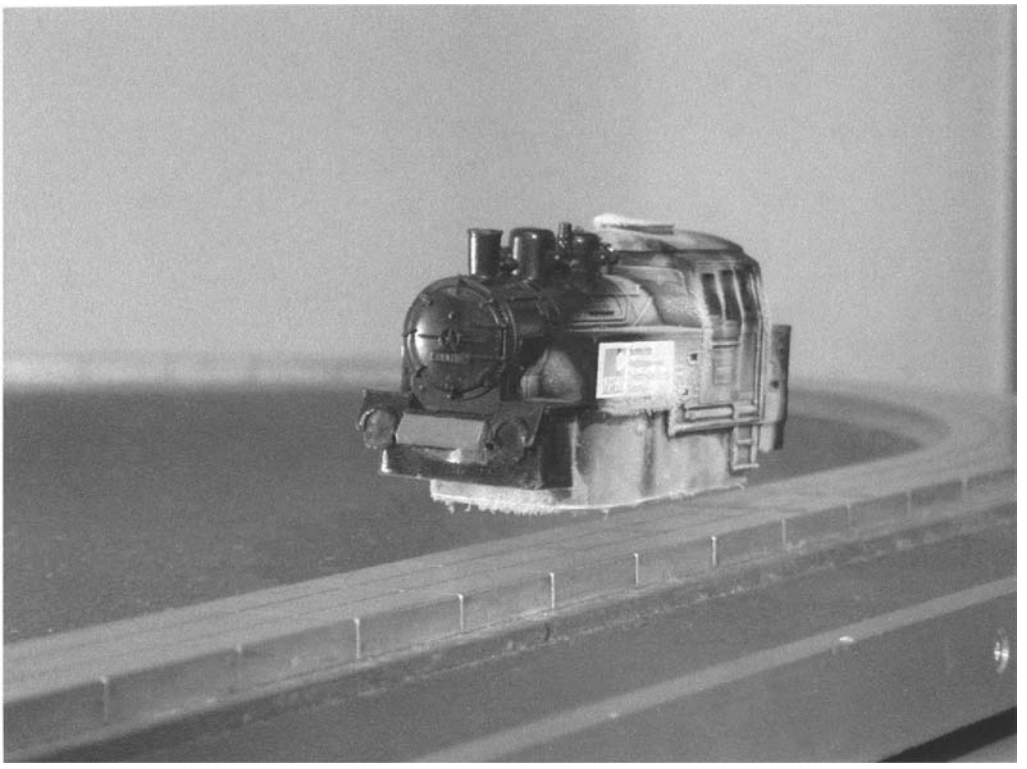

***Figure 8***
Model railway with steam locomotive equipped with two superconducting permanent magnets and cooled with liquid nitrogen as demonstration of stable levitation.

YBCO. They can be used in flywheels for energy storage, in motors for liquid gas pumps and for transportation systems (see *Superconducting Permanent Magnets: Potential Applications*). The possibility of linear transportation is nicely demonstrated by a model railway, where an old-fashioned steam locomotive equipped with superconducting permanent magnets and cooled with liquid nitrogen runs contactless and frictionless on a magnetic track (Fig. 8).

The levitation force between a permanent magnet and a superconductor cooled in the field of the magnet and containing a trapped magnetic flux can be written as

$$F \propto j_c R \mathrm{d}B/\mathrm{d}x \tag{3}$$

where $R$ is the size of the current loops in the superconductor and $\mathrm{d}B/\mathrm{d}x$ is the field gradient produced by the permanent magnet within the superconductor.

As the superconductor approaches the permanent magnet after zero field cooling, the repulsive levitation force increases and reaches a maximum value for a small distance. Typical values of the maximum levitation force $F$ between a samarium–cobalt permanent magnet (diameter 25 mm) and YBCO disks are between 50 and 90 N (Gruss *et al*. 1999) at 77 K. The corresponding levitation pressure $F/A$ ($A$ = area of the permanent magnet) varies between 10 and 18 N cm$^{-2}$.

The levitation pressure of this type of superconducting magnetic bearings is mainly limited by the surface field of the available permanent magnets, which is lower than the maximum trapped field of YBCO at 77 K. Therefore, the bulk YBCO can not be magnetized up to the maximum value of the trapped field, especially in the temperature range below 77 K, where the trapped field of the superconductor becomes yet higher.

The upper limit of the levitation force achievable for a given permanent magnet would be obtained for an ideal superconductor of infinite size and infinitely large critical current density perfectly shielding the magnetic field of the permanent magnet. The resulting levitation force corresponds to the force between two permanent magnets and is given by (Teshima *et al*. 1996)

$$F_{\max} = A B_s^2 / 2\mu_o \tag{4}$$

where $B_s$ is the surface field of the permanent magnet. For a permanent magnet with $B_s = 0.4$ T, the

maximum achievable levitation pressure is $F_{max}/A = B_s^2/2\mu_o = 25\,N\,cm^{-2}$. The experimental values for YBCO samples mentioned above achieve 50–72% of this upper limit. Much larger levitation pressures up to $5000\,N\,cm^{-2}$ are expected if a superconducting permanent magnet with a trapped field as high as 11 T were to be used instead of a conventional permanent magnet.

The most important problem which has to be solved in order to realize YBCO magnets for superconducting permanent magnets or for other applications at temperatures lower than 77 K is to magnetize the superconductor. Pulsed magnetic fields can be used for magnetizing YBCO disks, however, large viscous forces act on the penetrating magnetic flux, especially in the case of short rise times ($\sim$1 ms) of the pulsed field. Therefore, (i) higher pulsed fields are needed in order to trap the same magnetic field in the superconductor as by applying a static field and (ii) heat generation due to the rapid motion of magnetic flux strongly reduces the trapped field achievable at temperatures lower than 77 K (Yanagi *et al*. 1998). At 77 K, promising results were achieved by using pulsed fields with a relatively long rise time of 16 ms (Gruss *et al*. 1999).

## 7. Conclusions

These new superconducting permanent magnets form a new class of ultrahigh performance permanent magnets. The trapped flux density can be higher by an order of magnitude compared to the remanence of the best ferromagnetic permanent magnets (see *Rare Earth Magnets: Materials*). Since stored magnetic energies and forces scale quadratically with the trapped flux density, these new ''cold magnets'' offer magnetic energies and forces two orders of magnitude higher than conventional magnets, reaching completely new fields of applications accessible for permanent magnets. Two examples are the rotational frictionless support, i.e., superconducting magnetic bearings, and frictionless linear transportation. The latter should allow transportation of extremely heavy goods which can not easily be moved by wheeled systems, like concrete ports or moving bridges. Additionally, contactless transportation, which does not create any wear debris, can be advantageously used in clean rooms in the microelectronics industry (for further reading, see *Superconducting Permanent Magnets: Potential Applications*).

# Superconducting Radiation Sensor Applications: Detectors and Mixers

Superconducting detectors and mixers belong to the wide class of small-scale applications of superconductivity. They are used in measurements of weak radiating electromagnetic fields and nuclear radiation. Superconductivity offers various basic principles for effective radiation detection. Several devices have been developed, exploiting the different features of the condensed matter in the superconducting state:

(i) heating by the absorption of radiation, which is sensitively detected by a superconducting device;

(ii) creation of nonthermal excitations by the absorption of radiation and their collection by a superconducting device;

(iii) capability of active superconducting devices of processing high-frequency electromagnetic waves.

The most relevant types of superconducting sensors for radiation detection are microcalorimeters, superconducting tunnel junction detectors, and mixers. Superconducting detectors are developed for visible, ultraviolet, and x-ray single-photon detection. They can also be applied in detecting large-mass molecules or nuclear radiation, like electrons, $\alpha$-particles, and neutrons. Mixers are typically used in measurements of electromagnetic radiation in the infrared and millimeter wavelength regions.

The major motivation for using superconducting sensors is their superior sensitivity. The detection of very small energy deposition (high sensitivity) with high energy resolution (i.e., the capability of distinguishing slightly different energies) is achieved by operating the sensors at low temperatures, where lattice vibrations (phonons) and excitation energy are more than one hundred times smaller.

The need for detectors with advanced performance is a continuous request from frontier experiments in elementary particle physics and astronomy. The progress in the development of both sensors and complementary technologies (cryogenics, in particular) opens the possibility of using these sensors in a novel generation of spectrometers for microanalysis of materials in civil applications (laboratory and industrial measurements).

## 1. Superconducting Microcalorimeters

Microcalorimeters have been developed for x-ray astronomy to detect single-photon events from faint sources in the energy range 0.1–10 keV ($1\,\text{eV} = 1.602 \times 10^{-19}\text{J}$). A microcalorimeter consists of an absorber in thermal contact with a thermometer (see Fig. 1). The energy ($E$) of the incident radiation, typically one photon, is converted to heat in the absorber, leading to a temperature rise $\Delta T = E/C$, where $C$ is the total heat capacity of the absorber and the thermometer. The temperature rise is read by the thermometer and indicates the radiation energy. Any microcalorimeter must have a low heat capacity mass to absorb incident radiation, a weak link to a low-temperature heat sink which provides the thermal isolation needed for a temperature rise to occur, and a thermometer with a high sensitivity to measure change in temperature. In a microcalorimeter, one exploits the fact that the heat capacity of superconductors or pure dielectric crystals becomes small at low temperatures (50–100 mK). Thus, the temperature rise can be measured by resistive thermometers (thermistors), for which a change in the electrical resistance accompanies a change in temperature. Thermistors are characterized by their sensitivity, $\alpha = \mathrm{d}(\log R)/\mathrm{d}(\log T)$, where $R$ is the electrical resistance and $T$ is the temperature. In an ideal thermistor-based calorimeter, the energy resolution, $\Delta E$, scales as $T(C/|\alpha|)^{1/2}$ so that low operating temperatures and heat capacities contribute to achieve good energy resolution.

Two types of thermistors are used in microcalorimeters: doped semiconductor thermistors and transition edge sensors (TES). Microcalorimeters of neutron transmutation doped (NTD) germanium thermistors paired with superconducting tin absorbers have provided an energy resolution of $\Delta E = 5.2\,\text{eV}$ at $E = 5.9\,\text{keV}$ (Alessandrello *et al*. 1999). TES are thin superconducting films deposited on the absorber. The temperature rise is measured by the TES which works in the region of its normal-to-superconductor phase transition (see *Superconducting Materials, Types of*), where the temperature dependence of the resistance is steep. TES are made from superconductors (aluminum, titanium, tungsten, or proximity bilayers, like Al/Ag, Ir/Au, Mo/Au), with transition temperatures in the range 50–100 mK (see Fig. 2).

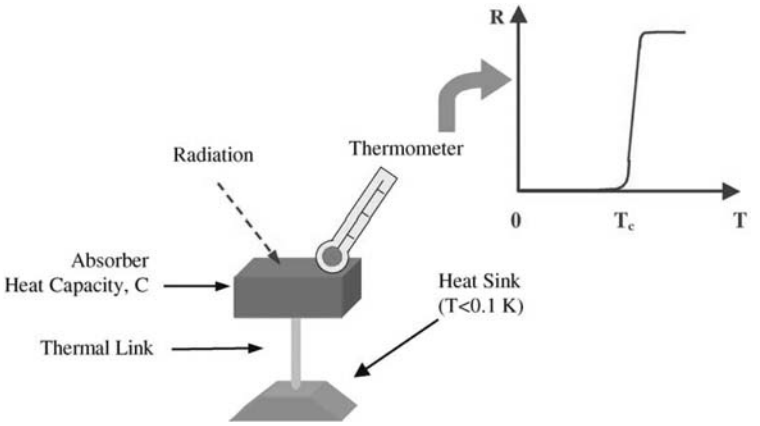

***Figure 1***
Sketch of a microcalorimeter with the resistance vs. temperature curve of a TES thermometer.

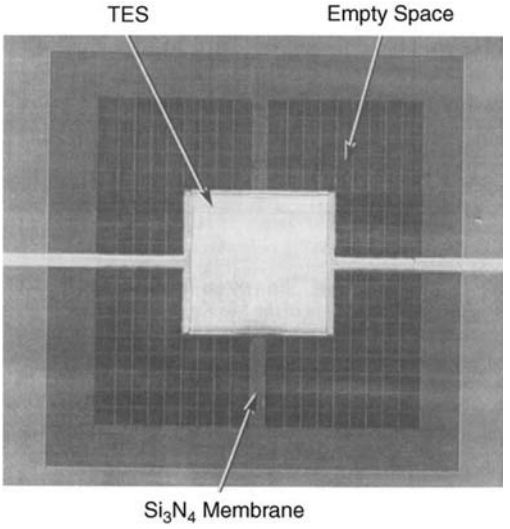

***Figure 2***
A Mo–Cu TES microcalorimeter on a $Si_3N_4$ membrane patterned as a "fly-swatter." The TES has dimensions $400 \times 400\,\mu m$. The large bars are $50\,\mu m$ wide, and the small bars are $5\,\mu m$ wide on $50\,\mu m$ centers. The device was fabricated at NIST, Boulder, CO, USA (from Irwin *et al*. 2000, reprinted with permission from Elsevier Science Ltd.).

Because the transition from the normal to the superconducting state occurs over a very narrow temperature range, a TES is a much more sensitive thermometer than a semiconductor thermistor. The advantage of TES-based devices is that a large volume of normal metals, off-limits to semiconductor-based microcalorimeters, can be used. The rapid and efficient thermalization of metal absorbers allows better energy resolution and faster detector response. TES microcalorimeters achieved energy resolution $\Delta E < 4.7\,eV$ at $E = 6\,keV$ and $\Delta E = 2.38\,eV$ at $E = 1.5\,keV$, with count rates in excess of 500 counts per second.

## 2. *Superconducting Tunnel Junction Detectors*

A superconducting tunnel junction (STJ) consists of two superconducting thin films ($\sim 200\,nm$ in thickness) separated by a very thin insulating barrier ($\sim 1\,nm$ in thickness) (see the sketch in Fig. 3). Typically used superconductors are niobium, tantalum, or aluminum. Normal electrons (so-called quasiparticles) can flow across the barrier via quantum tunneling processes. In STJ detectors, one exploits the fact that the energy gap of a superconductor is of the order of millielectronvolts, so that millions of electrons can be created after a complex energy cascade following the absorption of a single x-ray photon. The amount of created charge is proportional to the energy of the absorbed radiation. The absorber of an STJ detector can be either one of the two junction electrodes or a separate superconductor which injects the STJ with the excitations in the form of electrons or high-energy phonons.

The nonequilibrium electronic charges produced by the radiation diffuse and flow across the tunneling barrier of the STJ, where they are measured as an extra tunneling current. The tunneling barrier is made transparent to improve tunneling so that STJs are physically the same as the more widely known Josephson tunnel junctions (see *Josephson Junctions: High-$T_c$*; *Josephson Junctions: Low-$T_c$*), but the Josephson supercurrent is suppressed by applying a weak magnetic field. STJs are biased in the subgap region of the current–voltage characteristics and are operated at very low temperature ($T \sim T_c/10$) in order to reduce the thermal population of electrons and the recombination

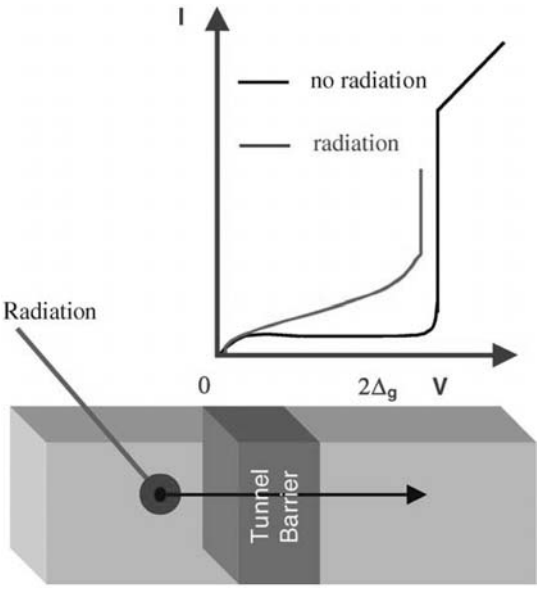

***Figure 3***
Sketch of a STJ with the corresponding current–voltage (*I–V*) curves with and without radiation. The red curve shows the increased tunneling current with respect to the dark condition (black curve).

of the extra electrons. Compared with semiconductor detectors, the very high number of charges generated gives rise to improved energy resolution and detection threshold. Intrinsic energy resolution of few electronvolts at 6 keV is possible and 12 eV has been measured in Al-STJ (Angeloher *et al*. 2001).

STJs are nonthermal, single-particle detectors. In nonthermal detectors, the nonequilibrium distribution of excitations is detected before it relaxes. This feature makes STJs particularly suitable in high-count-rate applications (5000 counts per second can be achieved). Similarly to TES, STJ detectors were developed to answer the demanding request of x-ray astronomy for high-energy resolution detectors. However, they are also capable of detecting single photons with lower energy, like ultraviolet and visible photons. At these short wavelengths, thousands of electrons are still created in a superconductor, sufficient to generate an appreciable pulse signal. Imaging can be obtained by arrays of STJ pixels (see Fig. 4).

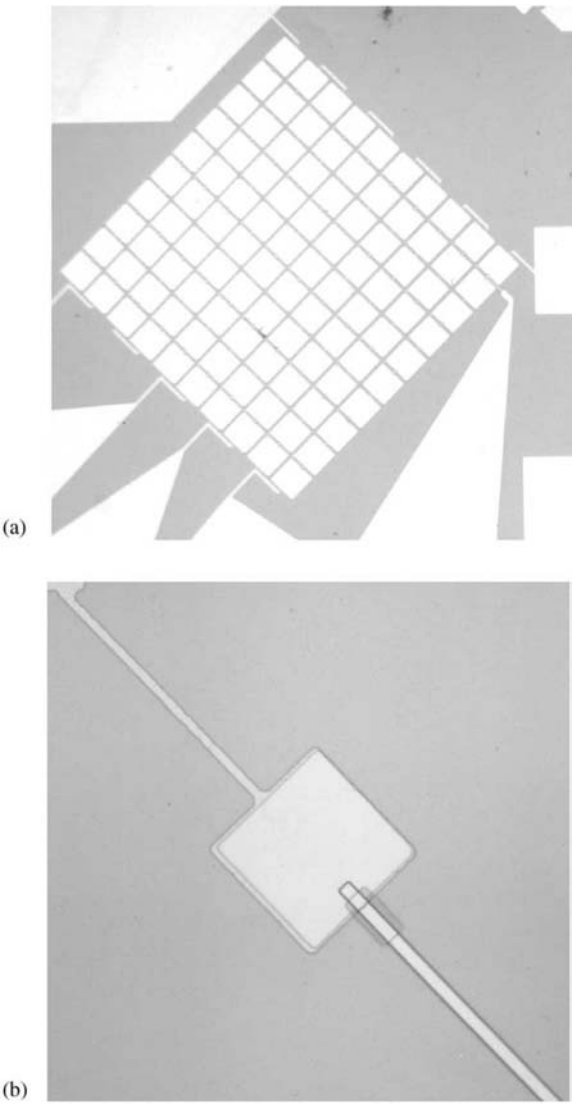

***Figure 4***
(a) A $10 \times 10$ array of STJs. Each STJ has dimensions $100 \times 100\,\mu m$. (b) A single STJ detector on a silicon substrate patterned as an "island." The STJ has dimensions $50 \times 50\,\mu m$, and the narrow wirings are $3\,\mu m$ wide. (The devices were fabricated at CNR-Istituto di Cibernetica, Pozzuoli, Naples, Italy.)

## *3. Superconducting Mixers for Infrared Detection*

Infrared and millimeter wave radiation detectors are realized by several superconducting devices, like STJs (in this context often called superconductor insulator superconductor (SIS) junctions), Josephson junctions, or hot electron bolometers. Applications in radioastronomy, in passive molecular spectroscopy for environmental monitoring and air quality control, have been developed. Infrared and millimeter wavelengths correspond to energy values too low ($\sim$meV) for single photon detection and to frequencies too high ($\sim$0.1 GHz–10 THz) where amplification and processing of electronic signals are difficult. In this case a useful concept is the mixing to down-convert high-frequency (HF) signals. In heterodyne mixers

the HF signal, which has to be detected, is mixed with a laboratory local oscillator (LO), at a slightly different frequency, to give a low difference frequency signal (IF) that can be amplified and studied by conventional devices. In the output signal the information about the frequency and the phase of the incoming signal is preserved. The spectral resolution is limited only by the line width of the LO. The conversion efficiency (ratio between the power of incoming signal to the power at IF signal) and the noise temperature (equivalent noise level added by the mixer during the conversion process) characterize the performance of the mixer. Superconducting mixers have one common advantage over conventional (Schottky) mixers, namely extremely low LO power requirements (of the order of nanowatts).

SIS mixers are the technology of choice in the range 40–800 GHz. These receivers are now in daily use in several millimeter-wavelength telescopes in observatories. SIS mixers are based on the photon-assisted tunneling process and exploit the strong nonlinearity of the SIS current–voltage characteristics. SIS mixers exhibit the best performance (conversion efficiency close to unity and noise temperature close to the quantum limit, $T_n = 50-170$ K). However, their operation is limited to the frequency range below the gap frequency of superconductor. This is about 700 GHz for niobium and slightly above 1 THz for NbN.

Josephson effect mixers, with photon-assisted tunneling of Cooper pairs of electrons as the underlying operational mechanism, show moderate performance ($T_n = 1200-2000$ K), but they can be fabricated using the high transition temperature superconductors (HTS). HTS allow the use of liquid nitrogen ($T = 77$ K) as coolant or cryogen-free cryocoolers, so that they are specifically indicated for space applications.

Hot-electron bolometers (HEBs) can also be operated as mixers in heterodyne receivers. Intrinsically, frequency-independent performance and no gap limitation predestinates these type of mixers for operation at very high frequencies, around and well above 1 THz. Two concepts of HEB mixer materials are exploited: phonon-cooled bolometers (relying typically on NbN, $T_n = 400-2000$ K) and diffusion-cooled HEB (fabricated mostly of Nb, $T_n = 650$ K).

## 4. Conclusions

Superconducting sensors are undergoing continuous evolution. The above overviewed sensors are not exhaustive of devices under development. The reader is referred to the literature for a complete review of the subject (Booth *et al.* 1996, De Korte and Peacock 2000)

An interesting perspective for applications is represented by spectrometry for high-sensitivity microanalysis. This is due to the fact that both superconducting microcalorimeters and STJ detectors have surpassed the ultimate energy resolution of semiconductor detectors ($\Delta E = 120$ eV at $E = 6$ keV), which are typically used in x-ray fluorescence energy-dispersive spectrometers (EDS). The improved energy resolution of superconducting sensors combined with their fast count rate makes possible the realization of spectrometers having the energy resolution of Bragg crystals used in wavelength-dispersive spectrometers as well as the fast operation mode and the simplicity of use of EDS-like instruments (Wollman *et al.* 1997). Furthermore, the detection principle of TES and STJ detectors is heat transfer rather than ionization. This opens the possibility of an efficient detection of very slow massive ions like macromolecules (biopolymers, proteins, DNA fragments) and neutral particles (neutrons). The sensitivity allows high throughput, even in the presence of dilute samples with traces of significant elements. To exploit this property, time-of-flight mass spectrometers equipped with superconducting detectors have been proposed (Hilton *et al.* 1998).

# Superconducting Thin Films: Materials, Preparation, and Properties

The crystal structures of high $T_c$ superconductors are described in this article together with the deposition methods used to produce high-quality films of these materials. This article complements *High-temperature Superconductors: Thin Films and Multilayers*. It is impossible to include all of the important work contributed by the large number of groups active in this rapidly progressing field. Additional information can be found in reviews of high $T_c$ materials and deposition methods (Humphreys *et al*. 1990, Eckstein and Bozovic 1995, Schlom and Harris 1995, Matijasevic and Bozovic 1996, Fisk and Sarrao 1997, Wördenweber 1999).

## 1. Materials

### 1.1 Crystal Structures and Types of Building Layers

All high $T_c$ superconductors have perovskite-related structures. The crystal structure of perovskite ($CaTiO_3$) and some of the better-known high $T_c$ superconductors are shown in Fig. 1. All high $T_c$

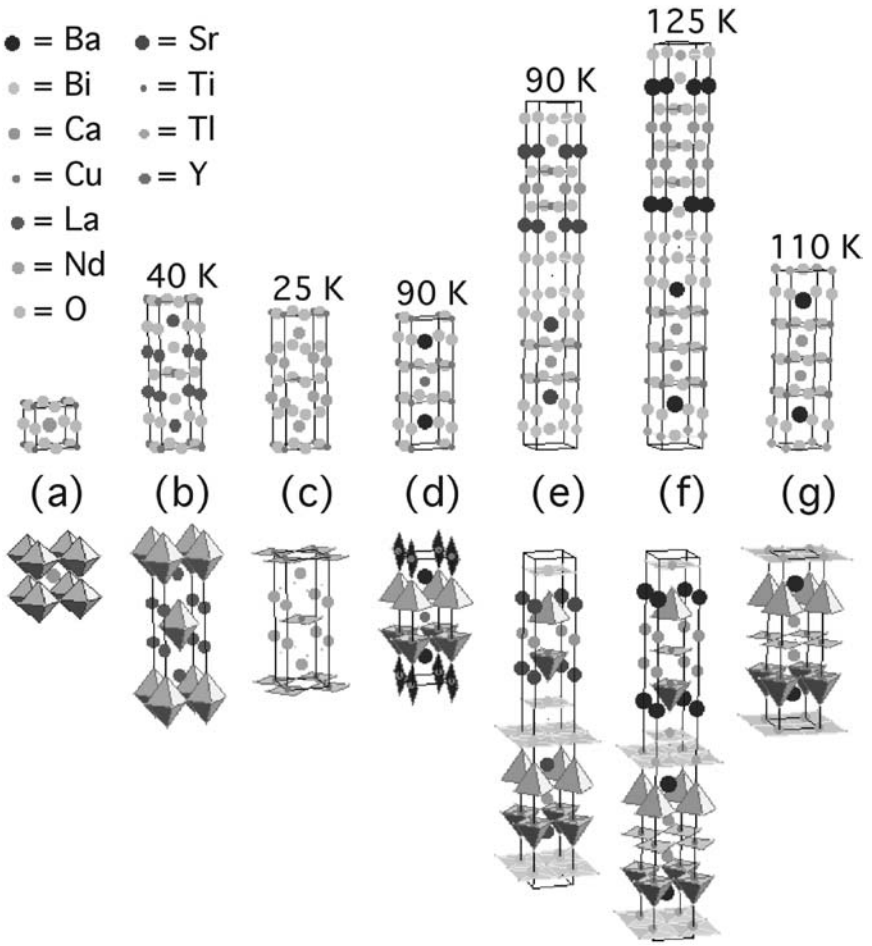

***Figure 1***
Crystal structure of (a) perovskite ($CaTiO_3$) and some of the better known high $T_c$ superconductors: (b) $(La,Sr)_2CuO_4$, (c) $(Nd,Ce)_2CuO_4$, (d) $YBa_2Cu_3O_{7-\delta}$, (e) $Bi_2Sr_2CaCu_2O_8$, (f) $Tl_2Ba_2Ca_2Cu_3O_{10}$, and (g) $TlBa_2Ca_2Cu_3O_9$. Two equivalent representations of these crystal structures are shown: the atomic positions (above) and the copper coordination polyhedrons (below). The oxygen atoms occupy the vertices of the copper coordination polyhedrons. The tetragonal subcells of the $(La,Sr)_2CuO_4$ and $Bi_2Sr_2CaCu_2O_{8+\delta}$ structures are shown for clarity and to illustrate the similarities between these perovskite-related phases. The approximate superconducting transition temperatures are also shown.

structures can be assembled from a relatively small number of more fundamental layer types (Tokura and Arima 1990), referred to as building layers (Schlom and Harris 1995). A common feature of the crystal structures of all known copper-containing high $T_c$ superconductors is the presence of $CuO_2$ layers. The $CuO_2$ layers are separated from one another along the *c*-axis of the crystal structure by various intervening layers, the known types of which are shown in Fig. 2. By stacking the building layers shown in Fig. 2 on top of one another along the *c*-axis direction, all known copper-containing high $T_c$ structures can be assembled.

There is only one other known oxide superconductor with a relatively high $T_c$ that does not contain $CuO_2$ layers, $(Ba,K)BiO_3$, which has a $T_c$ of about 30 K (Cava *et al*. 1988). Like the structurally related solid solution $Ba(Pb,Bi)O_3$ with $T_c$ of approximately 13 K (Sleight *et al*. 1975), $(Ba,K)BiO_3$ has a simple cubic perovskite structure, shown in Fig. 1, with bismuth occupying the octahedrally coordinated titanium position and barium and potassium occupying the larger calcium site. From a building layer standpoint, $(Ba,K)BiO_3$ consists of alternating $BiO_2$ and (Ba,K)O building layers.

Although high $T_c$ phases are commonly referred to by formulas implying that they are stoichiometric, e.g., $Bi_2Sr_2CaCu_2O_8$, this is an oversimplification. In reality, significant cation mixing, anion vacancies, or cation vacancies often occur within the building layers, with several percent mixing quite common in some layers, although not within the $CuO_2$ layers. For example, site-sensitive structural refinement of a single crystal of the high $T_c$ superconductor $Bi_2Sr_2CaCu_2O_8$ has determined that its overall composition

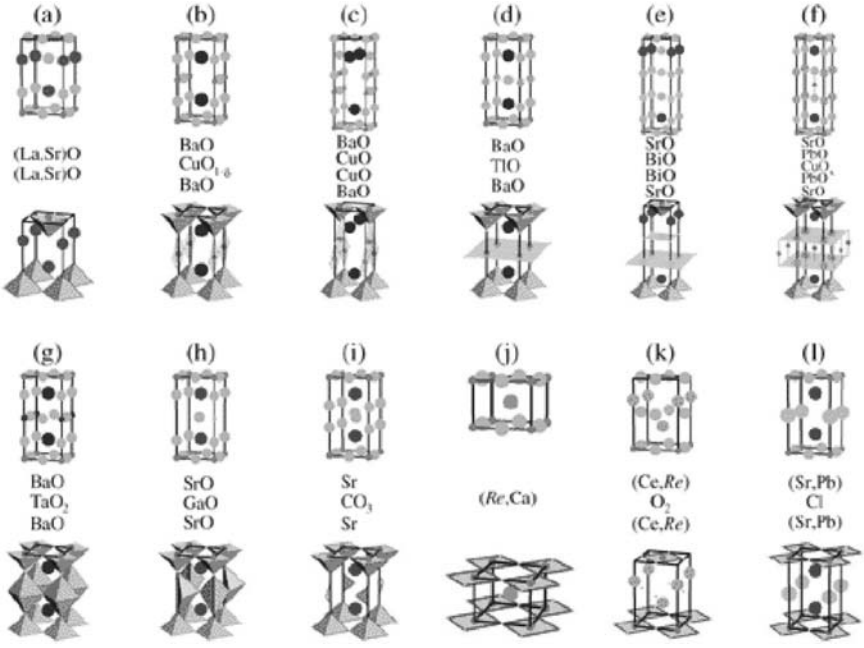

***Figure 2***

Building layers of all known layered $CuO_2$ structures: (a) [(La,Sr)O–(La,Sr)O] or [(Sr,Ca)(Br,Cl)–(Sr,Ca)(Br,Cl)]*, (b) [BaO–$CuO_{1-\delta}$–BaO], (c) [BaO–CuO–CuO–BaO], (d) [BaO–TlO–BaO] or [BaO–$HgO_x$–BaO] or [SrO–(Bi,Cu)$O_x$–SrO] or [SrO–(Bi,Cd)O–SrO] or [SrO–(Pb,Sr)O–SrO] or [SrO–(Pb,Cu)$O_x$–SrO] or [SrO–(Pb,Cd)O–SrO] or [SrO–(Ce,Cu)$O_x$–SrO]* or [SrO–(Ce,Cd)O–SrO], (e) [BaO–TlO–TlO–BaO] or [BaO–$HgO_x$–$HgO_x$–BaO] or [SrO–BiO–BiO–SrO] or [(Ba,Sr)O–(Pb,Cu)$O_x$–(Pb,Cu)$O_x$–(Ba,Sr)O], (f) [SrO–PbO–$CuO_x$–PbO–SrO], (g) [LaO–$SnO_2$–LaO]* or [BaO–$TaO_2$–BaO]* or [SrO–$TaO_2$–SrO] or [SrO–$NbO_2$–SrO], (h) [SrO–GaO–SrO] or [SrO-CoO–SrO]* or [SrO–AlO–SrO]*, (i) [Sr–$CO_3$–Sr] or [(*Re*,Ba)–$BO_3$–(*Re*,Ba)] where *Re* is a rare earth ion, (j) [(*Re*,Ca)], (k) [(Ce,*Re*)–$O_2$–(Ce,*Re*)], and (l) [(Sr,Pb)–Cl–(Sr,Pb)]*. The tetragonal subcell of each building layer is outlined. $CuO_2$ layers are shown above and below each building layer to illustrate their attachment positions. Partial substitution for the constituents of these basic building layers is frequently possible and may be used for doping purposes (e.g., Bi ↔ Pb, Tl ↔ Pb, Sr ↔ Ba, Sr ↔ La, Sr ↔ Ca, Ca ↔ Re). Most of these building layers are constituents of the copper-containing high $T_c$ superconductors discovered to date. Those intervening layers known to occur between $CuO_2$ layers, but so far not constituents of superconducting structures, are marked with an asterisk (reproduced by permission of Noyes Publications from "Molecular Beam Epitaxy: Applications to Key Materials," 1995, pp. 505–622).

is $Bi_{2.15}Sr_{1.92}Ca_{0.75}Cu_2O_{8.1}$ with the "calcium site" occupied by 75% calcium, 19% strontium, and 6% bismuth (Petricek *et al.* 1990, Coppens *et al.* 1991). Other sites in the crystal structure also show cation mixing, although to a lesser extent.

Nonstoichiometry is an important aspect of high $T_c$ superconductors. For some phases, the adjustable nonstoichiometry (solid solution) within a particular building layer is explicitly stated, e.g., $(La,Sr)_2CuO_4$, $(Nd,Ce)_2CuO_4$, $YBa_2Cu_3O_{7-\delta}$, and (Ba,K)$BiO_3$. As described below, nonstoichiometry in the building layers provides charge carriers via chemical doping. Pure $Bi_2Sr_2CaCu_2O_8$ would not be superconducting, since the average oxidation state of copper would be exactly $+2$ and there would be no charge carriers, whereas $Bi_{2.15}Sr_{1.92}Ca_{0.75}Cu_2O_{8.1}$ is superconducting and the average oxidation state of copper is $+2.21$.

### *1.2 Chemical Doping*

In addition to structural control, realizing the optimal carrier concentration in the $CuO_2$ layers is a crucial part of the synthesis of high $T_c$ materials. The building layers surrounding the $CuO_2$ layers serve as "charge reservoirs" to dope the $CuO_2$ layers by chemical means (Cava 1990). Doping the $CuO_2$ layers with holes or electrons is a necessary, although not sufficient, condition for achieving superconductivity in these materials. A convenient method for charge counting to assess chemical doping is through the use of the concept of oxidation states. Note that the oxidation state of an ion is not the same as the true charge on the ion. For simplicity, the oxidation state of an oxygen ion (O) is defined to be –2; hence, in order to quantify the doping of the $CuO_2$ layers, it is sufficient to know the oxidation state of copper. The average oxidation state of copper is determined from the phase composition, the standard oxidation states of the remaining ions (e.g., $Sr^{2+}$, $La^{3+}$, etc.), and the condition of charge neutrality. For example, in $La_{2-x}Sr_xCuO_4$ the average oxidation state of copper is $(2+x)$, and in $Nd_{2-x}Ce_xCuO_4$ (where $Ce^{4+}$ is present) it is $(2-x)$.

In the parent compounds, $La_2CuO_4$ and $Nd_2CuO_4$, where no chemical doping is present ($x=0$), the oxidation state of copper is $+2$ and the compounds are not superconducting. As $x$ increases and the parent compounds are doped, charge carriers (holes) enter the $CuO_2$ layers and the average oxidation state of copper deviates from $+2$. Some high $T_c$ compounds contain elements that may assume a variety of oxidation states (e.g., bismuth, lead, thallium, or mercury); these must be known in order to determine the oxidation state of copper in the $CuO_2$ layers. The same is true for compounds with nonequivalent copper sites, e.g., those that contain $CuO_{1-\delta}$ "chains" (see Fig. 2(b)).

The oxidation state of copper is greater than 2 for *p*-type superconductors and less than 2 for *n*-type superconductors. The amount of charge transferred from the surrounding (charge reservoir) building layers to the $CuO_2$ layers is given by the deviation of the oxidation state of copper from $+2$. One can also talk of the deviation of the oxidation state of each $CuO_2$ unit from $-2$: $[CuO_2]^{-2+\delta}$, where $\delta$ is positive for hole-doped (*p*-type) and negative for electron-doped (*n*-type) superconductors. (While the two jargons are mathematically equivalent, the latter may be closer to the physical reality: in high $T_c$ cuprates, the holes in $CuO_2$ layers reside in states of predominantly O $2p$ character, with relatively small admixture of Cu $3d$ (Nücker *et al.* 1988).) Studies of the maximization of $T_c$ with doping (Tokura *et al.* 1988, Torrance *et al.* 1988, Tokura *et al.* 1989, Shafer and Penney 1990, Rao 1991) have revealed that a maximum $T_c$ for each structure occurs at about $|\delta| \approx 0.2$, as shown in Fig. 3 for several *p*-type superconductors.

### *1.3 Minimum Oxygen Partial Pressure for $YBa_2Cu_3O_{7-\delta}$ Stability*

While some high $T_c$ superconductors are thermodynamically stable at high temperatures and may be quenched to avoid decomposition, others (e.g., $YBa_2Cu_3O_7$) are not stable at any temperature or pressure (Sleight 1991). Their synthesis is commonly achieved by first forming a thermodynamically stable parent structure (e.g., $YBa_2Cu_3O_6$) and subsequently

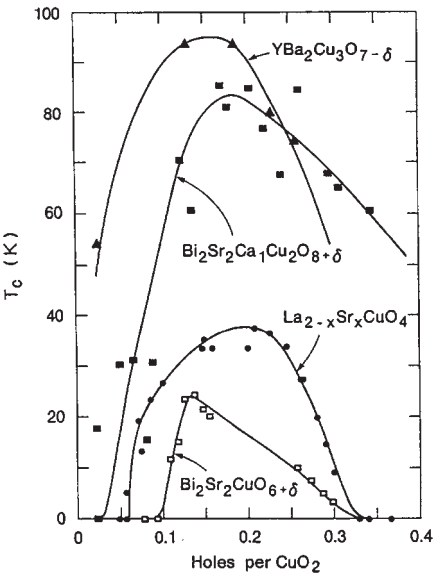

***Figure 3***
$T_c$ as a function of hole concentration, $n_h$, per $CuO_2$ unit for various high $T_c$ superconductors as determined by chemical titration (reproduced by permission of World Scientific from *Mod. Phys. Lett. B* 1992, **6**, 555–71).

altering its composition after the sample has been cooled to a temperature where the parent structure is kinetically prevented from decomposing (e.g., by venting the deposition chamber with oxygen as the film cools from its growth temperature).

It is for this reason that the growth of $YBa_2Cu_3O_{7-\delta}$ films with $\delta \approx 0$ involves a minimum of two steps: (i) formation of the $YBa_2Cu_3O_6$ parent structure and (ii) oxidation of this parent structure to $YBa_2Cu_3O_7$. For $YBa_2Cu_3O_{7-\delta}$, temperatures in the vicinity of 700 °C and 400 °C are used for these two steps, respectively. The latter temperature is low enough to kinetically prevent the decomposition of $YBa_2Cu_3O_{7-\delta}$, but high enough that the kinetics of oxygen uptake are rapid (Shi and Capone 1988).

The minimum $P_{O_2}$ at which a desired high $T_c$ structure (or its parent structure) is thermodynamically stable is a major constraint in thin-film synthesis by vacuum deposition methods. The lines $d_1$, $m_1$, and $d_2$ shown in Fig. 4 bound the region in which the oxygen-deficient parent structure of $YBa_2Cu_3O_{7-\delta}$ is stable as a function of substrate temperature and oxygen pressure. The lines were established for bulk $YBa_2Cu_3O_{7-\delta}$ (Lindemer *et al.* 1991); however, the region in which $YBa_2Cu_3O_{7-\delta}$ films may be deposited is the same for deposition techniques that use molecular oxygen

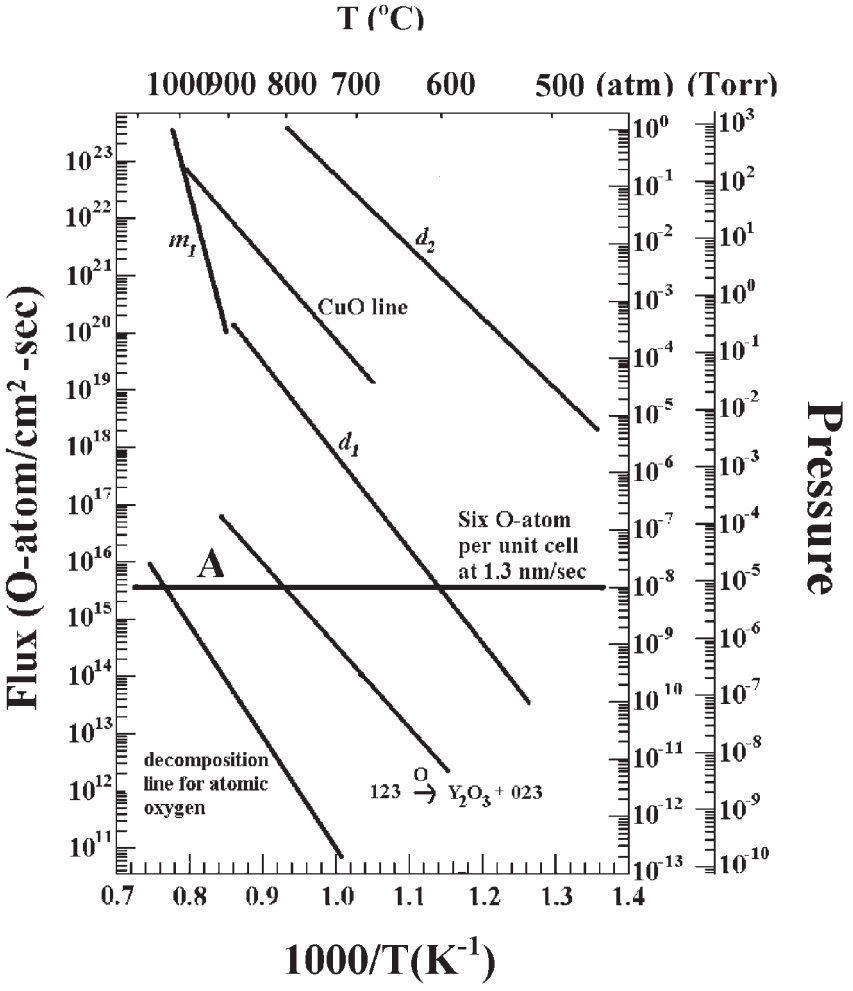

***Figure 4***
Temperature and oxidant pressure dependence of the region in which $YBa_2Cu_3O_{7-\delta}$ is stable. In molecular oxygen, $YBa_2Cu_3O_{7-\delta}$ is stable in the region bounded by $d_1$, $m_1$, and $d_2$. In atomic oxygen, it is stable in the region between the lowest two lines. The horizontal line A shows where the incident oxidant flux is just six oxygen atoms per unit cell for a $YBa_2Cu_3O_{7-\delta}$ growth rate of 1.3 $nms^{-1}$ (reproduced by permission of Elsevier Science from *J. Cryst. Growth* 2001, **225**, 183–9).

(Hammond and Bormann 1989). This constraint is particularly restrictive in the case of molecular beam epitaxy (MBE) growth, where one must keep the background gas pressure low in order to maintain the long mean free path necessary for MBE. This has necessitated the use of activated oxygen species such as ozone, atomic oxygen, and $NO_2$ (Nonaka *et al.* 1995, Schlom and Harris 1995).

The approximate lines that bound the region of $YBa_2Cu_3O_{7-\delta}$ stability when grown using atomic oxygen are also shown in Fig. 4. In addition to providing a growth environment that lies within the region in which $YBa_2Cu_3O_{7-\delta}$ is stable, it is also necessary for the oxidant flux to be sufficient to supply the six oxygen atoms per unit cell needed to form $YBa_2Cu_3O_{7-\delta}$. This minimum flux depends on the film growth rate and is shown by line A in Fig. 4 for a $YBa_2Cu_3O_{7-\delta}$ growth rate of $1.3\,nms^{-1}$.

## 2. *Deposition Methods*

In what follows, the key techniques for deposition of thin films of high $T_c$ superconductors are described. Note that the quoted deposition conditions are specific for these materials. The key limiting factor here is the necessity to fully oxidize copper, which requires film growth either under a relatively high partial pressure of oxygen, or using more reactive oxidants. This requirement has prompted attempts at deposition under unusual thermodynamic conditions, as well as the development of a range of new hardware tools. The latter include special heaters that are oxidation resistant, mechanisms for shuttling the film during deposition back and forth between neighboring low-pressure (deposition) and high-pressure (oxidation) zones, ozone distillation systems and oxygen plasma sources for delivery of activated oxygen to high-vacuum chambers, differentially pumped analytical tools, etc.

### 2.1 *Sputtering*

For the thin-film deposition of high $T_c$ superconductors by sputtering, one makes use of discharge in a gas, typically argon, plus oxygen to oxidize the film. The gas pressure is most frequently kept in the range 50–700 mtorr. The plasma is generated by an electric field, either d.c. or a.c. The ions from the plasma hit the surface of a target and eject from it mainly neutral atoms. These are collected onto a substrate, which is usually heated to promote crystallization. The composition of the film is largely determined by the stoichiometry of the target, which can involve a single element or a mixture of elements.

Soon after the discovery of high $T_c$ superconductors, sputtering from a single compound target was applied with success to grow high $T_c$ superconductor thin films, and this remains one of the simplest and most popular methods to grow such films. Good-quality films of $La_{1.85}Sr_{0.15}CuO_4$, $YBa_2Cu_3O_{7-\delta}$ (both *c*- and *a*-axis oriented), $Bi_2Sr_2CaCu_2O_8$, etc., have been deposited in this way (Suzuki and Murakami 1987, Xi *et al.* 1989, Eom *et al.* 1989, Wagner *et al.* 1993). A common problem is resputtering of the film by negatively charged oxygen ions and the resulting degradation of the film, but this can be overcome by using higher gas pressure (Poppe *et al.* 1988) or off-axis sputtering (Eom *et al.* 1990) as shown in Fig. 5.

More advanced sputtering systems contain several targets. The substrate is moved from target to target to make multilayers. Using multi-element targets and switching from one to another, superlattices have been made of $(YBa_2Cu_3O_{7-\delta})_n(PrBa_2Cu_3O_{7-\delta})_m$ (Triscone *et al.* 1990, Jakob *et al.* 1994) and $(Bi_2Sr_2CaCu_2O_8)_n(Bi_2Sr_2CuO_6)_m$ (Li *et al.* 1994) with remarkable crystalline coherence.

### 2.2 *Pulsed Laser Deposition*

In pulsed laser deposition (PLD), a short-wavelength laser—most frequently a KrF excimer laser ($\lambda = 248$ nm)—is focused onto a target to ablate material. Some of this ablated material reaches and deposits on the substrate (Dijkkamp *et al.* 1987). Like sputtering, PLD is generally done under a substantial pressure, typically 100–300 mtorr, during deposition. Unlike sputtering, argon is not necessary for the process so pure oxygen is usually used. Apart from the stoichiometry of the target, the composition of the resulting film may depend on the target-to-substrate distance, the pressure, the laser fluence (energy per illuminated area on the target per pulse), etc. Nevertheless, PLD is also a very simple technique that generally produces good results fast; in particular, it is well suited to switching from one material to another. A frequent problem is the occurrence of micrometer-sized particulates (''boulders'') that are observed in the films. Various solutions to this problem have been proposed, such as using off-axis PLD.

More advanced PLD systems have also been built, and many of these include multiple, interchangeable targets. Efforts have been made to extend PLD to large-area substrates, by rotation and translations of both the target and substrate. Finally, by using ozone or $NO_2$, either of which is much more reactive than $O_2$, PLD has been performed under high-vacuum conditions (Tabata *et al.* 1989, Koinuma and Yoshimoto 1994). Here, the key advantage is that one can use *in situ* analytical tools such as reflection high-energy electron diffraction (RHEED) to monitor the crystallinity and morphology of the surface of the growing film. This has been accomplished more simply at the pressures conventionally used for PLD by differential pumping of the RHEED electron gun (see Fig. 6) (Rijnders *et al.* 1997). The growth of individual

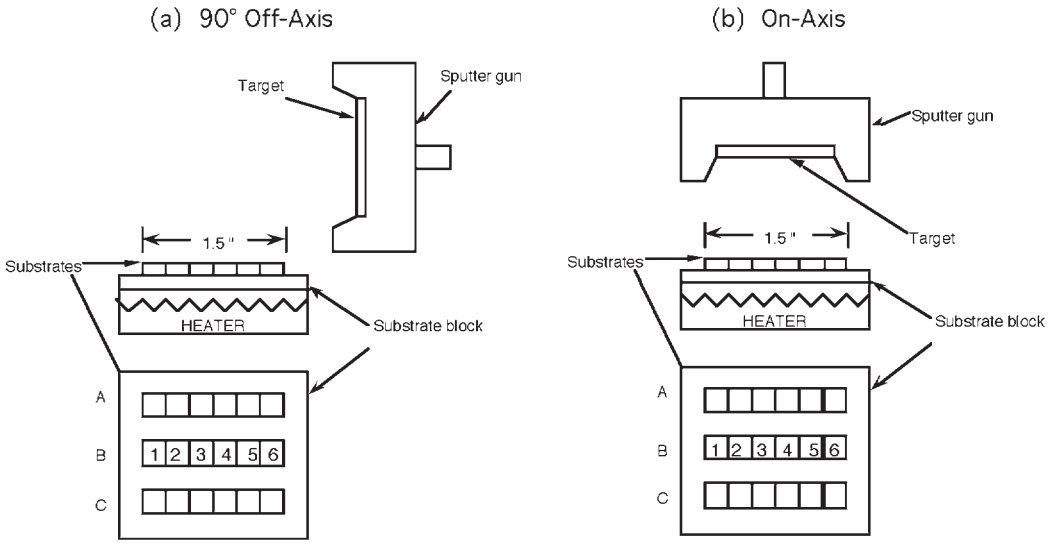

***Figure 5***

monolayers and the engineering of new structures at the atomic-layer level have been achieved using PLD in this way.

### *2.3 Reactive Evaporation*

The simplest variant of reactive evaporation is the use of resistively heated metallic "boats" as thermal sources of metal atoms. The evaporation rates are controlled by tuning the current, and monitored by quartz crystal microbalances (QCMs). One effective implementation of this technique, shown in Fig. 7, uses a black-body-type rotating disk heater, which has an "oxidation pocket" with a very narrow opening (Kinder *et al.* 1996). This allows for a relatively high pressure inside the oxidation pocket ($\sim 10^{-2}$ torr), and a low pressure in the rest of the chamber ($\sim 10^{-4}$ torr), which extends the lifetime and stability of the thermal evaporation sources. This is the preferred technique for the deposition of uniform $YBa_2Cu_3O_{7-\delta}$ films over large-area wafers (up to 9 in (23 cm) in diameter). The method also has a comparatively high throughput and is cost effective.

### *2.4 Molecular Beam Epitaxy*

The coherence length in high $T_c$ superconductors is very short, a couple of nanometers at most. To fabricate good active devices such as Josephson junctions, one thus needs a capability to deposit ultrathin layers, with perfect interfaces. This becomes even more critical when one is concerned with large-scale integration where the devices have to get denser and smaller, while the uniformity demands increase.

One of the most successful techniques that enables one to control the film deposition at an atomic-layer level, for high $T_c$ superconductors as well as for other complex oxides, is reactive MBE (Eckstein and Bozovic 1995, Schlom and Harris 1995). It is similar to reactive evaporation, except that (i) the pressure during deposition must be low enough such that the mean free path of the depositing species (atoms or molecules) is longer than the source-to-substrate distance and (ii) the chamber walls must be cold enough such that the metal atoms or molecules that collide with them are not re-emitted. Under such conditions (typically $10^{-5}$ torr or less), the supply of the desired species, in whatever overlapping or nonoverlapping order desired, can be precisely controlled.

The molecular beams are chopped by mechanical shutters, and the timing is computer controlled. Radiatively heated effusion cells are typically used to provide molecular beams of the elemental constituents of the materials to be grown (see Fig. 8). For atomic-layer engineering, it is not enough to monitor relative ratios; one needs an absolute measurement of the atomic fluxes. For this purpose, spectroscopic techniques such as measurements of absorption or emission of visible or UV characteristic radiation from the atomic beams have been used with success, usually in addition to the more conventional QCMs.

Using MBE, a variety of high $T_c$ superconductor heterostructures have been fabricated, including trilayer Josephson junctions (known also as planar or sandwich junctions). The superconductive electrodes are made of $Bi_2Sr_2CaCu_2O_8$, $YBa_2Cu_3O_{7-\delta}$ (both *c*- and *a*-axis oriented), or $La_{1.85}Sr_{0.15}CuO_4$. For the barrier layers, various materials have been used including titanates and manganites, with the layer thickness down to one unit cell. High $T_c$ superconductor layers of one unit cell thickness have also been fabricated with $T_c$ equal to bulk samples, as well as various superlattices, and even some novel, artificial high $T_c$ superconducting compounds (Bozovic *et al.* 1994, Schlom and Harris 1995).

### *2.5 Other Techniques*

Some of the high $T_c$ superconductors with the highest $T_c$ contain highly volatile (and toxic) elements, such as mercury or thallium. The techniques described above

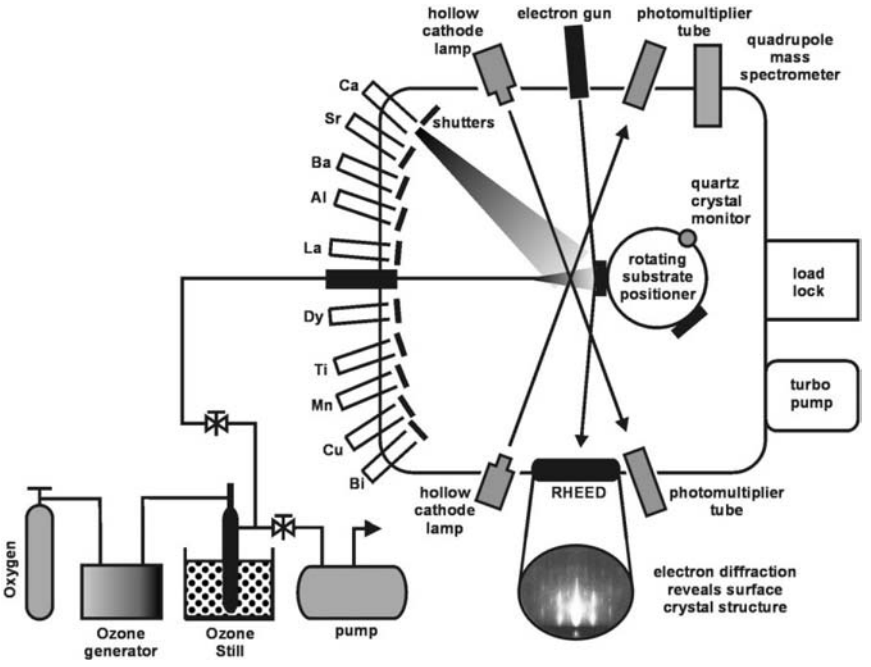

***Figure 8***
Schematic of an MBE system for atomic-layer synthesis of oxide superconductors (reproduced by permission of Annual Reviews Inc. from *Annu. Rev. Mater. Sci.*, 1995, **25**, 679–709).

are not well suited for handling such elements. For this reason, special approaches have been adopted: either a two-step process, where the precursor film is deposited first, and then postannealed (*ex situ*) under a high vapor pressure of thallium or mercury, or a single-step (*in situ*) process where sputtering of the precursor and high-rate thermal evaporation of thallium are applied simultaneously (Tsuei *et al*. 1994, Myers *et al*. 1994).

Several techniques have allowed films with excellent in-plane texture to be realized on polycrystalline substrates of practical importance. One method makes use of ion beam-assisted deposition (IBAD) to create an in-plane oriented buffer layer of yttria-stabilized cubic zirconia (Iijima *et al*. 1992) or MgO (Wang *et al*. 1997) on the underlying substrate. Films of high $T_c$ superconductors are then epitaxially grown on top of this buffer layer. Another method, which has achieved comparable in-plane texture to IBAD, uses rolling and annealing to achieve texturing in metal strips, e.g., nickel, that are then used as substrates for film deposition (Goyal *et al*. 1996, Norton *et al*. 1996). The freedom from single-crystal substrates that these techniques bring offers flexibility for the integration of high $T_c$ superconductor films with other materials and forms the basis of a growing coated-conductor technology (see *Superconducting Wires and Cables: Low-field Applications*).

Other techniques, such as metal-organic chemical vapor deposition (MOCVD), etc., have also been applied with success to grow high $T_c$ superconductor thin films, but they are less widespread.

## 3. Summary and Outlook

As discussed in this article, films and multilayers containing a great number of high $T_c$ compounds are now grown routinely and have exceptional properties (see *High-temperature Superconductors: Thin Films and Multilayers*)—quite an accomplishment, given that high $T_c$ superconductivity was discovered only in 1986. Multilayers have progressed from combining known materials to literally engineering new materials at the atomic-layer level.

The progress achieved and the knowledge acquired will be applied in the future to the growth of films and heterostructures of other oxide or nitride compounds, into which high $T_c$ superconducting films will be embedded. As in semiconductors, through doping and material selection, the functionality of individual layers can be tailored in heterostructures. It is expected that the challenges and the potential benefits of such heterostructures will stimulate further improvements in the control of film growth.

## Acknowledgments

We gratefully acknowledge our many collaborators with whom, beginning in early 1987, we have worked on high $T_c$ superconducting thin films and multilayers, especially D. Anselmetti, M. R. Beasley, J. G. Bednorz, A. Catana, K. Char, Ch. Gerber, J. N. Eckstein, C.-E. Eom, T. H. Geballe, R. H. Hammond, J. S. Harris Jr., E. S. Hellman, A. Kapitulnik, M. E. Klausmeier-Brown, J. Mannhart, and G. F. Virshup. We also thank D. H. A. Blank, C. B. Eom, and H. Kinder for providing us with original figures of their work for use in this article. DGS acknowledges the support of DOE through grant DE-FG02-97ER45638 and a research fellowship from the Alexander von Humboldt Foundation during his sabbatical stay at Augsburg University.

# Superconducting Thin Films: Multilayers

Over the years superconducting multilayer technology has been developed either for scientific curiosity or for technological applications. One of the simplest multilayer structures is the superlattice where superconducting layers and nonsuperconducting layers alternate either in a periodic order or in a nonperiodic special order. The nonsuperconducting layers are usually normal materials that can allow some coupling between the superconducting layers. Without any further processing, these superlattices have been used for investigation of their superconducting properties. The main scientific interest has been the interaction between the superconducting layers as a function of their coupling strength. Most studies were on artificially made two-dimensional superconducting structures before the discovery of high-temperature superconductivity (HTS) in 1987.

Some of the investigations of the superlattices have led to important technological discoveries, one of which being Nb/Al:$Al_2O_3$/Nb tunnel junctions. While the tunneling phenomena were being studied in Nb/Al superlattices, the idea of using the proximity effect between niobium and aluminum was considered and the excellent barrier properties of $Al_2O_3$ were discovered. This tunnel junction technology has been very important in low $T_c$ superconducting (LTS) electronics since the early 1980s.

While most low $T_c$ superconductors are based on conventional metals, the discovery of HTS has brought on a completely new class of materials, namely the metal oxides in complex perovskite structures. These new oxide materials require new deposition and processing techniques.

This article describes the deposition and processing technology of superconducting multilayers and their applications for the case of high $T_c$ superconducting materials. The LTS case will be briefly mentioned for comparison.

## 1. Deposition Technology

### 1.1 LTS Multilayers

When lead was used before niobium was introduced to LTS technology, the preferred thin-film deposition technique was evaporation, because the soft lead was almost impossible to sputter. However, when the more refractive niobium material is used, sputtering techniques are possible, although the evaporation technique continues to be used, especially for careful epitaxial growth of niobium thin films. The sputtering technique for niobium is found to be very reliable once ultrahigh vacuum and stress-free deposition conditions are obtained.

The majority of niobium growth is for polycrystalline thin films and the adjacent nonsuperconducting layers are also polycrystalline. For many technological applications $SiO_2$ is used as the insulating layer between the niobium wiring layers, and chemical vapor deposition techniques are often used to take advantage of the developments made in the semiconductor industry. LTS technology based on metals is very similar to that of metallization in the semiconductor industry.

The sputtering, evaporation, and chemical vapor deposition techniques mentioned above are standard methods used throughout the electronics industry (see *High-temperature Superconductors: Thin Films and Multilayers*).

### 1.2 High $T_c$ Superconducting Multilayers

High $T_c$ superconductors, discovered in 1987, turned out to be very complex metal oxides that had to be grown in high-oxygen environments (greater than 1 mtorr) and at high temperatures (greater than 700 °C). Laser ablation, or pulsed laser deposition (PLD), is a newer technique that has gained much popularity because it is ideally suited for deposition at a high oxygen pressure. The relative ease of this technique in depositing multicomponent oxides makes it especially effective for exploring new materials for HTS electronics, such as epitaxial dielectrics or barrier layers. A short-wavelength (170–260 nm) excimer laser is focused onto a rotating target of the material to be deposited. At the energy of the laser beam (0.1–2 J per pulse) the matter emitted from the target forms a plume that carries it to the substrate at supersonic velocities. In general, a higher gas pressure is required during laser ablation owing to the very high energy of the vaporized material from the surface of the target. The laser plume glows brightly from the target and deposition is usually done near the end of the plume, about 5 cm away. As in the case of sputtering, the various species scatter differently and therefore the ''sweet spot'' of the deposition process is relatively small, usually 1–2 cm, depending on the geometry. The deposition rate per laser pulse ranges from a fraction of an angstrom to a few angstroms. The technique is fairly reproducible and has been used extensively for research and development purposes. Although other techniques are potentially more manufacture-friendly, laser ablation is very actively used for prototyping multilayer devices made up of several complex materials, such as superconductors, dielectrics, ferroelectric oxides, magnetic oxides, and other conducting oxides.

A particular problem associated with PLD is the deposition of micrometer-sized droplets, so-called ''boulders,'' on the grown film. These particles originate at the target and are emitted from the action of the laser pulse. A variety of procedures have been used to reduce this problem so that the boulder density can be very low in the best films. Such procedures

include target preparation, such as frequent polishing, defocusing the laser spot, mechanically chopping the plume, or spatially filtering the beam. The quality of multilayers made by PLD depends on being able to reduce these boulder problems.

Although PLD can produce relatively high deposition rates (up to tens of nanometers per second), the area on which one deposits is relatively small. A straightforward way to increase the deposition area is to scan wafers over the plume either by moving the substrate vertically and horizontally or by rotating the substrate. Another scheme uses a rotating cylindrical target with a linear laser profile to obtain larger deposition areas.

Another major difficulty of these techniques is the uniform heating of large wafers. Most of the heating methods for small-area laser ablation mount a substrate on a heated metal surface with silver paste, which is difficult to extend to larger sizes. In order to overcome this difficulty of heating a large wafer, an off-axis laser ablation technique has been developed. A large wafer (2–3 in (5–8 cm)) can be mounted parallel to the direction of the plume inside a relatively simple black-body-like heater. The deposition takes place when the atoms collide with the background pressure and are scattered to the surface of the wafer. By rotating the wafer and selecting an appropriate pressure for the geometry, a fairly uniform deposition can be achieved over 2 in (5 cm) wafers. This technique allows for simultaneous deposition on both surfaces of the wafer, which is an important benefit for microwave applications requiring a ground plane. A drawback of this technique is its low deposition rate because of the off-axis geometry. Typical conditions for 2 in (5 cm) wafer deposition results in a deposition rate lower by about a factor of 10 than that for on-axis deposition. However, the added advantage of off-axis laser ablation is the reduction of the boulder density, especially important for multilayer work.

By using a laser fluence just enough to evaporate a few atomic layers of the target in a low-oxygen environment (less than $10^{-4}$ torr) and at the same time by using a sequence of metal or metal oxide targets, one can obtain a process similar to molecular beam epitaxy (MBE) by evaporation, here called laser-MBE. Some *in situ* diagnostic tools can then be used to characterize the growth of the materials. This technique has mainly been used to grow artificially layered superconducting materials, such as the infinite-layered superconductor.

## 2. Processing Technology

### 2.1 LTS Multilayers

LTS multilayer technology has made significant progress since the 1980s, mainly in Japan, based on niobium thin films primarily for SQUID and high-speed digital circuit applications. The main challenge has been to define the junction structure, the Nb/Al:$Al_2O_3$/Nb trilayer, without degrading the uniformity of its properties. A new process of defining the junction area by anodization rather than etching has been invented and is a very reliable process for minimizing the damage along the edges of the trilayer structure.

A reactive ion etching process of niobium uses a fluorine-based gas such as $CF_4$. By using dielectrics such as $SiO_2$, multilayer structures including a ground plane, a trilayer structure, and wiring layers have been fabricated.

### 2.2 High $T_c$ Superconducting Multilayers

Unlike polycrystalline niobium, HTS multilayer structures need to be epitaxial mainly because of a large anisotropy and the weak grain boundaries of HTS materials. Epitaxial growth requires a high-temperature deposition of each material and this complicates the heating methods. No large-area ($>1$ in (2.5 cm)) HTS multilayer process is available, although fairly complicated structures including a ground plane and edge junctions have been successfully fabricated (see *High-temperature Superconductors: Thin Films and Multilayers*; *Films and Multilayers: Conventional Superconducting*).

Of several HTS materials, $YBa_2Cu_3O_{7-x}$ (YBCO) is the most frequently used material for multilayer work. This is because the anisotropy of YBCO is the smallest of all HTS materials and YBCO is least susceptible to the damage caused by etching. It is inevitable that a patterned multilayer structure will require a current path perpendicular to the substrate. A weak current-handling capability in this direction, namely a large anisotropy, will cause a problem in such a multilayer structure. In order to minimize the sudden current flow in the perpendicular direction, edges have to be patterned in such a way that the edge angle is very small ($<20^\circ$), although this will make the edge area wider.

Unfortunately, no good reactive etching method for these complex metal oxides has been found, and a dry ion beam milling (usually by an argon ion beam) technique has been the primary method for etching. Several wet etching methods have been found but they have not been very popular because of severe undercut below the photoresist during the etching process. During dry ion beam etching, the YBCO material is cooled by a thermal contact with a water-cooled plate in order not to lose oxygen when heated in vacuum. A line width as small as 1 μm has been found to carry high critical current density by this method.

YBCO is a semistable material at room temperature, and when it is bombarded with high-energy particles, such as argon ions, it starts to lose oxygen and then the materials becomes amorphous. This has

been observed during transmission electron microscope sample preparation. However, the lost oxygen can be restored by annealing the material in an oxygen ambient at about 400–500 °C where the oxygen intake is maximum. One can also restore the ion beam-damaged crystallinity by annealing the material around 800 °C in the appropriate oxygen environment (usually around 100 mtorr). Especially for multilayer work in which one relies on the epitaxial growth of the subsequent layer on top of the edges, the restoration of the crystalline quality after etching is a very crucial step.

YBCO loses oxygen when heated but regains it during cooling in an oxygen environment at 400–500 °C. This means that if one grows a second epitaxial layer, through which the oxygen diffusion is very slow at 400–500 °C, on top of the first YBCO layer, the resulting structure will have an oxygen-deficient YBCO layer. This is because the oxygen cannot diffuse through the dielectric layer to get to the bottom YBCO layer. This problem gets worse as one develops a more perfect dielectric layer because defects such as grain boundaries or oxygen vacancies in the dielectric layer are often the channels for oxygen diffusion.

The most frequently used dielectric layers are $SrTiO_3$, $LaAlO_3$, $Sr_2AlTaO_6$, or $Sr_2AlNbO_6$. These all have a perovskite structure, similar to YBCO, allowing epitaxial growth adjacent to YBCO. Of these dielectric materials, $SrTiO_3$ is the easiest to deposit and the first that was developed. However, the high dielectric loss of $SrTiO_3$ does not allow its use for high-speed circuits. Other similar dielectric materials with low dielectric loss, such as $LaAlO_3$, $Sr_2AlTaO_6$, and $Sr_2AlNbO_6$, were later developed. However, all these dielectric materials have low oxygen diffusion rate problems especially when a better material with fewer defects is grown.

Materials that have exactly the same structure as YBCO but are not superconducting have been used in multilayer structures. These include $PrBa_2Cu_3O_{7-x}$ and doped YBCO. They have the advantage of having an identically layered structure, which allows for perfectly matched growth from the edges. In addition, they have an almost identical oxygen diffusion rate, resulting in a fully oxygenated YBCO layer underneath. However, their insulating properties are far from ideal, making them impossible for use as dielectric layers. For this reason, these materials have been used mainly for barriers for Josephson junctions (see *Josephson Junctions: High-$T_c$*).

Because of its anisotropy, a Josephson junction process for YBCO has been developed in an edge junction geometry. The process requires forming a low-angle slope for the first YBCO layer and then depositing the barrier layer and the second YBCO layer on top of it. As mentioned above, restoration of the crystallinity after etching is critical in allowing for good epitaxial growth of the subsequent barrier and YBCO layers. A technique to modify the edge and convert the interface region into an insulating phase by annealing them in a different environment has been developed.

It remains to be seen how much further HTS multilayer technology will be developed. The answer to this may lie in the prospects for its application in the future.

## 3. Applications

### 3.1 LTS Multilayers

LTS multilayer technology has been used for developing SQUID sensors. Multilayer flux transformers or gradiometers coupled with trilayer tunnel junctions have been successfully developed and are used in practical SQUID instruments. In the case of high-speed electronic circuits, both the voltage state logic and the single-flux quantum logic require multilayer technology and niobium mutilayer technology is being used to demonstrate many high-speed circuits (see *SQUIDs: The Instrument*).

### 3.2 High $T_c$ Superconducting Multilayers

Unfortunately, the use of HTS technology for SQUID applications is by its single-layer process. Multilayered flux transformers for SQUID applications have been demonstrated, but the extra low-frequency noise does not improve its performance over that of single-layered flux transformers.

For microwave applications, double layers of HTS materials on both sides of a wafer are used. One of these layers is the ground plane in a microstrip geometry. It is very likely that many microwave applications of this multilayer technology will be developed with the proliferation of wireless communication. It remains to be seen how this will affect HTS multilayer technology.

A few very simple multilayer HTS digital circuits of the single-flux quantum logic kind have been demonstrated in spite of the many problems described above (see *Superconductors: Rapid Single Flux Quantum (RSFQ) Logic*).

# Superconducting Wires and Cables: High-field Applications

The performance of superconducting wires is fundamentally limited by the magnetic flux density or field, the current density, and the operating temperature, while the magnet applications are limited by current, voltage, and stored energy. Thus the term ''high-field applications'' is really a generalization for high-performance applications, involving all of these conductor and magnet constraints. As a rule, high field is easiest to obtain in small bores and at low temperatures. This article reviews progress in strands and cables that improves the performance capabilities of large-scale superconducting applications.

All high-current and many high-field superconducting applications use conductors that are made up of cables with multiple strands. A large variety of cable topologies have been used, but two are the most common. High-energy physics multipole (dipole, quadrupole, etc.) magnets generally use Rutherford cables, a high aspect ratio topology with two layers, and a highly regular cabling and crossover pattern. Large energy storage, fusion research, and detector magnets more frequently use cable-in-conduit conductors (CICC), round cables that are built up from smaller round subcables, then compacted into a square or low aspect ratio conduit. The two cable types are illustrated in Fig. 1.

Rutherford cables are favored for multipole magnets, because they can achieve tighter bends with lower conductor strain, while multipole magnets are characterized by modest bore sizes and high length-to-minimum-bend-radius ratios. Cable-in-conduit conductors are favored for the larger bore fusion, detector, and superconducting magnetic energy storage (SMES) magnets, because of their ability to be built up to nearly unlimited current-carrying capabilities, making them most appropriate for very large, high-energy applications. CICC conductors have been built and tested up to 200 kA for large SMES applications (Peck and Michels 1991) and large magnets have been tested to 80 kA (ITER 2001).

## *1. Strand*

Commercial and scientific applications of superconducting cables are dominated by niobium titanium (NbTi). NbTi, the first practical superconducting material for large-scale applications, is strong, ductile, and relatively inexpensive. The production of NbTi strand is approximately 200 t per year. The largest commercial application is medical magnetic resonance imaging (MRI) magnets, while scientific applications are currently dominated by production of the Large Hadron Collider at CERN (Perin 1991). NbTi magnets have been built with peak flux densities ranging from under 1 T to peaks of 8–9 T at 4.2 K (the boiling temperature of liquid helium) and 9–11 T at 1.8 K (Perin 1991) (near the lambda point of superfluid helium). NbTi is a mature technology, which has slowly been improving, so that it is now possible to purchase large quantities with critical current densities of 3000 A $mm^{-2}$ at 5 T and 4.2 K.

All other magnet applications use $Nb_3Sn$ with an annual production of approximately 2.5 tonnes per year. $Nb_3Sn$ is used in nuclear magnetic resonance and open MRI magnets. Scientific applications include next-generation magnets for high-energy physics and fusion, including 20 t of $Nb_3Sn$ in the KSTAR tokamak being built in South Korea (Lee *et al.* 1999) and an equivalent amount for the recently tested ITER CS Model Coil in Japan (Martovetsky *et al.* 2001). $Nb_3Sn$ cables have been used in large pulsed cables up to 13 T (Tsuji *et al.* 2001), dipole magnets up to 14.7 T (Gourlay *et al.* 2001), small solenoids up to 17 T (Takeo *et al.* 1987), and inserts up to 21 T. $Nb_3Sn$ has superior critical temperature and field, but it is an order of magnitude more expensive than NbTi, requires a long heat treatment at 600–700 °C to become superconducting, and is brittle, requiring great care in handling during fabrication and cool-down to the cryogenic operating temperature.

However, the conductor development program for a high-field Very Large Hadron Collider (VLHC) has achieved spectacular progress in critical current density, which has risen over just a few years from 700 A $mm^{-2}$ to 2900 A $mm^{-2}$ at 4.2 K and 12 T. Significant progress in the programme's goal of reducing the cost of $Nb_3Sn$ in large quantities from \$1000 to \$200 $kg^{-1}$ would make several new high-field applications possible.

New materials have been proposed, but have not yet had practical impact on high-field magnet

applications. The two most widely studied high-temperature superconductor materials, BSSCO-2223 (bismuth strontium calcium copper oxide) and YBCO (yttrium barium copper oxide), are not available as strands. Artificial pinning center strands have been proposed as an alternative to NbTi, because of superior properties at low field and projected low manufacturing costs (Rudziak *et al.* 1995). $Nb_3Al$, which has been proposed as an alternative to $Nb_3Sn$, has similar critical properties, but much lower strain sensitivities.

A recently tested $Nb_3Al$ cable has shown performance at 13 T and 46 kA that equals that of previous generation $Nb_3Sn$ and with less degradation over time (Takeuchi 2001). BSSCO-2212 strands have been proposed as high-temperature superconductors, paradoxically because of their superior performance at low temperature and high field. Cables using BSSCO-2212 have achieved 10 kA. None of these alternative strands have demonstrated the existence of more than niche markets and, despite impressive progress, they remain single vendor prototypes. A new strand material that may have a better opportunity to "break out" into commercialization is the recently discovered medium-temperature $MgB_2$, which benefits from being potentially inexpensive to manufacture, lightweight, and ductile, although its critical temperature is lower than BSSCO or YBCO, while its critical field is lower than $Nb_3Sn$.

State-of-the-art performance of the different strands is listed in Table 1.

## 2. *Rutherford Cable*

The Rutherford cable is a two-layer cable of round or square strands, whose high aspect ratio allows winding around the relatively tight radii of constricted end turns in magnets with long straight sections. The simplest form of the Rutherford cable is a two-layer cable with uniform superconducting strand placement and uniform crossover of strands. Several variations of these two forms have been built into a number of historic high-field magnets. Some of these historic cables are illustrated in Fig. 2. Rutherford cables can be compacted for higher strength and packing factor, and "keystoned" so that a winding can fit without gaps on a circumference. As shown in Fig. 2, they can be reinforced by a central core—either steel to add strength and reduce losses, or copper to improve stability and quench protection (Beard *et al.* 1988).

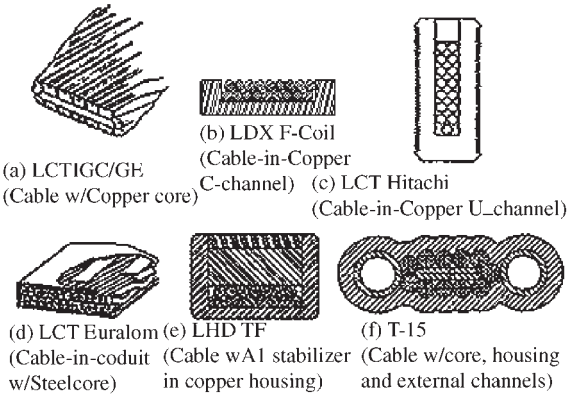

***Figure 2***
Historic Rutherford cable design options, drawn to scale: (a) large coil task, IGC/General Electric, cable with a copper core; (b) levitated dipole experiment floating coil, cable in a copper C-channel; (c) large coil task, Hitachi, cable in a copper U-channel; (d) large coil task, EURATOM/Vacuumschmelze, cable-in-conduit with an insulated steel core; (e) large helical device, cable with an aluminum stabilizer in a copper housing; (f) T-15 tokamak, cable with core in a housing and external cooling channels.

Figure 2 also shows how a Rutherford cable can be inserted horizontally or vertically into a copper channel, improving strength, stability, and protection (Beard *et al.* 1988, Schultz *et al.* 1999). It also shows cables that functionally resemble a CICC, by being inserted into a sealed can with forced-flow helium circulating directly through the conductor or through side-channels (Beard *et al.* 1988, Chernoplekov and Monoszon 1982). The two-layer configuration can

also benefit from the ability to achieve a highly regular cabling pattern and near-uniform contact resistances, permitting analysis of cable supercurrents. Cables with as many as 47 strands have been used in high-energy physics dipole magnets (McInturff *et al.* 1997).

Since Rutherford cables are typically used in quasi-steady-state applications, they are usually designed for low contact resistance between strands. The specification for the Large Hadron Collider (Perin 1991) is 10 μΩ per contact. Such a low contact resistance tends to be dominated by the oxide layer on the strand surface. In Tevatron (Cooper and Fisk 1983) and HERA (Meinke 1991), the strands are covered by a thin layer of SnAg (5%) to reduce surface resistance. For applications requiring a significant ramp rate, such as injector magnets, a compromise has to be made between good current transfer for stability and good resistance for low losses. This can usually be accomplished by a thin steel core in the center of the cable, allowing strand–strand current transfer, while eliminating large circulating currents.

## 3. CICC

Although it has many variants, the cable-in-conduit conductor (CICC) concept has changed little since its invention in the 1960s. Strands are cabled into successive stages, called subcables, in which typically 3–6 subcables are bundled into the next larger cable stage. Cables with as many as 1440 strands have been built up in this manner (ITER 2001). The cable is then jacketed, i.e., inserted into a helium-tight conduit that provides support against winding and Lorentz loads, as well as being a pressure vessel for helium coolant. The most common CICC is a simple circular cable, inserted into a conduit that is squared off with Turks-head rollers, then welded together, either with a continuous seam weld or by orbital welding of discrete sections of pipe. The aspect ratio can be higher than one, when this improves the overall winding packing factor.

A circular conduit has the dual advantage of being indifferent to angular position due to any twist during winding or transitions and it also has the lowest stress multiplier for holding internal helium pressure. However, it is incapable of sustaining much compression from radial loads in the winding pack, and has a low packing factor, so that it must be placed in a scalloped structural plate. The cable may have a central coolant hole (Tsuji *et al.* 2001), or it can be placed in a thin inner conduit, leaving four unobstructed cusps in the corners (Steeves *et al.* 1989), so that the hydraulic path will have a larger hydraulic diameter and less friction, allowing the removal of higher heat loads. This philosophy can be extended to where the central hole is much larger than the cable space for very long channels or when needed to allow conduction cooling by superfluid helium (Peck and Michels 1991). Historic examples of these design options are illustrated in Fig. 3.

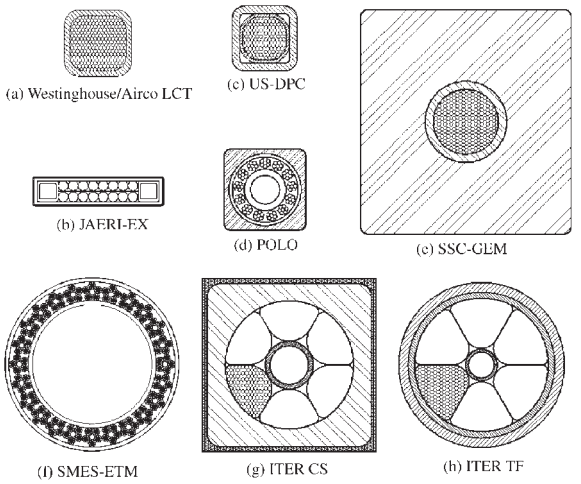

***Figure 3***
Historic cable-in-conduit design options, drawn to scale: (a) large coil task, Westinghouse/AIRCO, $Nb_3Sn$; (b) dual purpose coil, Japan Atomic Energy Research Institute, cable-in-conduit with through cable and external cooling channels; (c) US dual purpose coil, central CICC in thick walled conduit and corner channels; (d) POLO, insulated subcable, dual channel CICC; (e) SSC GEM detector, cable in thin steel tube in thick aluminum conduit; (f) superconducting magnetic energy storage-engineering test magnet, large central channel; (g) International Thermonuclear Experimental Reactor (ITER) central solenoid, thick conduit, central cooling channel; (h) ITER toroidal field magnets, thin conduit in plate, central cooling channel.

CICC has several structural, electrical, and conductor cooling advantages. The conduit can be a high-strength superalloy and the winding pack can be completely potted, giving both mechanical rigidity and high electrical integrity. The cable is in direct contact with helium coolant with a high wetted perimeter and can utilize the much higher enthalpy of the helium to give it an energy margin against disturbances that is orders of magnitude higher than a dry magnet. The disadvantages of CICC are the additional cost of the conduit, closure welds, and cable insertion, local stress concentrations in the conduit walls, the need for a forced-flow refrigerator, and the need for electrical isolation from the helium headers. Because of the nearly unlimited ability to build up the cable to high currents and the demonstration of electrical isolation to 25 kV, CICC is favored in large-bore, high-energy storage magnets.

Progress in conduit design and manufacture has included (i) the development of reliable closure welds, (ii) conduit materials and welds with high strength

and toughness, even after being subjected to long superconductor heat treatments, and (iii) conduit materials with a good thermal contraction match to the superconductor. Reliable seam welds were demonstrated in thick JBK-75 (Beard *et al*. 1988) and Incoloy (Steeves *et al*. 1989) conduits in the 1980s. The International Thermonuclear Experimental Reactor (ITER), which would have required hundreds of kilometers of high current cable, developed orbital welding techniques with two advantages. The total length of welds in the system was greatly reduced and the welds were fully inspectable, before the insertion of cable.

ITER has also demonstrated excellent performance in high-current cables using Incoloy 908 and titanium alloy (Martovetsky *et al*. 2001). Incoloy 908 has the dual advantages of a good thermal contraction match with $Nb_3Sn$ and higher strength and toughness than stainless steel conduits, after a long heat treatment. Titanium puts the lowest strain in the superconductor of any practical material. Both Incoloy 908 and titanium alloy require tight control of the atmosphere during heat treatment to avoid severe embrittlement during heat treatment. Less-expensive 304 and 316LN stainless steels have been used with NbTi and a low-carbon 316 has been developed to survive the $Nb_3Sn$ heat treatment (Miller *et al*. 1994).

## 4. State-of-the-art Magnets and Future Progress

Several metrics are available for measuring state-of-the-art performance from magnets using strands and cables. These include magnets of solenoidal, toroidal, and multipole topologies, achieving the highest field, the highest current density for the current and voltage, the highest superconducting pinning force (current density-field product), and the highest average stress (e.g., the current density-field-radius product in a solenoid). International experts were surveyed for this article, and the highest historic values of these metrics that were identified are listed in Table 2.

Further improvements in high-field superconducting strands and cables will probably be driven by steady increases in the critical current density, temperature, and field of the strands. It should also be possible to significantly lower the manufacturing costs of all of the advanced strand materials, when they are produced in commercial quantities. The same potential for reducing costs with quantity exists for the advanced conduit materials desired for CICCs with heat-treated strands. The copper needed for the protection of CICC magnets should be reduced by the development of internal heaters and sensors with high signal/noise ratios. Advances in the understanding and performance of cables are expected if fully

## Superconducting Wires and Cables: Low-field Applications

The discovery in 1986 of high-temperature superconductors (HTSs) with the prospect for operation at liquid nitrogen temperature (77 K) or above provided new impetus for superconducting electric power applications. HTS materials also exhibit higher heat capacity than low-temperature superconductor (LTS) materials that markedly improves their electrical stability, i.e., ''normalization'' of the superconducting state, during thermal transients. The higher transition temperatures also ease the refrigeration requirements and facilitate cryogenic operation (Blaugher 1996).

### *1. Cables*

Type II superconductors available in the shape of wires and tapes appear as almost ''natural'' candidates for such electrotechnical applications as power transmission cables. Traditionally, network engineers have relied on increasing voltage to transmit a larger amount of power. Superconducting cables have the capability of carrying much higher currents, so providing the opportunity for reducing the number of circuits, or using lower voltage rating.

In the 1980s a significant research effort, including design studies and experimental activity, was devoted to the assessment of power cables based on low $T_c$, liquid-helium-cooled materials. Such research led to the conclusion that, although technically attractive, such cables were not economically viable, unless for very high transmitted power, above 2–5 GVA. The main cause for this was identified as the projected cost of refrigeration, which resulted from the high cost and low efficiency of liquid helium, combined with the intrinsically unfavorable geometry (very high surface to volume ratio) of cables. Since 1986 the availability of the new class of high $T_c$ superconducting materials, potentially suitable for (far more effective) cooling with liquid nitrogen, has therefore given a renewed impetus to the development of superconducting power cables.

A range of applications is envisaged. A few instances worth mentioning are the upgrading of existing underground circuits, the matching of the power rating of an overhead line for sections to be relocated underground, and the elimination of intermediate voltage transformations in urban distribution networks.

The expected benefits include, for example, increased transmission efficiency (energy saving, improved stability of high-power circuits), drastic reduction of electromagnetic pollution, an effective solution to the expanded energy demand in congested metropolitan areas, etc.

Development activities are underway in several countries, and include both feasibility studies and experimental work with prototype fabrication and testing. In a number of such experiments, prototype terminations and joints are also being developed. The lengths of such prototypes range from a few meters to more than a hundred meters (Norman *et al.* 1999, Kelley *et al.* 1999).

The first experimental installations of a three-phase superconducting connection in a ''real'' environment are being realized in the USA. Actually, one link made with cold dielectric (CD) cables (see below) fabricated by SouthWire has already been installed at an industrial plant, and another link, made by Pirelli based on a warm dielectric (WD) design (see below), was planned to be installed in a part of a utility (Detroit Edison) network by the end of 2001.

As type II superconductors show true zero resistance only under d.c. conditions, d.c. cables would appear as the ''natural'' way of best exploiting HTS materials, by achieving a virtually zero dissipation in the conductor, in addition to negligible dielectric losses. In fact, most power lines transmit a.c. power, and so a.c. designs are also typically assumed for superconducting cables. These are in turn generally classified, according to two main choices that can be made regarding electrical insulation, into ''warm'' or ''cold'' dielectric types.

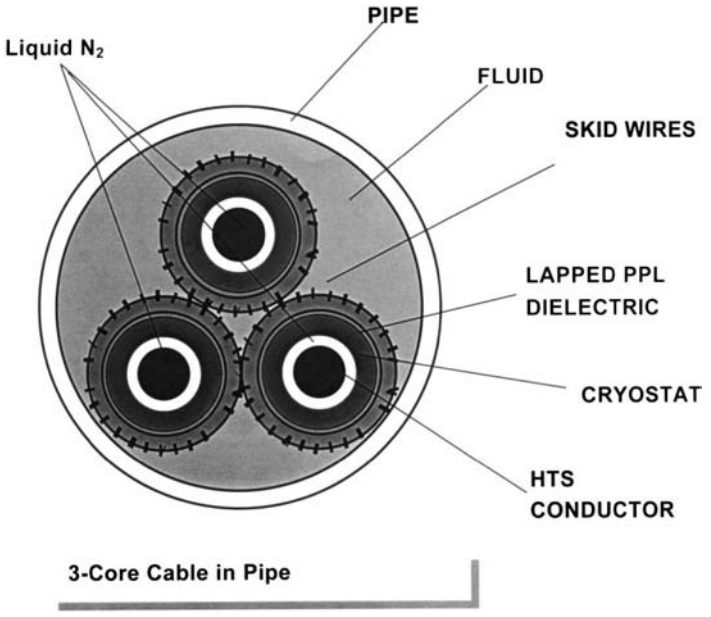

***Figure 1***
Example of a three-phase WD cable in a pipe.

In the WD cable design (Fig. 1), the HTS, made up of one or more layers of current-carrying HTS tapes, is enclosed in a cryogenic environment (the so-called "cryostat"), which in turn is covered by conventional dielectric materials.

This design has several advantages, such as:

- it has similar performance and requires similar installation procedures as a conventional cable.
- it can carry, at the same level of losses, more than twice the power of a conventional cable.
- it uses already developed dielectric materials.
- it needs accessories, both termination and joint, that can be derived in a relatively easy way from conventional ones.
- it requires fewer HTS tapes than the CD coaxial design.

In the CD design, two coaxial HTS conductors, separated by a dielectric at liquid nitrogen temperature, are enclosed in the cryostat (Fig. 2).

This approach, which is characterized by the presence of a superconducting "sheath" that acts as a return path for the current and cancels out the external magnetic field, represents the best technical solution for very high-power transmission. It allows one to:

- transmit a large amount of power with reduced losses in "compact" cable systems, eliminating a.c. losses due to external magnetic field of the other phases; and
- eliminate eddy current losses in metallic components, allowing installation close to other cables in service.

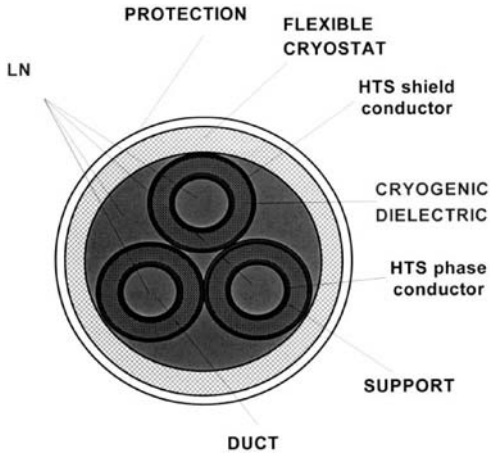

***Figure 2***
Example of a three-phase CD cable in a pipe.

However, it requires about twice the amount of superconducting material compared to the WD design, and requires a suitable cryogenic insulation in addition to the development of specific accessories.

Generally, the design of the conductor of a superconducting cable includes a multilayer stranded

structure around a suitable former of adequate internal dimension.

Optimization of the conductor involves several parameters such as the tape laying angle, the laying tension, the use of binding and/or insulating materials between superconducting layers, the number of tapes and layers, and the former material and dimensions to comply with both electrical and mechanical constraints during fabrication, handling, and service.

Cable manufacturing requires that the superconducting materials are available in the shape of long, flexible wires. Most of the cable prototypes fabricated have been made with BSCCO 2223 tapes typically a few millimeters wide, with a thickness of a few tenths of a millimeter.

For the optimization of the overall electrical and mechanical performance, superconducting tapes are made with a ''multifilamentary'' structure, with the number of filaments typically ranging from a few tens to over a hundred.

It is worth remarking that the long length required for a wire to be used in cable technology also imposes obvious constraints in terms of performance uniformity. This in turn requires a very good control of the processing parameters (mechanical, ''chemical,'' and thermal) throughout the whole wire fabrication process.

The development of flexible tapes with biaxially textured YBCO, being pursued in the USA, Europe, and Japan with promising results, has not yet reached a stage as to allow the manufacturing of long prototypes. The possibility of replacing BSCCO sintered tapes with YBCO thick films deposited on a flexible substrate is, however, considered extremely interesting for cable applications. In fact, provided that the performances already demonstrated on shorter lengths can be maintained to a significant extent over kilometer-long tapes, the use of YBCO is expected to provide an important improvement in terms of cost-effectiveness, and will therefore possibly give further impetus to the development of superconducting cables.

## 2. *Fault Current Limiter*

A fault current limiter (FCL) is, in principle, a device that is capable of protecting a power grid from very high surge currents that can arise when a fault (short circuit) occurs anywhere in the grid. As such fault currents are expected to increase with increasing grid interconnection, which is presently a worldwide trend, the need for an effective protection will become more necessary. The problem has been solved partially with the use of nonsuperconducting devices as circuit breakers, fuses, high-impedance transformers, etc, which in general have some drawbacks such as increased operating losses or at least nonideal efficiency. In fact, there is no direct ''equivalent'' for a superconducting FCL among conventional, nonsuperconducting power components.

A superconducting device can take advantage of the unique property of superconducting materials to undergo a rapid transition to normal state upon a quench, and therefore can in principle offer ideal performance in terms of fast response, fast recovery, and zero impedance throughout normal operation.

As it did for cables, and substantially for the same reasons (insufficient cost-efficiency with low $T_c$ materials), the discovery of HTSs has given new impetus to research activities on FCL development in Europe, the USA, Israel, and Japan. Such activities include design studies as well as demonstrations of small- to full-scale prototypes (Leung 1997).

Various design approaches are considered, namely:

- ''Resistive,'' i.e., the superconducting device is connected directly in series with the power line. The sudden increase of current due to a fault would induce the superconductor-to-normal transition of the material, hence increasing the impedance of the line.
- ''Inductive,'' or ''screened core,'' when the superconductor is *magnetically* (and not galvanically) connected to the line. Such a device is substantially based on a transformer, which has a superconducting shielding tube as the secondary. Under fault conditions the HTS becomes unable to screen the magnetic field generated by the primary coil and the flux penetrates into the iron core thus increasing suddenly the impedance of the device. Different from the resistive type, the HTS component will experience higher current but at lower voltage and does not need current contacts.
- ''Hybrid,'' which is also based on a transformer configuration that includes a resistive superconducting element combined with resistive or inductive shunts.

The different designs are typically based on different superconducting materials. Being studied for FCL applications are BSCCO 2212, BSCCO 2223, and YBCO, in various shapes, namely wires, bulk, and films.

Long tapes with good uniformity are available in the case of a composite tape with BSCCO 2223, which would therefore be a candidate for resistive FCLs. Unfortunately, the composite includes a high-conductivity matrix, which poses severe limits on the efficiency of a type of device based on such tapes. Tapes made with YBCO films deposited on a high-resistivity metallic substrate are available only in short lengths, but, assuming that kilometer-long tapes can be produced, they could represent a good candidate for that purpose. An alternative approach has already been demonstrated with prototypes of resistive FCLs made with YBCO thick films deposited on nonmetallic substrates in a suitable pattern.

YBCO films have also been used as the resistive element in a prototype of a hybrid (with inductive shunt) type of FCL. BSCCO 2212 is more suitable for the manufacture of large pieces, and has been used in prototypes of inductive FCLs in the shape of bulk cylinders.

In general, key material features of superconducting elements for both resistive- and hybrid-type FCLs are essentially their critical current density and normal state resistivity, which determine the required length of the element and the amount of power that will be generated during quench transition, and the sharpness of the superconducting-to-normal transition, which determines the time response of the device.

Other extremely important requirements concern the stability of the superconducting element against the creation of "hot spots" and subsequent thermal instability. From this viewpoint, thin films on nonmetallic substrates imply a different design approach compared to tapes with a metallic matrix or substrate.

As a general consideration, however, it must be noted that there will never be a universal superconducting FCL, since depending on its location inside the network the requirements in terms of recovery, limitation current, and protection coordination are very different. The requirements for the material are also very different. There will therefore probably be opportunities for different materials to be implemented in different types of FCLs in the future.

## Superconducting Wires and Cables: Materials and Processing

### *1. Introduction*

The phenomenon of superconductivity was first observed in 1912 in the laboratory of Heike Kamerlingh Onnes, at the University of Leiden (Holland). At low temperatures certain materials ($\sim$ 800 superconducting compounds have been recently tabulated by Poole and Farach 2000) suddenly lose their resistance to the flow of electricity. The phenomenon remained a laboratory curiosity until 1954 when G. B. Yntema at the University of Illinois made the first successful superconducting magnet. At that point, magnet performance fell well below that predicted by the properties of the superconductor. The slow progress can be partially attributed to (i) the difficulty in obtaining the extremely low temperatures required and (ii) the lack of understanding of how to create electrically and thermally stable wires from superconductors. The primary limitation, however, was that the superconducting phenomenon was not only limited to low temperatures but also to a restricted range of electrical current density and magnetic field and that the range of these properties was particularly limited in early superconductors. The maximum values of temperature, electrical current, and magnetic field are interdependent and, when plotted in three axes, form a "critical surface" (Fig. 1). Those early superconductors, such as Pb, In, and Hg are classified as type I superconductors. These are superconductors in which magnetic flux is excluded from their bulk and the critical current density is limited to a surface layer of approximately one-tenth of a micrometer. The maximum fields in which these superconductors can operate are usually less that 0.1 T (similar to the flux density between the poles of a horseshoe permanent magnet). These limitations make type-I superconductors impractical for wire and cable applications. All "technical superconductors," i.e., superconductors that can be readily fabricated into wires and cables for high-current applications, are type-II superconductors. In type-II superconductors, magnetic flux penetrates the bulk of the superconductor to form individual flux

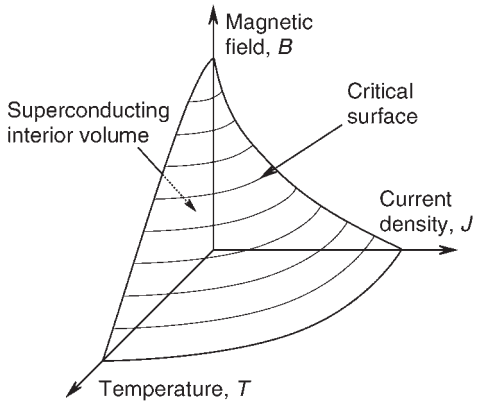

***Figure 1***
Schematic illustration of the critical surface for a type-II superconductor. The applied field ($B$), the temperature ($T$), and the current density ($J$) must be maintained below the critical surface in order to retain superconductivity.

quanta (see *Electrodynamics of Superconductors: Flux Properties*). In the most widely used technical superconductors, Nb–Ti and $Nb_3Sn$, the upper critical fields are 13 T and 27 T, respectively, and current densities $> 10^9\,A\,m^{-2}$ can be carried (compared to $\sim 10^7\,A\,m^{-2}$ for domestic Cu wire). In Fig. 2, the critical current densities at 4.2 K are compared for strands or tapes that are fabricated in lengths of more than 100 m. The temperature range is still limited (the critical temperatures for Nb–Ti and $Nb_3Sn$ are 10 K and 18 K, respectively), but for many applications the cost of insulation and refrigeration is more than offset by the reduced energy costs resulting from nonresistive current flow. Because the amount of energy lost in current flow through a superconducting magnet is extremely low, it can be operated without a power supply once the magnet has been charged. This mode of operation, termed "persistent" is very desirable for MRI and NMR applications because the current flow (and consequently the field) is very stable. Liquid He is now readily available and provides cooling to 4.2 K at atmospheric pressure and as low as 1.8 K at reduced pressure. Recent advances in insulation and refrigeration technology have also made the application of superconductors more widespread. The discovery of high-temperature superconductivity (HTS) superconductors (ceramic superconductors with critical temperatures above the boiling point of liquid nitrogen (77 K) in 1986 (see *High-temperature Superconductors: Thin Films and Multilayers*)) dramatically increased interest in the application of superconductivity. The discovery of superconductivity at 39 K in $MgB_2$ in 2001 further extended the temperature range for intermetallic superconductors.

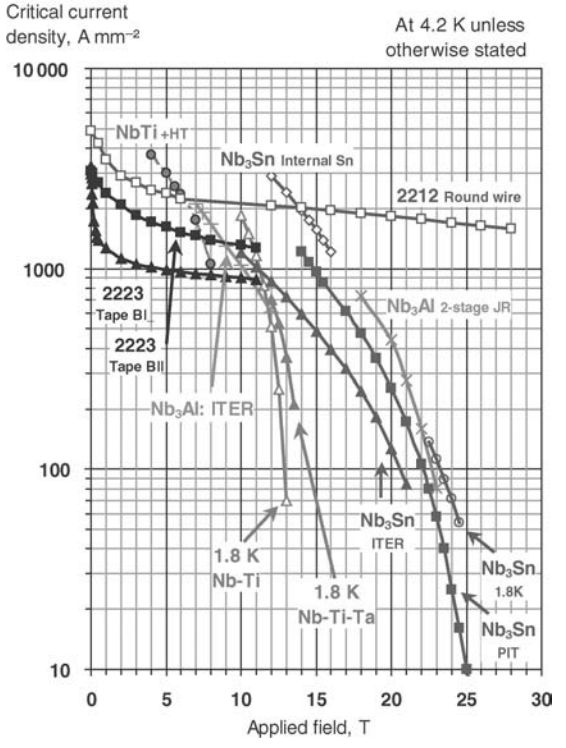

***Figure 2***
Comparison of critical current densities (at 4.2 K unless otherwise stated) available in strands and tapes of more than 100 m.

Superconductors must be formed into composite wires in order for them to be used in high-current applications and these wires may also be cabled. The wide variety of mechanical properties of superconductors: the range from strong ductile alloys like Nb–Ti to brittle ceramics such as HTS superconductors means that the wire processing routes vary greatly. Of the HTS superconductors only one, Bi-2212, is manufactured in round-wire form and HTS superconductors are more commonly manufactured as multifilamentary tapes. The brittle superconductors cannot undergo wire drawing and are consequently mechanically processed in the form of ductile precursors or fine powders that are reacted to form the final superconductor. For Nb–Ti, the alloy can be cold-worked to a remarkable extent but heat treatments are also applied during processing in order to introduce a second phase into the microstructure that will ultimately pin the fluxoids in the final wire. Because of these variations, the types of processing will be introduced separately and by superconducting material. There are, however, key components that are common to all superconducting strands.

## 2. *General Strand Requirements*

### *2.1 Matrix and Filaments*

Superconducting wires are almost always of a multifilamentary design in which individual continuous filaments ($< 30\,\mu m$ in diameter) are embedded in a high-conductivity matrix. When conditions in a localized region of a superconductor exceed the critical surface conditions, that area will start to conduct resistively and produce local heating. The resulting heat and current transfer will start a cascade effect and result in a rapid transition of the whole superconductor to the normal state. The ability to transfer heat and current away from localized regions by sub-dividing the filaments into a high-conductivity matrix was a key step towards producing practical superconductors. The primary components of cryogenic stabilization were not formulated until the mid-1960s (Stekley and Zar 1965). The most desirable matrices are Cu or Al, but Ag is required for the processing of HTS superconductors where oxygen diffusion through the matrix is required during heat treatment. External stabilizer is often added after heat treatment; this is particularly the case for Al, which has thermal and density advantages over Cu, but is difficult to

fabricate as the matrix of a composite wire. In addition to stability requirements, fine filaments also serve the purpose of limiting hysteretic loss, not only for a.c. applications but also for d.c. applications. The filament diameter requirements for a.c. applications are quite severe with desired filament diameters of less than 1 μm. For a.c. applications, a Cu–Ni matrix is often used to reduce proximity coupling of the filaments.

### 2.2 Filament Uniformity

As the critical current per unit cross-sectional area is limited by the material properties, the amount of current that can be carried by an individual filament is reduced if the filament is locally necked to a smaller diameter. Current may be locally transferred to adjacent filaments, but there is a broadening of the critical current transition and a reduction in time that the strand may be operated in the persistent mode (crucial for MRI application). With final filament diameters of less than 20 μm often required, this imposes a very high level of quality control on the processing of the strands. The degree of filament uniformity is reflected in the sharpness of the superconducting transition with increasing current. In the early stages of the resistive transition; the curve of voltage, $V$, against current, $I$, can be described by the power law:

$$V \propto I^n \tag{1}$$

The value of $n$ (the transition index) decreases with field; the more uniform the filament cross-sectional areas, the more linear the decrease in $n$-value and the higher the initial low field value (Warnes and Larbalestier 1986). An electric field, $E$, is generated along the superconductor carrying a current density, $J$, that is related to the critical current density of the superconductor $J_c$ at field $E_c$ by the transition index, $n$:

$$E = E_c(J/J_c)^n \tag{2}$$

For composites based on Nb–Ti strands, the value of $n$ (5 T) can be 50–100, in $Nb_3Sn$ for NMR application the values are in the range of 40–80. The high $n$-values in Nb–Ti strands correspond to variations in filament cross-sectional area of less than 2% (coefficient of variation) (Lee and Larbalestier 1993). In HTS superconductors the range of available $n$-values is presently only 10–20 and persistent mode operation is not feasible under these conditions.

### 2.3 Critical Current Density and Flux Pinning

Pure annealed superconductors do not carry very much current because once current passes through the superconductor, a Lorentz force is induced on the flux lines. When they move, the flux line lattice (FLL) dissipates energy and the superconductor eventually goes "normal" (see *Electrodynamics of Superconductors: Flux Properties*; *Superconducting Materials: Irradiation Effects*). The flux lines, however, can be held in place by defects in the superconductor, a process termed "flux pinning." In A15 based superconductors (such as $Nb_3Sn$), increasing the grain boundary density has been shown to increase critical current density (Scanlan *et al.* 1975, Ochiai *et al.* 1986). In Nb–Ti a linear increase in critical current density is observed with vol.% of α-Ti precipitate (Lee *et al.* 1990). Consequently, the introduction of pinning defects and the refinement of grain size are key elements to the success of technical superconductors.

### 2.4 Twisting

Twisting of the strand about its drawing axis is typically required to reduce flux-jump instability caused by varying external fields, and to reduce eddy-current losses. The twisting is ideally applied just before a multifilamentary strand has reached final size, so that the twist can be locked into place by a further die-pass. The higher the expected rate of change of field, the tighter the required twist pitch. For the relatively steady-state dipole magnets for the Superconducting Supercollider, ~80 rotations along the drawing axis per meter were required, for a.c. application with a similarly sized strand the number of twists per meter might be 300. Typically, twist pitches cannot be higher than 8 times the wire diameter, and normally a twist pitch of 10–20 times the diameter is used.

### 2.5 Final Shaping and Cladding

The final cross-section of the strand can be controlled by die shape and size or by using independently adjusted rollers operating along the strand surface. In this way, square or rectangular cross-section filaments can be produced. Alternatively, the strand can by inserted into a channel in a larger form, most commonly a rectangular aluminum external stabilizer.

### 2.6 Cabling

Individual strands can be cabled or braided together to form a conductor with a higher current carrying capacity. The most common design for Nb–Ti magnets is the Rutherford cable, which consists of a fully transposed, flat cable. Using this approach, high-aspect-ratio cables can be produced with as many as 46 strands (Scanlan *et al.* 1997). Strands may also be drawn into a larger conduit or combined with external stabilizers. A cross-section of a cable-in-conduit-conductor (CICC) is shown in Fig 3. As in the single strand-in-channel aluminum process, multiple strands have been applied to surface channels in circular cross-section aluminum rods.

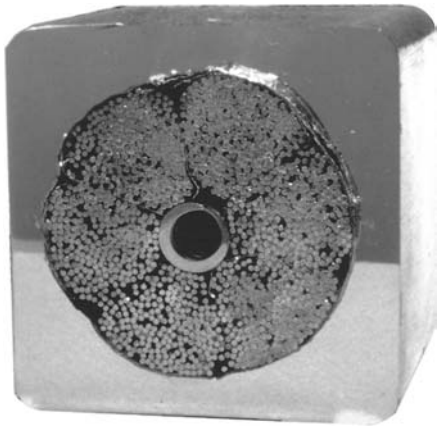

***Figure 3***

### *2.7 Length-dependent Parameters*

Both commercial Nb–Ti and $Nb_3Sn$ strands are made in lengths of over a kilometer and variations can occur over the length of the strand, due to differences in mechanical properties of the components and bonding of the monofilaments that occurred during mechanical reduction. In Nb–Ti variations in critical current, $I_c$, along the length of strands can be directly correlated with variations in Cu/Nb–Ti ratio along the length as shown by Kanithi *et al*. (1990). In their study of strands developed for the Superconducting Supercollider project, they showed that the variation in $I_c$ (due to variations in the intrinsic superconducting properties, the strand diameter and Cu/Nb–Ti ratio as well as measurement error) was more than twice the variation seen in $J_c$ (due to just the intrinsic superconducting properties and measurement error). As HTS-based strands are still in their production infancy, a different phenomenon is observed: as production length is increased, the overall $I_c$ declines because it is very difficult to maintain the ideal conditions (grain alignment, heat treatment temperature, low porosity) necessary for good HTS strand over long lengths.

## *3. Superconducting Strand and Cable Manufacture by Material*

### *3.1 Nb–Ti*

#### *(a) Alloy composition*

Nb–Ti has become the dominant commercial superconductor, because it can be economically manufactured in a strong and ductile form with both high current density and high resistive transition index. The starting point for fabrication of Nb–Ti strand is an alloy of between 46.5 wt.% Ti and 50 wt.% Ti. Decreasing Ti over this range increases both the critical temperature, $T_c$, and the upper critical field, $H_{c2}$ (which at 4.2 K has a maximum value of 11.5 T at 44 wt.% Ti). The increase in $T_c$ and $H_{c2}$, however, is offset by a decrease in the amount of Ti available for precipitation of the $\alpha$-Ti phase desired for flux pinning and high critical density. The composition of the Nb–Ti also affects the precipitate morphology: if the $\alpha$-Ti is formed at grain boundary intersections, it tends to be uniform in size and distribution and does not significantly affect strand ductility. Higher Ti compositions, however, also produce fine distributions of Widmanstätten-type precipitation in the grain interiors resulting in both a nonuniform microstructure and a significant hardening of the Nb–Ti. As all these factors are sensitive to composition, it is very important to start with a homogeneous alloy. With final filament diameters well below 0.05 mm, the alloy must also be free of unmelted Nb or nonductile inclusions that may result in filament and ultimately strand breakage. Although the large difference in the melting points of Ti and Nb makes this a difficult alloy to manufacture, homogeneity levels in commercial Nb–47 wt.% Ti alloys are now typically much better than $\pm 1.5$ wt.% Ti. Impurity content has been traditionally kept low and consistent, but recent work has shown that increasing the allowable content of iron can considerably refine the precipitate size without adversely affecting the precipitate volume (Smathers *et al*. 1996).

#### *(b) Extrusion and billet assembly*

The (as-cast) Nb–Ti ingot is (hot forged) to the required diameter and then annealed in the single phase $\beta$ region ($\sim 2$ h at 870 °C). For fine filament Cu matrix composites, the Nb–Ti ingot is then sealed inside a high-purity Cu extrusion can, that subsequently (warm-extruded) forms a (well-bonded) monofilament. Monofilament production billets ready for extrusion are shown in Fig. 4. Billet assembly is performed in a clean environment, in order to avoid introducing particles that would not co-deform to the sub-0.05 mm filament size. Where high critical current densities and fine filaments are desired, an Nb diffusion barrier is wrapped around the Nb–Ti rods in order to inhibit the formation of brittle Cu–Ti intermetallics during heat treatment (Wilson 1972). The monofilament is then reduced in diameter by wire drawing, typically finishing with a hexagonal die to produce filaments that can be efficiently (restacked). The thickness of Cu around the Nb–Ti at this stage is important because it determines the spacing between Nb–Ti filaments when Cu/Nb–Ti monofilaments are stacked together. For optimum mechanical stability in Nb–Ti/Cu multifilamentary composites, a filament spacing to filament diameter ($s/d$) ratio of 0.15–0.20 is

***Figure 4***

ideal (Gregory *et al.* 1987). Usually, additional stabilizer is required and that may be added by increasing the wall thickness of the extrusion can or adding a central core of stabilizer. For d.c. magnet application, it has been established by Ghosh *et al.* (1987) that a minimum Cu thickness of 0.4–0.5 μm is required to reduce the magnetization associated with proximity filament coupling. For $s/d$ ratios of 0.15–0.20, the minimum Cu thickness requirement limits the minimum filament diameter to $\sim 3$ μm when using a pure Cu matrix. If smaller filaments are required, Ni or Mn can be added to the Cu between the filaments (Hlasnik *et al.* 1985, Cave *et al.* 1989, Kreilick *et al.* 1988).

The monofilament is then restacked inside another Cu extrusion can to form the final multifilamentary composite. The size of this extrusion can be up to 330 mm in diameter with a weight of 400 kg. As many as 4000 filaments may be assembled in one extrusion. Alternatively, large numbers of fine filaments can be produced by restacking a previously extruded multifilamentary billet. Using this approach, strands with up to 40 000 filaments have been manufactured. Where a small number of large filaments are desired (typically for low-field MRI application), Nb–Ti rods can be directly inserted into gun-drilled holes in a solid high-purity Cu extrusion billet. Warm extrusion helps bond the composite, as much of the subsequent processing involves cold work by wire drawing, and the resulting strain introduces into the Nb–Ti an essential element in developing the high critical current microstructure.

### *(c) Precipitation heat treatment*

Such a treatment is applied after sufficient cold work has been carried out following the multifilamentary extrusion. If too little cold work is applied before heat treatment, Widmanstätten-type precipitation will occur, causing increased hardness (reducing drawability) and producing a non-optimum precipitate size and distribution. Lee *et al.* (1989) found that the amount of (prestrain) required increases linearly with wt.% Ti. Consequently, a higher prestrain is required to suppress Widmanstätten-type precipitation in a chemically inhomogeneous alloy than would be required in a homogeneous alloy. For Nb–47 wt.% Ti, the required prestrain is $\sim 5$ but this rises steeply to 9 for a 55 wt.% Ti alloy. Heat treatments are typically at 375–420 °C, ranging from 20 h to 80 h in duration. Multiple heat treatment and drawing cycles are required to produce high critical current densities (Cheng-ren *et al.* 1983). Whereas an initial heat treatment will only yield $\sim 10$ vol.% precipitate, by applying additional cold work strain, the effect of the slow diffusion rate at these temperatures is again overcome and more precipitate is produced. Second and third heat treatments typically yield 15 vol.% and 20 vol.% of α-Ti precipitate, respectively. The strain between heat treatments is 0.8–1.5 and at least three heat treatments are usually applied. A linear relationship between the optimized critical current density and the volume of precipitate Nb–47 wt.% Ti alloys has been established by Lee *et al.* (1990) 20% volume of α-Ti precipitate is sufficient to produce a critical current density of $> 3000$ A mm$^{-2}$ at 5 T, 4.2 K. Increasing Ti content increases the precipitation rate and amount, but higher pre-strains are required if good ductility and long piece length is to be maintained. Alternatively, the pinning sites can be introduced mechanically by hand-assembling the desired microstructure at a large size, in the same way as the multifilamentary billets are assembled, and then reducing the dimension to match the fluxoid spacing by multiple restacking and drawing cycles. This approach is called APC for artificial pinning center. With APC strand, no additional heat treatment is necessary and a greater flexibility is possible in the microstructural components. Despite superior low field ($< 5$ T) performance, the APC approach has not reached commercialization because of the costs associated with the multiple restacking approach.

### *(d) Final wire drawing*

After final heat treatment the α-Ti precipitates are roughly equiaxed in transverse cross-section, 100–200 nm in diameter with an extension along the wire axis giving an aspect ratio of 5–20. The extensive final wire drawing (an engineering true strain of 5), however, produces a plain strain condition in the b.c.c. β-Nb–Ti, which is supported by (inter-curling) of the Nb–Ti grains. This results in distortion of the α-Ti precipitates into densely folded sheets during final wire drawing (Fig. 5(a)). The folding process rapidly decreases the precipitate thickness and spacing with a

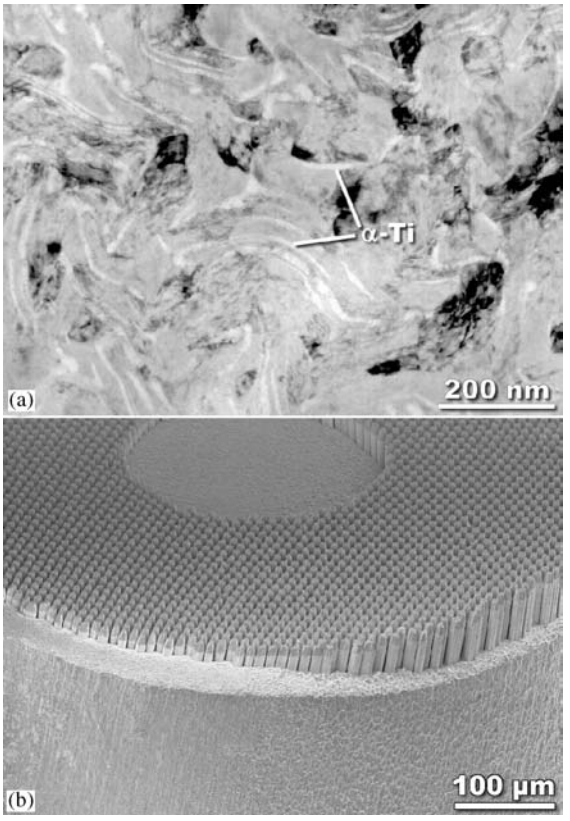

***Figure 5***
(a) Transmission electron microscope image of high critical current density Nb–Ti microstructure with folded sheets of α-Ti precipitate. (b) Etched cross-section of Nb–Ti-based superconducting strand fabricated by IGC-AS (now Outokumpu Advanced Superconductors) for the Interaction Region Quadrapole Magnets of the Large Hadron Collider at CERN.

dependence of $d^{1.6}$ (where $d$ is the strand diameter) and increases the precipitate length per area with a dependence of $d^{-1.6}$, as measured by Meingast *et al.* (1989). The critical current density increases as the microstructure is refined until it reaches a peak, after which there is a steady decline. The peak in critical current density for a monofilament or a multifilamentary strand with uniform filaments occurs at a final strain of $\sim 5$. If the filaments are nonuniform in cross-section (sausaged), the peak occurs earlier and at a lower critical current density. A strand that has a premature (and lowered) peak in critical current density during final drawing is described as ''extrinsically limited'' because it has not attained the intrinsic critical current density of the microstructure. The most common source of extrinsic limitation is sausaging of the filaments, due to intermetallic formation or lack of bonding between the components of the composite. A high-performance strand (Fig. 5(b)) has sausaging reduced to a very low level—a coefficient of variation for the filament cross-section of $\sim 2\%$. With tight quality control, uniform properties and piece lengths exceeding 10 km should be expected.

### *3.2 $Nb_3Sn$*

$Nb_3Sn$ is the second most widely used superconductor and has a higher upper critical temperature (18.2 K) than Nb–Ti. It is one of several A15 structure compounds that are superconducting. Other A15 superconductors of interest include $Nb_3Al$ ($T_c$ of 19.1 K) and $Nb_3Ge$ ($T_c$ of 23.2). $Nb_3Al$ has been manufactured in long lengths and has a better strain tolerance than $Nb_3Sn$ and better performance at a very high field ($>22$ T) making it important to high-field NMR inserts. $Nb_3Al$ is much more complex and expensive to fabricate than $Nb_3Sn$ because of the mechanical differences between Nb and Al and because the optimum $Nb_3Al$ composition for a A15 structure, can only be formed by high temperature processing ($>1000\,^{\circ}$C). $Nb_3Sn$, on the other hand, is widely manufactured and has shown sufficient strain tolerance in practice to be used successfully in very large solenoids such as the ITER CS model coil which stored 640 MJ of energy (Kato *et al.* 2001) and high-field ($>21$ T) inserts for NMR application (Kiyoshi *et al.* 2001). Because A15 materials are brittle, all production routes use ductile precursors that are heat treated to form the A15 at final size by solid-state diffusion. At an early stage it was found that the presence of Cu greatly aids the formation of $Nb_3Sn$ at temperatures below $800\,^{\circ}$C. It has also been found that adding Ti (0.7–1 wt.%) or Ta (7.5 wt.%) improves the critical current density at high fields ($>12$ T).

The three basic production routes currently used by commercial $Nb_3Sn$ vendors—the bronze process, the internal Sn, and the powder-in-tube (PIT) fabrication techniques—are illustrated in Fig. 6. The internal Sn process may use a jelly roll of Cu and Nb sheets, as illustrated in Fig. 6, or may use Nb (or Nb alloy) rods in a Cu matrix as shown in Fig. 7.

#### *(a) Bronze process*

For MRI application the most common route is the ''bronze process'' in which Nb alloy rods are first clad in high-purity ductile Cu–Sn bronze and then assembled inside another Cu–Sn tube in a way similar to the production of Nb–Ti filaments in Cu for Nb–Ti strand. As with Nb–Ti alloy, multiple restacks can be used to increase the filament number. Under heat treatment (typically 650–725 °C) the Sn from the bronze reacts with the Nb to form the superconducting A15 compound. As the Cu–Sn alloy does not act as a stabilizer, additional high-purity Cu must be

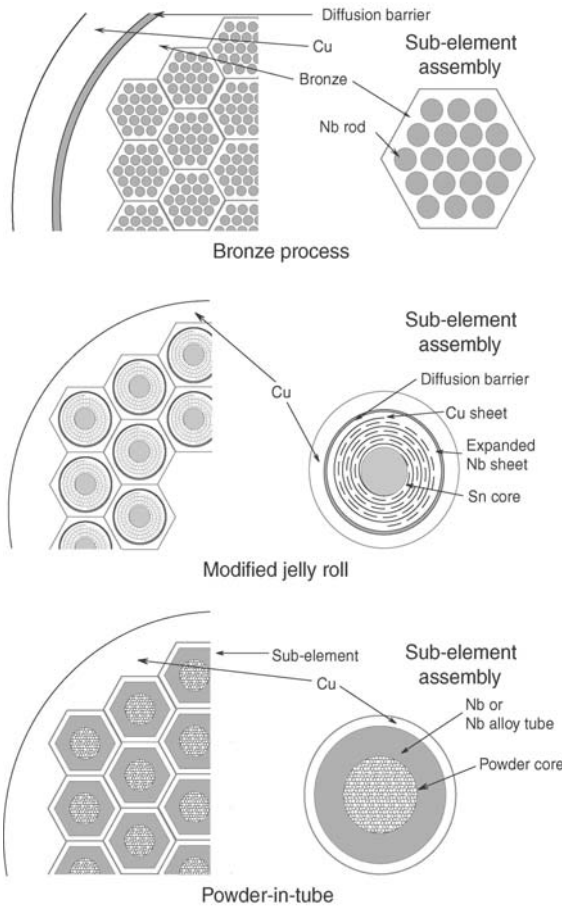

***Figure 6***
Schematic illustration comparing the bronze process, modified jelly roll (internal Sn), and PIT fabrication techniques for $Nb_3Sn$-based superconducting strand.

added outside, and/or inside the bronze–Nb filament composite, with a Ta and/or Nb diffusion barrier to eliminate Sn contamination of the stabilizer. An example of a bronze–process strand is shown in Fig. 8. Vanadium has also been used as a barrier but results in a reduced critical current density. This process can yield a strand with a very high uniformity in filament size and distribution, which makes it an ideal product for high-field NMR and other applications where a minimum of hysteresis loss is desired. The bronze, however, quickly work hardens during wire drawing and must be annealed frequently in order to maintain strand ductility, this extra processing step significantly increasing the cost of the strand. The Sn content in the composite is also limited by the amount of Sn ($<15$ wt.% Sn) that can be added to bronze while maintaining ductility. The impact of insufficient Sn is

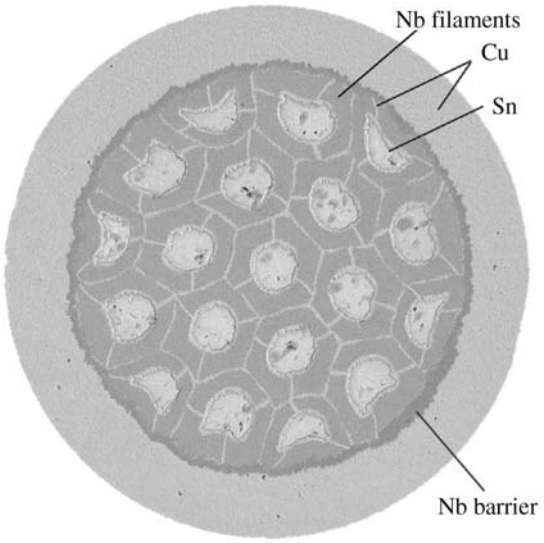

***Figure 7***

most noticeable on critical current density. Recent developments in the bronze process have centered on the use of specially processed high Sn bronzes (up to 16 wt.% Sn) that have good ductility and high homogeneity (Sakamoto *et al.* 2000) (Fig. 9).

*(b) Internal Sn process*

Higher Sn content and higher critical current density can be achieved by keeping the Sn separate from the Cu during strand fabrication. This is the basis for the internal Sn process which places an Sn core inside an Nb–filament/Cu matrix. The Sn core can be alloyed as a carrier for the $Nb_3Sn$ allowing-element or to improve the mechanical properties of the soft Sn. Strands produced by this process have achieved the highest critical current densities for $Nb_3Sn$ (in excess of 2400 A $mm^{-2}$ in the non-stabilizer package). The high critical current densities are achieved, in part, by reducing the amount of Cu in the Cu/filament/Sn package and the resulting reduction in filament coupling results in an undesirable increase in filament coupling. There are two distinct sub-categories of internal Sn process strand based on the form of the Nb filaments. In the "rod-in-tube" (RIT) process internal Sn–Nb filaments are assembled by inserting rods of Nb into pre-drilled holes in a Cu billet. The second internal Sn method is termed modified jelly-roll (MJR) and used an expanded metal sheet of Nb co-wrapped with a Cu sheet to create the individual Nb

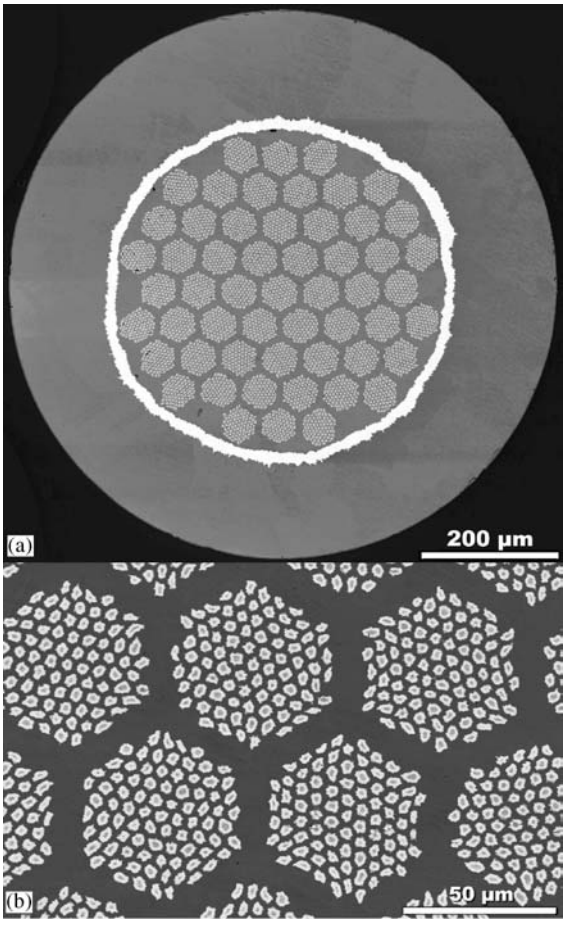

***Figure 8***

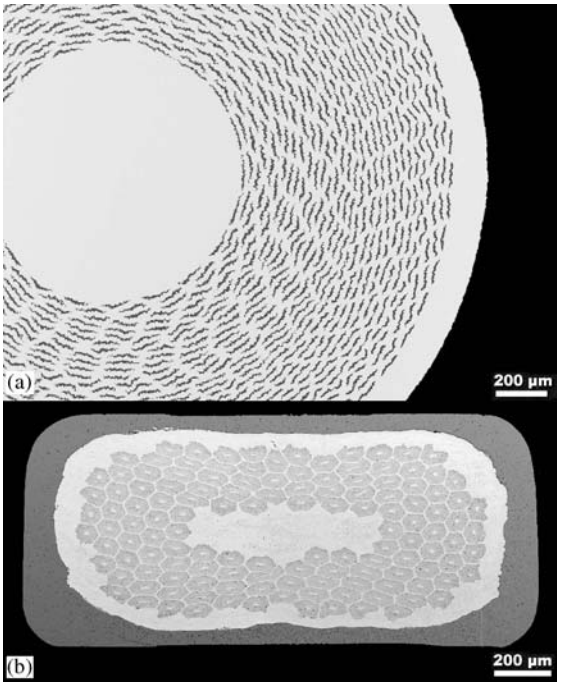

***Figure 9***

filaments in a Cu matrix. Both of these techniques achieve very high current densities, but limitations to the sizes of the billets (because of the restricted depth of the gun-drilled holes for rod-process and size limitations to deforming the MJR stacks) means that billet sizes are typically only 20 kg and processing costs are subsequently much higher than for Sn. As in the bronze process, the individual Cu–Nb–Sn subelements are clad in a diffusion barrier (Ta or Nb or TaNb alloy) to prevent poisioning of the Cu stabilizer by Sn diffusion. Sn diffuses rapidly through Cu at the temperatures used for the A15 forming heat treatment (up to 700 °C) and barrier integrity is consequently of great concern. The heat treatment of the strands to form the A15 phase is preceded by multiple lower-temperature steps designed to combine the Sn with the Cu without Sn melting. Both the RIT and MJR technique can also be used to fabricate precursor strand for $Nb_3Al$ production.

*(c) PIT process*

$Nb_3Sn$ may also be formed from higher Sn content Nb–Sn phases ($Nb_6Sn_5$ and $NbSn_2$) by inserting the intermetallics in powder form into tubes of Nb and reacting at 650–700 °C. The presence of Cu is also required to allow the formation of the A15 phases in the 650–700 °C temperature range in which fine grain size is maintained (Lefranc and Muller 1976). Elemental Sn is also added to improve the Sn-to-Nb ratio. No low-temperature heat treatment is required for these strands and the A15 formation heat treatment takes a relatively short time, 50–75 h (180–270 ks). This process uses the best combination of high critical current densities ($>2200\,A\,mm^{-2}$ at 12 T and 4.2 K in the nonstabilizer volume) and low effective filament diameter (as low as 30 μm in high critical current density strand). The process is used to manufacture small quantities for demanding applications

(Lindenhovius *et al.* 2000) and has not received the cost benefits of commercial scale-up. The PIT technique can also be used for $MgB_2$, Bi-2223, and YBCO, but porosity is an issue for these conductors when fabricated by this technique.

### 3.3 $Nb_3Al$

$Nb_3Al$ has not achieved commercial strand status, but it can be described as a technical superconductor as it has been fabricated into high performance and uniform kilometer lengths that have in turn been fabricated into full-scale devices. At magnetic fields above 20 T, critical current densities can be obtained that are comparable to the best $Nb_3Sn$ strands and useful critical current densities ($>100\,A\,mm^{-2}$ non-stabilizer) can be achieved above 24 T. Perhaps the most important feature of $Nb_3Al$ is the high strain tolerance of the $Nb_3Al$ strands compared to $Nb_3Sn$. One ton (total length of 210 km) of mass-produced "jelly-roll" process strand (Yamada *et al.* 1994) was manufactured for the 13 T–46 kA $Nb_3Al$ insert for the ITER Central Solenoid model coil. The jelly-roll of Nb and Al is created by co-winding sheets of Nb and Al together on an oxygen-free pure copper core. This will eventually become an individual filament in the final multifilamentary strand. The assembled jelly-roll and core are inserted into an oxygen-free pure copper tube to create an extrusion billet. After hydrostatic extrusion, the billet is drawn down to a small enough size that it can be restacked to create a multifilamentary billet. The billet is hydrostatically extruded and drawn for a second time, to the desired strand diameter size. The extrusion and restack process reduces the thickness of the Nb–Al layers in the filaments to less than 1 μm. The production yield rate for the ITER insert strand was 70% for strands longer than 1.5 km. The final strand is heat treated (800 °C for 10 h is typical) to produce $Nb_3Al$. The critical current densities obtained by this technique are $\sim 600\,A\,mm^{-2}$ at 12 T and 4.2 K (Hosono *et al.* 2002).

The highest critical fields and critical temperatures for $Nb_3Al$ are based around high-temperature heat treatments and rapid cooling. In the rapid-heating, quenching, and transformation (RHQT) (Iijima *et al.* 1997) process Nb/Al composites (MJR or RIT) are resistance heated to 1900–2000 °C and then rapidly quenched into a molten Ga bath at 40–50 °C producing a metastable b.c.c. supersaturated solid solution, $Nb(Al)_{ss}$, inside an Nb matrix. The heating time is $\sim 0.1$ s. The $Nb(Al)_{ss}$ has excellent ductility and the strand can consequently be mechanically clad or cabled with Cu at this stage and the stabilized strand may also be wound into device form. The $Nb(Al)_{ss}$ is then transformed to $Nb_3Al$ at 800 °C. Both the critical temperature, $T_c$, of $\sim 17.8$ K and the critical magnetic field, $B_{c2}$, of $\sim 26$ T are 0.7 K and 4 T lower for RHQT composites than the highest values obtained by laser or electron beam irradiation processed $Nb_3Al$ (Takeuchi *et al.* 2000) and this difference has been attributed (Kikuchi *et al.* 2001a) to stacking faults formed in the A15 phase. Two successful modifications to the basic RHQT technique specifically address the stacking fault issue. In the double rapidly heating/quenching technique (DRHQ), the standard RHQT process is followed, but instead of a conventional low temperature (<1000 °C) transformation heat treatment, a second RHQ process produces the A15 phase and this is followed by a long-range ordering heat treatment at 800 °C for $\sim 12$ h (Kikuchi *et al.* 2001b). The $T_c$ for these stacking fault free strands has been measured at 18.4 K, which suggests very good stoichiometry. Furthermore, a critical current density of $135\,A\,mm^{-2}$ was obtained at 25 T (Kikuchi *et al.* 2002). A disadvantage of this technique is that the brittle A15 phase is formed during high-temperature processing. Alternatively, the transformation-heat-based up-quenching technique (TRUQ), follows the initial RHQ of the RHQT process with a short heating step to 1000 °C. At this temperature, the heat released by local transformation from the $Nb(Al)_{ss}$ to the A15 phase produces a rapid local heating and propagation of the reaction along the length of the strand. As the self-heating is localized to the A15 volume, the heat is quickly dissipated after reaction across the Nb and stabilizer volumes, so that external Cu stabilizer applied after the initial RHQ process is not melted (Takeuchi *et al.* 2000).

### 3.4 HTS Superconductors

HTS superconductors have demanded great interest because of their ability to superconduct with relatively inexpensive liquid nitrogen cooling and their impressive high-field performance. HTS wires and tapes have not achieved the same commercial impact as LTS strands, however, because of the relative difficulty of producing long, low-cost lengths of conductor. The primary sources of this difficulty are the anisotropy in their superconducting behavior and the barrier to current flow presented by high-angle grain boundaries in these materials. Consequently, the strands must be fabricated with a remarkable degree of grain alignment. Further complicating the process is a high sensitivity to heat treatment temperature (<1 °C control must be exerted across the entire strand length for Bi-2212) and a need for oxygen diffusion into the HTS composite during fabrication. This second requirement effectively means that silver must be used as the superconducting strand stabilizer. Of the HTS superconductors, only Bi-2212 can be readily made into round-wire form strand. All the other HTS superconductors require a tape format. $(Bi,Pb)_2Sr_2Ca_2Cu_3O_x$ based conductors have been shown to be capable of application to superconducting power cables, magnetic energy-storage devices,

transformers, fault current limiters and motors, but widespread application will require significant cost reduction in processing. YBCO-based superconductors have the highest recorded critical current densities, but at present there is no viable wire production technique available for YBCO and critical current densities fall rapidly with superconductor thickness above 0.5 μm and with length beyond 1 μm.

*(a) Bi-2223*

$(Bi,Pb)_2Sr_2Ca_2Cu_3O_x$ ("Bi-2223") is most readily fabricated using PIT techniques very similar to those used for $Nb_3Sn$, with Ag replacing the Cu tubes used for $Nb_3Sn$. In addition to standard wire drawing techniques, groove rolling is also incorporated to bring powder-filled monofilaments to restack size. Hot extrusion can then be used to bond the multifilamentary composite while increasing the powder density and reducing the billet diameter. Extrusion is followed by further drawing and groove rolling, and finally rolling into tape. As a conventionally mechanically processed material, this is readily scalable to large production quantities. The key issue is to increase the connectivity between the grains of the conductor. The prospect of two- to fivefold improvements in the performance of the present process, coupled to cost reductions triggered by significant scale-up and alternative routes such as overpressure processing (Rikel *et al.* 2001) or melt processing (Flükiger *et al.* 2001) could accelerate the early penetration of superconducting technology into the utility network.

Demonstration HTS transmission cable projects have utilized Bi-2223 strand including test installations at Detroit Edison and Southwire in the USA. For the Detroit–Edison project, a conductor was fabricated by American Superconductor that used four layers of Ag-sheathed Bi-2223 tapes (29 km in total), each tape having an average critical current of ~118 A d.c. at 77 K. The tapes utilized oxide-dispersion-strengthened silver matrices as well as stainless steel reinforcement added to both sides of the HTS tape (Masur *et al.* 2001). For the Southwire project, 30 m cables were produced from PIT Bi-2223 tapes manufactured by IGC. The measured critical current for the cables was 2980 A at 77 K (Sinha *et al.* 2001).

*(b) $MgB_2$*

Since its discovery in early 2001, $MgB_2$ has generated much interest as it has the highest $T_c$ (39 K) of any intermetallic superconductor and has the lowest cost components. Like Bi-2223, $MgB_2$ wires or tapes can use essentially the same technology as that used for $Nb_3Sn$ PIT composites. PIT offers a scaleable technology for future production of kilometer-length $MgB_2$ and has already been exploited for strand fabrication (Jin *et al.* 2001, Grasso *et al.* 2001). The perpendicular irreversibility field is less than that for $Nb_3Sn$, the most widely used intermetallic superconductor, and this may restrict $MgB_2$ to applications of lower field.

## 4. Summary

Nb–Ti and $Nb_3Sn$ superconductors are well established as commercial superconductors with stable markets for NMR and MRI devices as well as high magnetic field testing equipment. Future markets in fusion reactors, accelerator magnets, and energy storage drive further developments. The strain tolerance of $Nb_3Al$ should maintain interest in this material for high-field applications where conductor cost is not an issue. The ability to use liquid nitrogen as a coolant for HTS conductors, such as Bi-2223, is important for applications such as power transmission lines that are not well suited for low temperature refrigeration. Further performance improvement and cost reduction will be required before HTS strands are economically viable. $MgB_2$ offers the potential of a low-cost superconductor for the future that, while not being able to use liquid nitrogen cooling, is still able to benefit from reduced refrigeration costs due to its high $T_c$.

## Superconductors: Borocarbides

Superconductivity in quaternary rare-earth transition-metal borocarbides (*RT*BC) has been found in 1994 (Nagarajan *et al.* 1994, Cava *et al.* 1994). With the invention of these materials the new $LuNi_2B_2C$-type structure (see Fig. 1), space group I4/*mmm*, has been discovered which can be considered as the well-known $ThCr_2Si_2$ type interstitially modified by carbon. The $RT_2B_2C$ compounds are the $n = 1$ (so-called

single layer) variants of $(RC)_nT_2B_2$ structures where $nR$C layers alternate with single $T_2B_2$ layers. Details on the properties of these and related compounds can be found in the review articles listed in the Bibliography. Table 1 summarizes the known superconducting and non-superconducting $RT$BC compounds of $LuNi_2B_2C$-type structure where $R$ stands for 4*f*- and 5*f*-elements as well as for Sc, Y, and La. Among them $YPd_2B_2C$ has the highest superconducting transition temperature $T_c \approx 23$ K. However, no single-phase samples could be prepared of this particular compound so far. The growth of very high quality single crystals of various $RT$BC almost immediately after their discovery has had a profound impact on the quality of the work performed.

For certain combinations of elements $R$ and $T$, superconductivity and antiferromagnetic order have been found to coexist. The magnetic moments in these materials are localized at the $R$-sites whereas the Ni *d*-electrons are nearly nonpolarized. A striking feature distinguishing the superconducting $RT$BC from other superconductors known until 1994 is that the magnetic ordering temperature $T_N$ is comparable with $T_c$ (see Fig. 2), i.e., the magnetic energy is comparable with the superconducting condensation energy. Therefore, the investigation of these compounds is expected to result in new insights into the interplay of superconductivity and magnetism. The high values of $T_N$ demand that in $RT$BC, different from the situation in high-$T_c$ cuprates and the classical magnetic superconductors, exchange coupling between the rare-earth magnetic moments is the dominant magnetic interaction rather than magnetostatic interaction. Obviously the exchange is mediated by conduction electrons. Consequently, also the interaction between the magnetic moments and the conduction electrons must be relatively strong. Figure 2 shows a linear scaling of $T_N$ and, roughly approximated, also of $T_c$ with the de Gennes factor $DG = (g-1)^2J(J+1)$ of the $R^{3+}$ Hunds' rule ground state where $g$ is the Landé factor and $J$ the total angular momentum. Such so-called de Gennes scaling, at the same time for $T_N$ and $T_c$, is due to the fact that both effects, antiferromagnetism and the suppression of

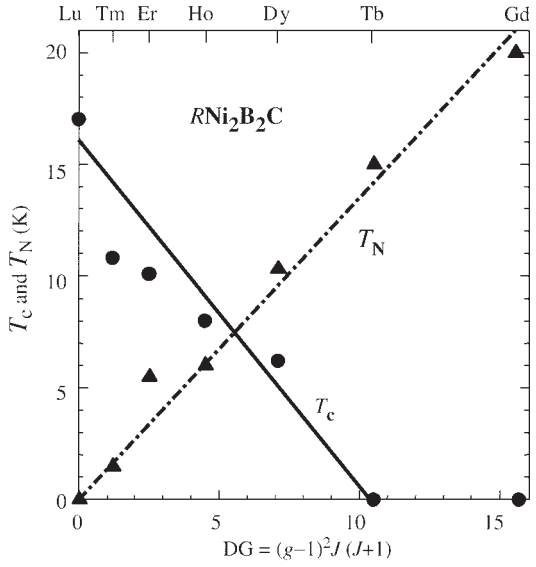

***Figure 2***
Critical temperatures for superconductivity, $T_c$, and for antiferromagnetic ordering, $T_N$, of $RNi_2B_2C$ compounds with $R$ = Lu, Tm, Er, Ho, Dy, Tb, and Gd. DG, $g$, and $J$ are explained in the text. The straight lines represent rough linear approximations.

superconductivity, are governed by the exchange interaction of the conduction electrons with the $R$ 4*f*-electrons. According to Fig. 2 $YbNi_2B_2C$ should be a superconductor becoming antiferromagnetically ordered at sufficiently low temperatures. In this compound, however, hybridization of 4*f*-electrons with the conduction electrons connected with correlation effects results in heavy fermion behavior and suppression of superconductivity.

The *RT*BC superconductors have been classified as phonon-mediated type II superconductors (see *Superconducting Materials, Types of*) in the clean limit (i.e., the mean free path of the unpaired electrons is large compared to the coherence length of the Cooper pairs). They are *s*-wave superconductors with a strongly anisotropic energy gap. Their superconducting and magnetic properties can only be understood by taking into account details of the electronic structure and of the electron–phonon interaction. Thus, the positive curvature of the upper critical field $H_{c2}$ as a function of temperature $T$ of $LuNi_2B_2C$ (see Fig. 3) is due to a strong dispersion of the Fermi velocity and can be well described in a two-band model. The critical temperature $T_c$ is governed by nested regions of the Fermi surface. In the case of antiferromagnetically ordered *RT*BC, these nesting features induce peculiarities in the magnetic long-range order which is also strongly influenced by crystalline electric fields (CEFs). The interplay of itinerant-electron-mediated exchange and CEF results in a large variety of types of antiferromagnetic structures with temperature-dependent spin reorientation transitions as well as (field-dependent) metamagnetic transitions.

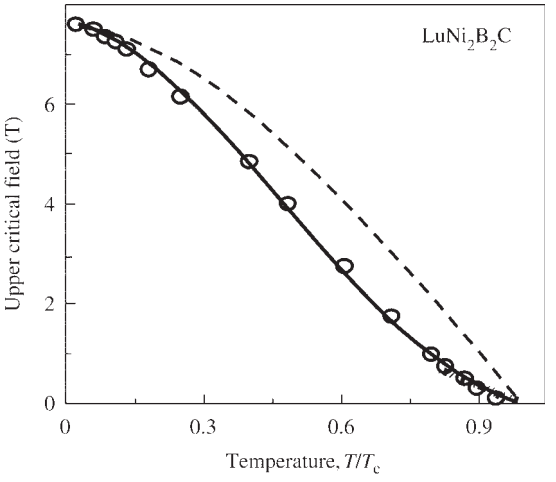

***Figure 3***
$H_{c2}(T)$ of an $LuNi_2B_2C$ single crystal measured parallel to the tetragonal *c*-axis (○). The solid curve was calculated using a two-band model. Dashed line: isotropic single-band model (Shulga *et al*. 1998).

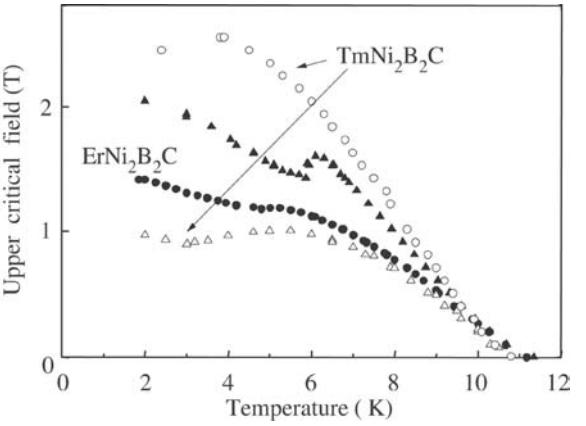

***Figure 4***
Temperature dependence of the upper critical field $H_{c2}$ for $TmNi_2B_2C$ and $ErNi_2B_2C$ single crystals. Circles: $H \| a$; triangles: $H \| c$ (after Canfield and Bud'ko 2001).

As expected these clean-limit superconductors show an anisotropy of $H_{c2}(T)$ due to the anisotropy of the Fermi surface. In *RT*BC superconductors with magnetic *R*-elements antiferromagnetic order causes further contributions to the anisotropy of $H_{c2}(T)$ as can be seen in Fig. 4. $ErNi_2B_2C$ and $TmNi_2B_2C$ even show a different sign in the anisotropy of their $H_{c2}$, which obviously is connected with the different directions of the $R$ magnetic moments in these two compounds.

In most known type II superconductors the flux line lattice does not depend on the symmetry of the crystal lattice and is hexagonal as described by the standard London or Ginzburg–Landau model. In *RT*BC superconductors, however, hexagonal-to-square vortex–lattice transitions have been observed, depending on strength and direction of the applied magnetic field as well as on temperature.

## Superconductors: Rapid Single Flux Quantum (RSFQ) Logic

RSFQ superconductor digital devices were first suggested in 1985 and developed experimentally mostly in the 1990s; for detailed reviews see Likharev and Semenov (1991) and Bunyk *et al.* (2003). In comparison with the previous generation of superconductor logic, RSFQ logic offers a considerably higher speed (up to 800 GHz for simple niobium-based digital circuits) and much lower power dissipation (of the order of $10^{-18}$ Jbit$^{-1}$ at liquid helium temperatures) at comparable parameter margins (of the order of $\pm 30\%$). Because of these advantages, RSFQ logic is a focus of research and development work, despite the fact that its successful implementation requires higher circuit design standards.

### *1. Physical Basis*

RSFQ circuit operation is based on the natural property of superconductors to quantize magnetic flux $\Phi = \int B_n \mathrm{d}A$ through any closed superconducting loop in multiples of the flux quantum $\Phi_0$:

$$\Phi = n\Phi_0,\ \Phi_0 \equiv h/2e \approx 2 \times 10^{-15}\ \mathrm{Wb},\quad n = 0,\ \pm 1,\ \pm 2,\ \ldots \qquad (1)$$

Evidently, digital bits can be coded by certain values of the integer $n$; e.g., the flux states with $n = 0$ and $n = 1$ may be used to present binary zero and unity, respectively. If the superconducting loop is made of a bulk superconductor, switching between the different flux states would require the suppression and restoration of superconductivity in at least some cross-section of the loop; the latter process would take too much time ($\sim 100$ ps for the most popular superconducting material, niobium). However, if the loop is interrupted with one or more Josephson junctions (see *Josephson Junctions: Low-$T_c$*, *Josephson Junctions: High-$T_c$*), switching may be performed much faster (in a fraction of a picosecond for niobium).

Figure 1(a) shows the simplest single flux quantum (SFQ) circuit with just one Josephson junction. Stationary states of this system can be analyzed by combining the equation for Josephson supercurrent, $I = I_C \sin\varphi$, where $\varphi$ is the Josephson phase drop across the junction, with the usual equation for the total magnetic flux through the loop, $\Phi = \Phi_{ex} - LI$, where $L$ is the loop inductance, and $\Phi_{ex}$ is the external magnetic flux. (In electronic circuits it is frequently convenient to create this flux by passing an external current through a part of the loop: $\Phi_{ex} = MI_{ex}$, where $M$ is the inductance of this common part.) Taking into account the fundamental relationship $\varphi = 2\pi\Phi/\Phi_0$, these equations may be readily solved together to give the stationary relationship between $\Phi$ and $\Phi_{ex}$. This relationship shows that if the $LI_C$ product is

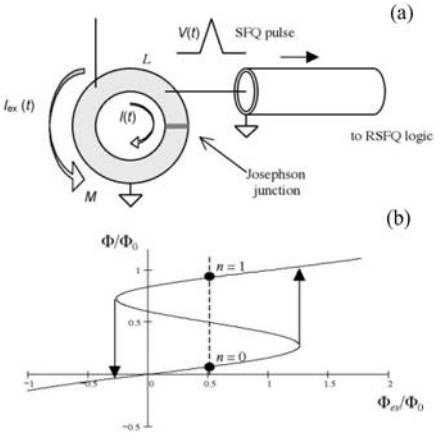

***Figure 1***
(a) Simplest SFQ circuit (''RF SQUID'' or ''DC/SFQ converter'') serving as an SFQ pulse generator. (b) Total magnetic flux $\Phi$ in the circuit as a function of applied flux $\Phi_{ex}$ for a value of $LI_C = \Phi_0$, typical for RSFQ circuits. Arrows indicate flux-state switching at critical values of the external field. The middle branch (with negative slope) corresponds to unstable states. Filled points show two stable states at the equilibrating value $\Phi_{ex} = \Phi_0/2$.

large enough ($>\Phi_0/2\pi$), the Josephson phase difference $\varphi$ (and hence the total magnetic flux $\Phi$ and persistent current $I$) may have several stable stationary states for the same external field $\Phi_{ex}$, with the difference close to $\Phi_0$ (see Fig. 1(b)). By fixing a d.c. flux bias at $\Phi_0/2$, one can work with just two states ($n=0$ and $n=1$) with equal energy and stability.

Switching between the states may be achieved by changing $\Phi_{ex}$ beyond a critical value at which one of the stationary states disappears (see arrows in Fig. 1(b)). In order to avoid irreproducible multiflux switching events, the Josephson junction has to be overdamped (i.e., the McCumber–Stewart parameter $\beta_C$ to be less than 1), for example by using external shunting by normal thin film. In practice, $\beta_C$ is made close to 1; in this case the switching time is minimal and is close to 3 units of

$$\tau_C = \Phi_0/2\pi I_C R_N \tag{2}$$

where $I_C$ is the junction critical current and $R_N$ the normal resistance. For typical Josephson junctions the switching duration is a few picoseconds. According to Faraday's law $V = d\Phi/dt$, during the switching, a short voltage pulse with the quantized area

$$\int V(t)dt = \Delta\Phi \approx \Phi_0 \approx 2\ \text{mV} \times \text{ps} \tag{3}$$

is formed across the junction (Fig. 1(a)). In RSFQ circuits these ''SFQ pulses,'' with amplitudes of the order of 1 mV, are passed to other devices causing their switching.

Figure 2 shows the basic RSFQ circuit, the set–reset (''RS'' or ''D'') flip-flop. Its quantizing loop with inductance $L \approx \Phi_0/I_C$ includes two (rather than one) Josephson junctions, but its characteristics are nevertheless almost identical to those shown in Fig. 1. The supply current (DC IN) is close to, but smaller than,

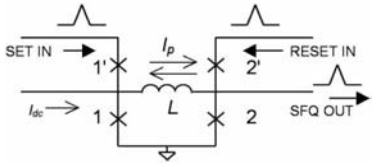

***Figure 2***
Simplest RSFQ logic cell, RS flip flop (crosses denote Josephson junctions). Its basic mode of operation is described in the text. Additional junctions 1′ and 2′ are necessary to avoid possible detrimental back action of the device on the input circuits. For example, if the pulse SET IN arrives when the flip-flop is in state 1 and junction 1 carries low current (d.c. supply current and persistent current subtract in the left branch of the loop), then junction 1′ performs the $2\pi$ leap of the Josephson phase, and the pulse is not reflected back to the source.

the total critical current $2I_C$ of Josephson junctions 1 and 2, so that it creates Josephson phase drops $\varphi_{1,2} < \pi/2$ across these junctions. Owing to its asymmetric injection, the same d.c. current also creates a magnetic bias $\Phi_{ex}$ close to $\Phi_0/2$ in the loop. Because of this bias, the loop has two equilibrated flux states: $n=0$ (with the additional persistent current $I_p \approx \Phi_0/2I_C$ circulating counterclockwise) and $n=1$ ($I_p$ of the same magnitude, but circulating clockwise).

Let the device be initially in state $n=0$, so that the d.c. supply current $I_{dc}$ and the persistent current add in junction 1, and bias it subcritically ($\varphi_1 \sim \pi/3$). When an SFQ pulse SET IN arrives from the left input terminal, it pushes the applied flux beyond the critical value (cf. Fig. 1(b)). As a result, the phase $\varphi_1$ leaps by $\sim 2\pi$, and the flux changes by $\sim \Phi_0$, i.e., the system switches from its flux state 0 to state 1 (with persistent current clockwise). Similarly, an SFQ pulse arriving from the right input (RESET IN) provides the reset of the device (i.e., switching from 1 to 0). Simultaneously the latter process develops an output pulse SFQ OUT, because the Josephson phase across junction 2 leaps by $2\pi$. This pulse may now go to other RSFQ devices.

Other logic gates (''elementary cells'') of the RSFQ family also have one or several coupled quantizing loops, each interrupted with 2–4 Josephson junctions. A detailed description of the available cells is available on the Internet (Bunyk *et al*. 1999). The following important features are common for all cells:

- the flux state is stored in the cell until it is reset by another pulse; hence each elementary cell can be considered as a combination of a logic gate and a latch in one device (''clocked gate'');
- the reset pulse not only triggers the output pulse, but also restores the device to its initial state, so that the shortest distance between the set and reset pulses may be just slightly longer than the width of the pulse—just a few picoseconds for niobium-based devices; and
- the d.c. bias current provides the necessary energy amplification of the SFQ pulses, thus compensating for the inevitable energy loss in the passive transmission lines and shunting conductances of the Josephson junctions.

When ultrafast processing of digital information in an RSFQ circuit is completed, the results may be transferred to the usual (voltage-level) form using a ''SFQ/DC converter'' circuit which uses a d.c. SQUID (see SQUIDS: The Instrument) to sense the flux state of the output RSFQ cell—in practice, galvanically coupled versions of such an SFQ/DC converter are used. The resulting d.c. voltage signal, with a swing of several hundred microvolts, can be amplified by a latching superconductor circuit to a few millivolts, extracted from the cryo-region using a copper cable, and amplified to the standard semiconductor transistor level of a few volts by inexpensive room-temperature semiconductor amplifiers.

Input interfaces for RSFQ circuits are even simpler, because the energy of RSFQ signals is much less than that of standard room-temperature electronics signals. For example, even the single-junction circuit shown in Fig. 1(a) may serve as the input stage (''DC/SFQ converter''), although its parameter margins may be improved by using two additional Josephson junctions.

## 2. Status

After a slow start in Russia, in the early 1990s intensive RSFQ technology development was begun at several US universities and corporate research and development groups, using both low-temperature superconducting (LTS) and high-temperature superconducting (HTS) materials. A few years later, several European groups started work on RSFQ circuits, mostly using HTS materials. In the late 1990s several Japanese groups started a five-year program focused on LTS RSFQ technology.

This progress has allowed the implementation of several relatively complex LTS RSFQ circuits with 1000–2000 Josephson junctions each, mostly using the 3.5 $\mu$m niobium trilayer fabrication technology of HYPRES Inc. (e.g., see Fig. 3). The maximum clock speed for this technology ranges from 20 GHz for VLSI circuits to 70 GHz for simple digital devices. The speed is inversely proportional to the linear junction size, so that for deep-submicrometer niobium trilayer technology the corresponding clock frequencies may reach approximately 150 GHz and 800 GHz, respectively (for details see Likharev 1999, Bunyk *et al.* 2003). Figure 4 shows an example of such an ultrafast device, a digital frequency divider (T flip-flop) tested to operate up to 770 GHz (Chen *et al.* 1999).

During the 1990s several simple HTS RSFQ circuits (with up to 30 Josephson junctions) designed for demonstration purposes were implemented and tested at temperatures from 4.2 K to 77 K (e.g., see Fig. 5). Unfortunately, both experiments (Ruck *et al.* 1999) and calculations (Likharev 1999, Bunyk *et al.* 2003) indicate that thermal fluctuations impose an upper bound for VLSI RSFQ circuits using HTS materials (copper oxides) at about 10 K if a low bit error rate ($<10^{-10}$) is a requirement. The potential advantage of HTS Josephson junctions is that they may have a higher $I_C R_N$ product and hence provide a higher operation speed than LTS junctions (see Eqn. (2)). However, the HTS thin-film junction fabrication methods developed so far do not deliver on this promise. Moreover, these methods still do not provide sufficiently low critical current spreads. As a result, by the end of the 1990s the development of HTS RSFQ technology was not continued by most research groups.

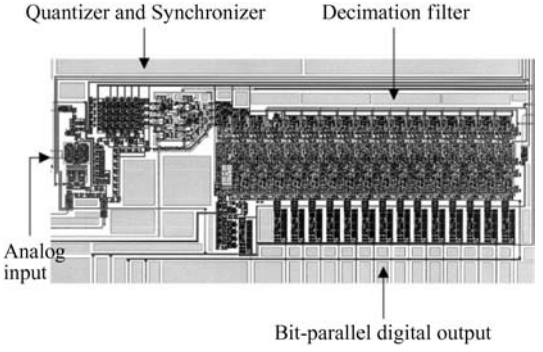

***Figure 3***
RSFQ analog-to-digital converter designed and tested by a HYPRES/SUNY collaboration (Rylov *et al.* 1998). The circuit has close to 3000 Josephson junctions, the total power consumption being below 1 mW, with an active area of 7 mm $\times$ 2 mm. By 2001 the spur-free dynamic range of the device had been improved to reach 12:3 effective bits for a 175 Mbps effective sampling rate, better than for any reported semiconductor transistor ADC.

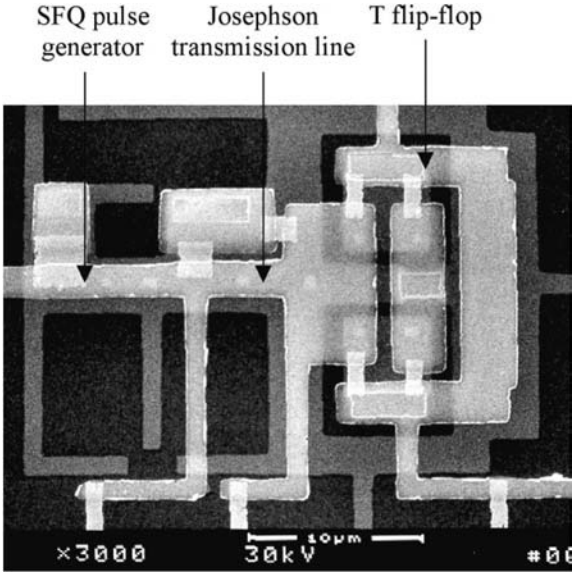

***Figure 4***
Scanning electron microscope image of an RSFQ test circuit including a digital frequency divider (DFD) with 0.5 $\mu$m, externally shunted niobium trilayer junctions. This device could operate up to 750 GHz, while 770 GHz has been reached using its version with 0.3 $\mu$m self-shunted junctions (after Chen *et al.* 1999). The power dissipated by the divider is just 1.5 $\mu$W, some $5 \times 10^4$ times lower than for the fastest reported semiconductor DFD operating below 70 GHz.

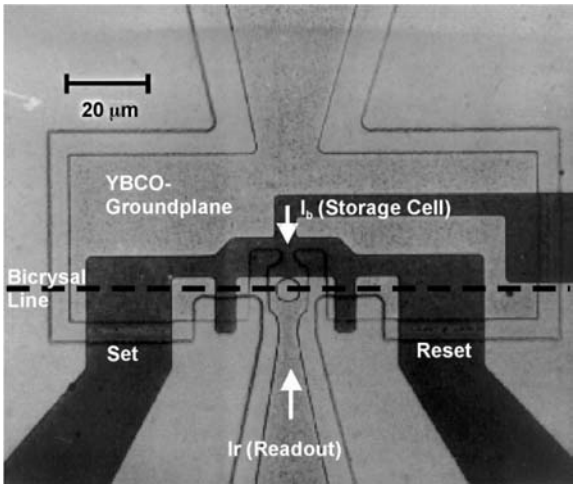

***Figure 5***
Scanning electron microscope image of a simple 14-junction HTS RSFQ circuit (two DC/SFQ converters, two Josephson transmission lines, an RS flip-flop, and an SFQ/DC converter) fabricated using two YBCO layers, which could operate up to 77 K (after Ruck *et al.* 1999).

## 3. Application Prospects

RSFQ circuits using submicrometer junctions are some 100 times faster than similar modern CMOS circuits. Even more importantly, RSFQ devices dissipate much less power energy per bit (about $10^5$ times less without taking into account refrigeration, and 30–300 times less including the refrigeration needs). One more important advantage of LTS RSFQ circuits is that their fabrication technology is much simpler that that of CMOS or digital circuits based on other modern materials (SiGe, GaAs, InP, etc.).

However, the necessity of deep refrigeration of RSFQ circuits limits their possible applications to a few narrow, though important, niches of the digital electronics market. These applications (Tables 1 and 2) can be divided into two major categories:

- circuits that may be competitive at the existing (or slightly upgraded) level of LTS fabrication technology; and
- applications that would require the transfer to submicrometer, VLSI technology.

Despite the relative simplicity of LTS fabrication, the cost of a pilot line for RSFQ VLSI circuits has been crudely estimated at $\times 30$ million. Towards the end of 1999 the most important prospective driver of RSFQ technology was the so-called Hybrid Technologies Multi-Threaded (HTMT) computing project started in the USA (Fig. 6). In this project, an RSFQ subsystem will be responsible for all "number-crunching," as well as for interprocessor communication networks (Dorojevets *et al.* 1999).

***Table 1***
Possible applications of LTS RSFQ logic devices: 3.5 μm technology with $<10^3$ junctions per chip.

| Circuit | Expected performance examples |
|---|---|
| A/D converters | 14 bits at 60 MHz; noise: 3 db |
| Digital SQUIDs | Noise: 1 f $THz^{-1/2}$ at $10^{10}$ $\Phi_0\,s^{-1}$ |
| D/A converters | 10 bits at 18 GHz, 100 mV |
| D.c. and a.c. calibrators | 10 V at 30 MHz, 10 ppb |
| Digital signal correlators | 1 bit at 1 024 channels, 16 Gbps; 8 bits at 8 channels, 128 Gbps |

***Table 2***
Possible applications of LTS RSFQ logic devices: 0.4 μm technology with $\sim 10^6$ junctions per chip.

| System | Expected performance examples |
|---|---|
| Communication digital switching cores | 100 Gbps at 128 channels; 1 chip, 0.1 W at 4 K |
| Digital signal processors | 100 gigaflops; 1 chip, 0.1 W at 4 K |
| High-end workstations and servers | 1 teraflops; 4 processors, 0.5 W at 4 K |
| Petaflops-scale computing systems | 1 petaflops; 4000 processors, 250 W at 4 K |

## 4. Material Issues

For the reasons outlined in *Sect. 2*, only LTS-based RSFQ circuits are being seriously developed. The leading role here belongs to the niobium trilayer technology that was developed during the 1980s (e.g., Hasuo *et al.* 1988). In this technology, the tunnel barrier of a Josephson junction is formed by thermal oxidation of a thin ($<10$ nm) aluminum layer deposited on the base niobium film. After a few minutes of oxidation in dry oxygen at a pressure of a few millitorr (Miller *et al.* 1993), a niobium counter electrode film is deposited without vacuum breaking, thus preventing any contact between aluminum and water vapor. The junctions fabricated using this technique may exhibit very high reproducibility (random spreads of the order of 1%) even for subnanometer

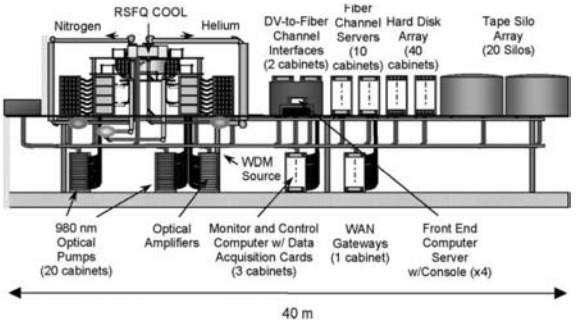

***Figure 6***
Preliminary design of the HTMT petaflops-scale computer room. Note that despite the RSFQ "COOL" subsystem being responsible for all the "number crunching," it occupies $<1\,m^3$, just a tiny fraction of the whole machine size. This compactness is possible owing to the extremely low power dissipation of RSFQ circuits, and is very important for providing very low (20 ns) interprocessor communication latency (courtesy of J. Morookian and L. Bergman, Jet Propulsion Laboratory).

aluminum oxide barriers providing very high critical current density $j_c$ (well beyond $1\,kAcm^{-2}$).

The important issues in the development of this technology include its extension to higher $j_c$ (up to $100\,kAcm^{-2}$), which is necessary for self-shunted operation of Josephson junctions with maximum speed, while retaining the low critical current spreads. A related issue is the chemical–mechanical polishing of the junction counter electrode, necessary for submicrometer junction definition, without disturbing the ultrathin aluminum oxide layer. Despite considerable progress in these directions (Miller *et al*. 1993, Chen *et al*. 1999, Patel and Lukens 1999), high $j_c$ RSFQ circuits of sufficiently high integration scale have yet to be developed.

For some (especially space-platform) applications the increase of operation temperature to $\sim 10\,K$ is important, because of higher refrigeration efficiency. Niobium nitride-based Josephson junctions with MgO tunnel barriers capable of operating at such temperatures have been demonstrated (e.g., Kerber *et al*. 1997, and references therein), but their fabrication technology has to be further advanced to enable VLSI circuit integration.

## Super-resolution: Optical and Magnetic Techniques

In optical recording, an optical head focuses the beam from a semiconductor laser to produce a probe spot on the recording medium. The focused spot has a Gaussian intensity profile and a width determined ultimately by the laws of diffraction. When limited only by diffraction, the diameter of the spot is directly proportional to the wavelength of the laser radiation, and inversely proportional to the numerical aperture (NA) of the objective lens. If the width of the spot ($d$) is taken as the distance between the half power points, then in the diffraction limit $d \cong 0.56\lambda/\mathrm{NA}$. In magneto-optics, as with most optical recording technologies, it is, however, possible to write "marks" much smaller than the total width of the diffraction-limited spot

(see *Magneto-optical Effects, Enhancement of*). As shown in Fig. 1, this may be achieved by exploiting the thermal nature of the write mechanism used by all current recording systems, and involves making the correct choice of the critical write temperature in conjunction with optimization of the thermal response or write sensitivity of the medium.

The resolution on readout, however, remains constrained by the total width of the beam, so that the density at which information can be stored is determined by the rate at which the depth of modulation (signal) falls as recorded marks are packed closer. When the minimum separation between recorded marks is reduced to half the diameter of the focused spot, the signal falls to zero. Therefore it is the readout process that limits the density at which information can be stored. At least three separate technologies are under active development with a view to overcoming this limitation, and they all rely heavily on the material and material processing for their successful operation.

The optical recording industry foresees (News Letter no. 4 OITDA 1998) the need for a technology in which the areal densities approach 1 Tbyte $in^{-2}$ by 2010. Since the launch of optical storage products, an intensive global research effort has driven down the wavelength of semiconductor laser diodes from around 800 nm to the 400 nm devices announced (Nichia Corporation Japan 1999) early in 1999. However, these developments alone only improve the resolution by a factor of four. Moreover, they have impacted primarily on the CD-ROM or other read-only formats, since the shorter wavelength ($\approx$650 nm) laser devices installed have been slow to realize the power required for high-speed writing.

The other parameter governing the resolution of an optical head is its numerical aperture. Unfortunately, the improvements of a similar order that might be achieved by increasing the numerical aperture become increasingly difficult to implement as the NA approaches its limiting value (1 in. air), while constrained to conventional optics by other system requirements. The NA of current systems remains limited to a value of around 0.55–0.65. It is clear that to realize the density figures quoted above will involve development of techniques that can bypass the diffraction limit. The optical and magnetic super-resolution techniques discussed here offer that very possibility, but implemented by very different means.

The simplest way of achieving optical resolution beyond the diffraction limit is to operate in what is known as the near-field regime, placing an aperture defining the required resolution between the laser source and the sample. Providing the aperture-to-sample separation is maintained at only a small fraction of the laser wavelength, then the resolution is determined by the diameter of the aperture and not by diffraction. Perhaps the best early demonstration of this technique is the work of Betzig *et al.* (1987) using metallized optical fibers tapered to an aperture of only 40 nm using access technology borrowed from scanning probe microscopy. Such techniques are of course very inefficient in their utilization of optical energy, and although more recent demonstrations (Hosaka *et al.* 1996) have achieved readout data rates of 10 MHz for phase-change recording using this principle, because of the current speed of their access they will not be considered further.

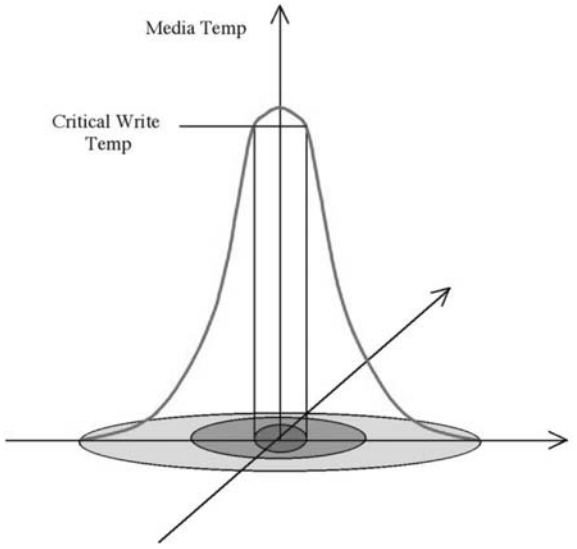

***Figure 1***
Writing below the diffraction limit.

## *1. Magnetic Super-resolution*

"Magnetically induced super-resolution" (MSR) as originally conceived is the term applied to various techniques developed to overcome the diffraction limit by creating, in the surface of the moving medium, an "effective dynamic aperture" much smaller than the width of the readout beam. This technique, first proposed by Sony (Ohta *et al.* 1991), is realized in a similar fashion to the direct overwrite (DOW) by light intensity modulation (LIM) technology conceived earlier by Nikon (Saito *et al.* 1987). The deposition process is controlled to produce a medium having a complex multilayer structure of magnetic films that are coupled to each other magnetostatically or, more commonly, through the exchange interaction. At the same time, the unique compositional dependence of the properties of various amorphous rare-earth–transition metal (RE-TM) alloys such as TbFeCo, GdFe, GdFeCo, etc., is exploited to control their Curie temperature, coercivity, and switching field (see *Magneto-optic Recording Materials: Chemical Stability and Life*

*Time*). The composition of each of the different coupled layers that comprise the medium is varied, so that its magnetic and thermomagnetic behavior is precisely tailored to a specific task within the MSR readout process. Activation of these different characteristics is achieved by using a somewhat higher laser power than employed for conventional readout, in conjunction with an applied magnetic readout field.

To appreciate the working principle of MSR systems, consider a basic three-layer medium such as shown in Fig. 2 consisting of a conventional storage layer, an intermediate or transfer layer, and a readout layer. Domains representing the stored data pattern are written conventionally into the storage layer, which has a high Curie temperature and a very large coercivity. An identical pattern becomes imprinted on to the readout layer by exchange coupling through the intermediate or transfer layer. The readout layer also has a high Curie temperature, but its coercivity is small, less than that of the applied readout field ($\boldsymbol{H}_{\mathbf{r}}$). It is also made thick enough so that the readout beam only interrogates this layer—no energy is allowed to reflect back from the storage layer to the detection system. As the beam tracks across recorded data, it produces in the medium a temperature profile that has the basic Gaussian profile of a laser beam, distorted in the direction of the medium's motion (Fig. 3). The Curie temperature of the intermediate layer is less than the temperature reached by the medium in the hottest part of the beam profile. In this region the data pattern in the readout layer is thus temporarily decoupled from the storage layer, and aligns instead with the readout field $\boldsymbol{H}_{\mathbf{r}}$.

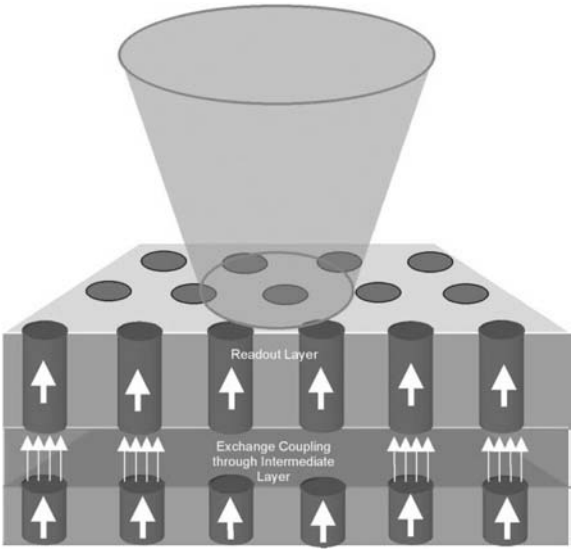

***Figure 2***
Trilayer exchange-couple MSR medium.

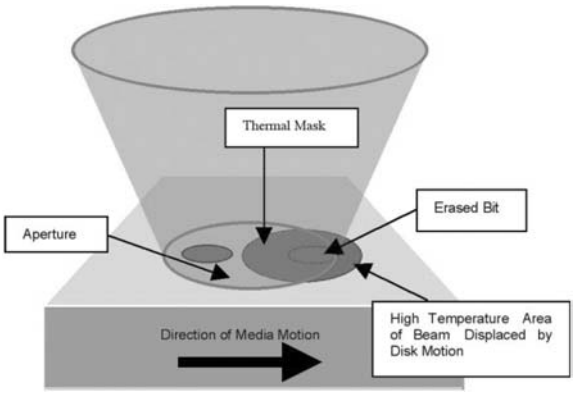

***Figure 3***
Reduced aperture and thermal mask in front aperture detection (FAD).

The data pattern under this part of the beam is effectively erased, creating a region that behaves as an active optical mask inserted into the beam in the plane of the surface. Magneto-optic information is therefore read out only with that portion of the focused laser spot that is reflected from the cooler part of the irradiated surface. This is crescent-shaped, as can be seen in Fig. 3. It is the width of the crescent, typically only one-third the width of the focused spot, along the track that now determines the resolution. After the beam has passed a given portion of data, the medium cools and the erased pattern is re-established as the coupling between the surface readout layer and the lower undisturbed storage layer is restored. Throughout this process, the integrity of the data in the storage layer is ensured by the high Curie temperature and coercivity of this layer. In a similar fashion, the high Curie temperature of the readout layer maintains the signal quality of the data being read out in the cooler aperture in the medium. Although Figs. 2 and 3 show the operation of the system with pulse position recording, it is also compatible with pulse length recording and magnetic field modulation, when the written domains themselves become crescent-shaped.

The basic system described above is characterized by the high-temperature mask trailing the detection aperture, and is therefore known as front aperture detection (FAD). Since it was first conceived it has been extensively developed and refined. For example, it is immediately obvious that if the relative positions of the mask and aperture could be reversed, then not only would the improved resolution be retained, but the mask would now cover adjacent tracks, precluding crosstalk and permitting higher track densities and/or land-and-groove recording. This is achieved in rear aperture detection (RAD), though usually at the expense of introducing an additional initializing field. In its most sophisticated embodiment, RAD can be

implemented as a double-mask system that further reduces the aperture and improves the resolution.

Finally, there is center aperture detection (CAD), in which the temperature dependence of the anisotropy of certain of the RE-TM alloys is exploited. The composition of the readout layer is made such that the magnetization lies in plane at ambient temperature, but rotates out of plane at much higher temperatures. A polar Kerr readout signal is therefore only detected from the very center of the temperature profile formed by the beam in the medium. The cooler areas are effectively masked since, as the magnetization still lies in plane, they display no polar rotation. A major benefit of this system is that it requires no additional fields applied during readout.

For a more extensive description of MSR technology, the reader is directed to the review by Kaneko and Nakaoki (1996). Recent achievements of the double-mask or CAD-MSR technology include the 2 Gbyte capacity, 90 mm disk reported by Fujitsu (Shono 1999) and the 9 Gbyte, 120 mm disk reported by Sharp (Murakami *et al*. 1996). Despite these successes, a major drawback of the MSR principle is that the signal level decreases with reducing aperture size, since an ever-reducing portion of the focused spot is actually used to detect the tiny domains. By 1996, it had become apparent that a more sophisticated system would be required to read out domains below about 0.2 μm in diameter.

## 2. *Magnetically Amplifying Magneto-optic System*

The magnetic amplifying magneto-optic system (MAMMOS) was proposed by researchers at Hitachi and Sanyo (Awano *et al*. 1996) to address the problems of reducing signal level in MSR systems. Again this is a multilayer system, with the functions of storage and readout separated into mutually coupled layers whose properties are tailored to their specific task through the correct combination of rare-earth and transition metal elements. In MAMMOS media, the coupling between layers is almost exclusively magnetostatic and the working principle is relatively straightforward.

The stable diameter ($d_o$) of a cylindrical reverse domain written into a perpendicular recording medium is determined by the balance of forces acting on it. Energy stored in the domain walls acts to collapse the domain, but is opposed by the resistance to wall motion provided by the coercivity. In the case of domains so small that MAMMOS is required for readout, the ratio of the thickness of the medium to the stable domain diameter in general becomes such that it is also necessary to take account of the contribution of the magnetostatic energy to the stability of the system. The demagnetizing field associated with a reversed domain acts with the coercive field to oppose the collapsing field and stabilize the bit at a smaller diameter. Previous studies (Callan and Josephs 1977, Honda *et al*. 1981) have treated these two opposing forces by combining them into an effective field ($H_{\text{eff}}$), with stable domains being obtained when this effective field is less than the coercive field ($H_{\text{eff}} < H_c$). In these circumstances, application of an alternating external applied field ($H_{\text{appl}}$) synchronized with the system data clock, and aligned to alternately either assist or cancel the coercive field, will expand or collapse any domain.

Data domains written in the storage layer with diameters as little as one-tenth of the full width of the readout beam are resolved on readout by first copying each in turn to the readout layer. There they are then temporarily expanded, so that each one fills or overfills the beam to produce signal levels approaching 100% saturation. The readout sequence may be understood by reference to Fig. 4. In Fig. 4(a), the instantaneous applied field is in a direction and of a magnitude such that it opposes coupling between the storage layer and the readout layer, so that there are no data domains in the readout layer. As $H_{\text{appl}}$ passes through zero, as shown in Fig. 4(b), coupling is established and a domain is copied to the readout layer. $H_{\text{appl}}$ now increases to a maximum in the direction that assists the coercive field and opposes the collapsing field. The copied domain is therefore caused to expand to a size that is readily detectable (Fig. 4(c)). During the opposite half of the applied field cycle, $H_{\text{appl}}$ again passes through zero when the domain is shrunk to its original size, before finally being fully collapsed and expelled from the readout layer as the cycle completes (Fig. 4).

Recent demonstrations of the potential of MAMMOS technology have included a carrier-to-noise ratio (CNR) of more than 50 db from 0.2 μm domains (Takagi *et al*. 1999), the observation of a MAMMOS signal from 0.04 μm domains (Takagi *et al*. 1999), and the combining of light intensity modulation direct overwrite with MAMMOS readout (Tokunaga *et al*. 1999).

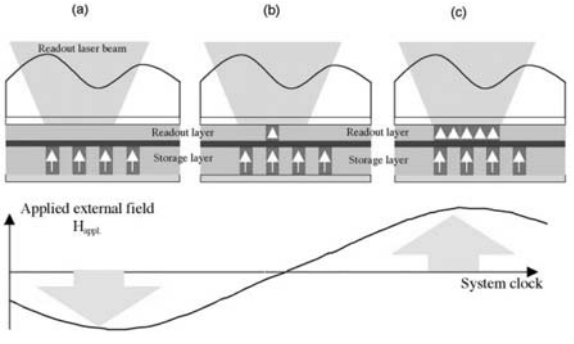

***Figure 4***
Basic MAMMOS mechanism using a.c. applied field synchronized to system clock.

### *3. Optical Super-resolution*

Optical super-resolution refers to a suite of techniques that seek to increase the resolving power of an optical head by circumventing the limiting value of 1 for the NA in air of conventional objective lenses. The principle employed is analogous to the use of oil immersion objectives in microscopy. A solid immersion lens (SIL) with a high refractive index in the form of a hemisphere or truncated super-sphere in used in conjunction with a conventional objective having NA of around 0.5. Figure 5 shows the simple case in which a conventional low NA objective is used to focus the beam at the center of the flat face of a SIL having hemispherical form. In this arrangement all rays enter the SIL along its radii and are undeviated or diffracted. Thus, although the angle subtended by the cone of incident rays is unchanged, the NA ($= n \times \sin\theta$) of the composite system is increased by a factor $n$, since final incidence to focus is now through a medium having a refractive index greater than air. The focused spot size is consequently reduced by a factor $n$, where $n$ is typically in the range 1.9–2.3. Adoption of the super-sphere offers yet further potential improvement.

It is well known (Nussbaum and Phillips 1976) that a beam directed through a sphere of radius $r$ is focused to a point free of both spherical aberration and coma at a distance $r/n$ below the center of the sphere. If the material below the point of focus is removed, as shown in Fig. 6, we have a situation similar to the simple hemisphere. However, the peripheral rays defining the NA that were originally converging at $\phi_1$ now converge at a larger angle $\phi_2$, given by $n \times \sin^{-1}\phi_1$, to a new focus at the center of the plane of truncation. The effective NA is in this case therefore increased by a factor of $n^2$, since the beam is again also incident through a media of refractive index $n$. Used in conjunction with blue lasers, this technology offers the potential to resolve domains as small as 100 nm. It is not, however, without its problems. Total internal reflection means that only a small part of the cone of radiation forming the focused spot can exit into air for coupling into the disk media. In order that adequate field propagates in the air gap between the lens and media, it is necessary to rely heavily on the evanescent wave whose intensity drops rapidly away from the lens surface. Implementation of the full potential of this technique therefore requires operating in the near-field regime, with the air gap ideally much less than the wavelength of the radiation.

Outside the near-field limit, i.e., at lens-to-media separations of around two to three wavelengths, the technology does make attainment of NA equal to 1

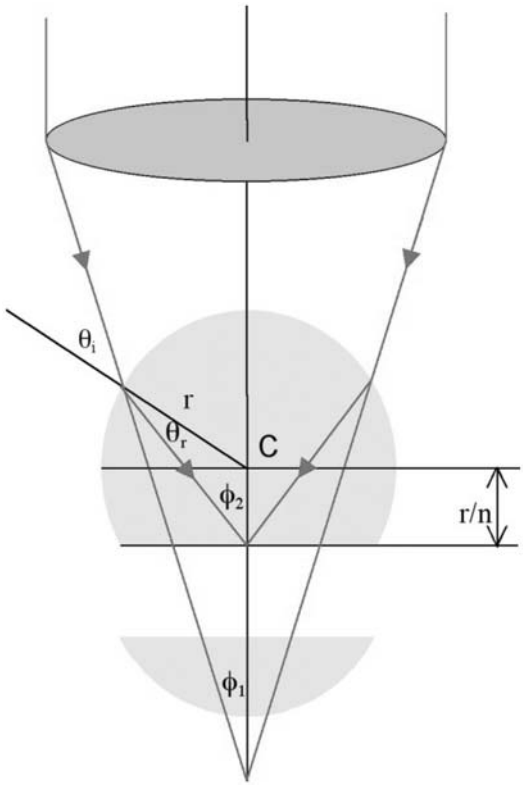

***Figure 6***
Supersphere SIL.

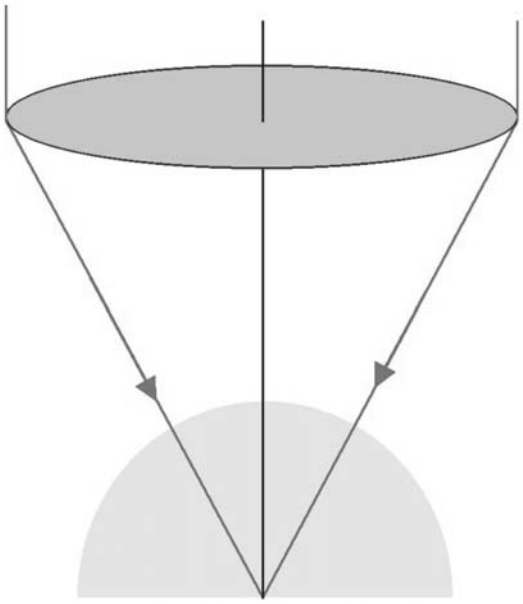

***Figure 5***
Hemispherical solid immersion lens (SIL).

a practical possibility, however. Of course, head gaps of these dimensions make it necessary to abandon some of the major advantages of optical disk technology. The large separations between head and media, and between the point of focus on actual recording media and the disk surface adjacent to the environment, can no longer be supported. The SIL must be flown like the head in a conventional magnetic hard drive, but considerably closer to the recording surface. In these circumstances, integration of the write coil on the same slider carrying the SIL is a natural step. Optical access to the actual recording medium can no longer be protected through the substrate and front-surface media a thin dielectric overcoat must be used. Fortunately, the refractive indices of the common protective overcoats such as silicon nitride match reasonably well to those of SILs. In general, it is also necessary, because of the extreme intensity in the very small spot, to desensitize the medium. A fuller treatment of near-field optics is given elsewhere in this encyclopedia.

## Textured Magnets: Deformation-induced

There are two different processes for producing anisotropic rare earth–transition metal–boron (RE–TM–B) magnets with high energy density. One is the conventional technique of powder metallurgy (see *Magnets: Sintered*). The crystal alignment is achieved by applying an external magnetic field during the cold-pressing stage. The alternative processing route is hot deformation of cast alloys or of fine-grained powder, the latter consolidated previously by hot pressing. The hot working process produces grain alignment along the *c*-axis perpendicular to the plastic flow direction. The key for understanding the formability of the inherently brittle alloys is the presence of the RE-rich grain boundary phase, which is liquid at the deformation temperature ($>700\,^{\circ}C$). It is conceivable that the liquid grain boundary phase can annihilate microcracks created during the deformation. However, a liquid cannot resist high tensile stresses. Therefore, the deformation must be performed under compressive stress.

### 1. *Deformation of Cast Alloys*

Permanent magnet production by hot deformation of cast alloys promises to be a potentially simpler and more economical option in comparison with the sintering route because of the troublesome handling of magnetic powder that is extremely sensitive to oxygen contamination.

The simplest deformation method is upsetting of cylindrical specimens between two punches. Extensive hot-pressing experiments performed by Shimoda *et al.* (1989) revealed that Pr–Fe–B alloys with the composition $Pr_{17}Fe_{79}B_4$ are particularly suitable for hot deformation. Hot pressing at 1000 °C with strain rates of $10^{-4}$–$10^{-3}\,s^{-1}$ introduces a preferred magnetization direction parallel to the press direction. Additionally, the magnetic alignment is closely related to the structure of the cast ingots and the direction of principal stress. The appropriate structure is a columnar structure in which the *c*-axis of the hard magnetic $Pr_2Fe_{14}B$ phase (2:14:1 or Φ phase) is in the plane perpendicular to the crystal growth direction. Therefore, the principal stress during deformation should also be perpendicular to the growth direction. Inserting the cylindrical specimens into an iron ring prevents cracking up to strain rates of $10^{-1}\,s^{-1}$ as well as squeezing out the liquid intergranular phase. Additionally, increasing the strain rate results in a grain refinement and with a consequent enhancement of the coercivity.

Studies concerning additive elements show that copper addition is effective in increasing coercivity and in improving the magnetic alignment. Microstructural studies reveal that copper (i) refines the as-cast grain size and (ii) reduces the melting point of the praseodymium-rich phase. Copper probably leads to a better wetting behavior and separation of the hard magnetic grains. In the studies of Shimoda *et al.* (1989) the magnetic properties of hot-pressed and annealed $Pr_{17}Fe_{76.5}B_5Cu_{1.5}$ magnets were as follows: remanence, $B_r = 1.25\,T$; intrinsic coercivity, ${}_iH_c = 796\,kA\,m^{-1}$; and maximum energy product, $(BH)_{max} = 288\,kJ\,m^{-3}$.

Hot rolling of RE–TM–B alloys has been studied by Ohki *et al.* (1989). The essential feature of the hot rolling is a high strain rate ($1$–$10\,s^{-1}$), which makes this process very suitable for mass production. The optimum rolling temperature is about 950 °C. Regarding the optimum structure, it is found that the primary crystallization of iron is necessary for the formation of fine-grained Φ crystallites during the following peritectic reaction. Optimum magnetic properties demand a postdeformation heat treatment that is beneficial to both the coercivity and the remanence. Regarding Pr–Fe–B alloys, the following maximum values have been achieved: $(BH)_{max} = 340\,kJ\,m^{-3}$ and ${}_iH_c = 1194\,kA\,m^{-1}$. Concerning neodymium-based alloys, the maximum published values are: $(BH)_{max} = 269\,kJm^{-3}$ and ${}_iH_c = 525\,kA\,m^{-1}$. Hot rolling of ingots is also used for the preparation of anisotropic powder suited for bonded magnets (Hinz *et al.* 1994).

Extrusion of RE–TM–B alloys results in magnets with radial *c*-axis orientation. Nozieres *et al.* (1988) carried out extrusion experiments with large ingots, cast in an iron sheath. Energy products in the range $120$–$160\,kJ\,m^{-3}$ have been obtained.

Regarding the mechanism of deformation and texturing, the microstructural feature of the hot deformation of cast alloys is the marked grain refinement. It is assumed that the crystal alignment is related to rotation of the grain debris in the liquid intergranular phase. The start of the alignment is supported by the plate-like shape anisotropy with its *c*-axis perpendicular to the larger and flat surface of the dendritic grains (Yuri and Ohki 1994). During the deformation process the cracking occurs preferentially along the *c*-plane of the main phase, resulting in an enhancement of the plate-like shape anisotropy and the rotation of the grains. In a later stage the rotation of the grains is accompanied by an irregular cracking at the surface of the grains. This generates significant amounts of small and unaligned grain debris. Postdeformation heat treatment results in grain growth with dissolution of the small and unaligned grains and in blunting of the sharp edges of the large grains.

### 2. *Deformation of Powder Precursors*

The possibility of an alignment of compacted melt-spun RE–TM–B powder precursors by hot

deformation was discovered by Lee *et al.* (1985). In the first step a fully dense isotropic precursor must be produced by hot pressing. The high densification is possible because the RE-rich grain boundary phase is liquid in the applied temperature range from 700 °C to 750 °C. In the second step the deformation of the precursor takes place at temperatures between 750 °C and 800 °C. In the case of the die-upset method, this step can be accomplished by transferring the sample to an oversized die cavity (Fig. 1). The deformation leads to an anisotropic magnet with the alignment parallel to the pressing direction.

Optimizing the composition in the Nd–Fe–B ternary system involves a compromise between maximizing the volume fraction of the $Nd_2Fe_{14}B$ phase and providing excess neodymium for the grain boundary phase. According to Nozawa *et al.* (1988) the optimum composition of die-upset magnets is in the range $Nd_{13.5–14}Fe_{80.5–80}B_6$. Because the coercivity is reduced after hot deformation of ternary alloys, the effect of additional elements has been investigated. A 0.5 at.% gallium addition proves to be favorable leading to a coercivity enhancement of up to 1600 kA m$^{-1}$ and also a relatively small reduction in remanence (Nozawa *et al.* 1988). The partial substitution of cobalt for iron leads to an enhancement of the Curie temperature of the magnetic main phase and, therefore, to better thermomagnetic stability of the magnets. According to Yoshida *et al.* (1991) the addition of cerium or silicon has a positive effect on the workability.

For melt spinning, a high quench rate should prevent the formation of coarse grains on the wheel-free surface of the ribbons. Surface velocities of 30–34 m s$^{-1}$ lead to an optimum alignment after upsetting (Fuerst and Brewer 1993). Concerning the deformation conditions, increasing the die-upset level results in an enhancement of the alignment up to a height reduction of about 75%. The optimum deformation temperature is in the range 750–800 °C and the optimum strain rate is $10^{-2}$–$10^{-1}$ s$^{-1}$. Die-upset magnets are commercially available. The energy product of the different grades ranges from about 255 kJ m$^{-3}$ to 340 kJ m$^{-3}$ and the intrinsic coercivity ranges from 955 kA m$^{-1}$ to 1670 kA m$^{-1}$ (Panchanathan 1995). The published maximum energy product is about 400 kJ m$^{-3}$. Saito *et al.* (1998) investigated the magnetic properties of amorphous powder consolidated by shock compression. Die-upset magnets with the composition $Nd_{13.5}(Fe_{0.975}Co_{0.025})_{80}Ga_{0.5}B_6$ show a maximum energy product of 433 kJ m$^{-3}$ and an intrinsic coercivity of 995 kA m$^{-1}$ offer optimal deformation.

Mechanically alloyed powder (see *Magnets: Mechanically Alloyed*) and HDDR powder (see *Magnets: HDDR Processed*) compacts can also be used as precursors for the successful production of die-upset magnets (e.g., Schultz *et al.* 1991). A comparison of deformation and magnetic properties has been given by Kirchner *et al.* (1998) (Fig. 2).

The hot deformation of fine-grained powder precursors is also suited to produce radially oriented ring magnets by backward extrusion (Croat 1989). Magnets with different dimensions and energy products of more than 280 kJ m$^{-3}$ are commercially available. The process seems to be especially attractive because the magnetic properties of rings surpass those of ring

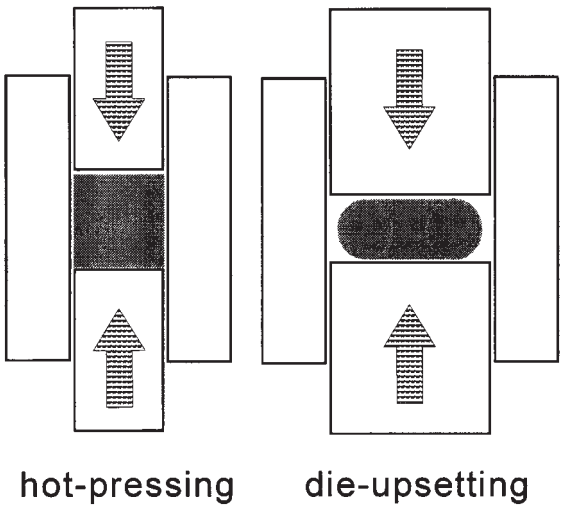

*Figure 1*

magnets made from sintered material, especially at small dimensions. Backward extruded ring magnets do not quite reach the maximum properties of die-upset magnets. The reason is the inherent inhomogeneity of the deformation process, which results in inhomogeneous properties in the cross-section of the rings (Grünberger *et al*. 1996).

Contrary to cast ingots, microstructural investigations in fine-grained alloys show the formation of flat platelet-shaped grains which are larger than those of the starting material (e.g., Lee *et al*. 1985). Therefore, it is consequent to discuss diffusion-supported mechanisms for deformation and texturing. It is believed that deformation and alignment are produced by a combination of grain boundary sliding and anisotropic grain growth caused by the inherent anisotropy of the crystal growth of the tetragonal Φ phase or by the anisotropy of the elastic properties. Lewis *et al*. (1997) published a survey of the existing literature in this field. Grünberger (1998) investigated the applicability of the model of solution precipitation creep. This is based on the transport of matter in the liquid intergranular phase caused by the local dependence of the solution equilibrium between solid and liquid on the local stress state. Because the local stress state depends on the elastic properties, the anisotropy of the latter can contribute to the development of texture. The kinetic analysis of the strain rate stress relationships of die-upset experiments indicates an interface-controlled process.

## Thin Film Magnetism: Band Calculations

The understanding and design of complex magnetic nanostructures is one of the current frontiers in magnetism. Research in this field is stimulated by its interesting fundamental physics as well as applications today and in the future in the field of data storage and magnetoelectronics. New experimental techniques, like molecular beam epitaxy and spin-polarized electron spectroscopy techniques, for growth and characterization of the nanostructures go hand-in-hand with powerful theoretical methods and provide a great deal of insight into these phenomena. Ab initio calculations based on density functional theory play a crucial role for the microscopic understanding of fundamental magnetic properties, such as magnetization and magnetic order.

### *1. Spin-density Functional Theory*

Ab initio calculation means that the system under consideration is described without any free parameter.

The problem that needs to be solved is the many-body problem of a system formed by interacting electrons and nuclei. With the Born–Oppenheimer approximation (Born and Oppenheimer 1927) the problem can be reduced to a system of $N$ interacting electrons moving in the electrostatic potential $V_{\text{ext}}$ caused by the nuclei

$$H = \sum_{i=1}^{N}\left(-\frac{\hbar^2}{2m}\right)\frac{\partial^2}{\partial \mathbf{r}_i^2} + \sum_{i=1}^{N} V_{\text{ext}}(\mathbf{r}_i) + \frac{1}{2}\sum_{i\neq j}^{N}\frac{\varepsilon^2}{|\mathbf{r}_i - \mathbf{r}_j|} \quad (1)$$

where $\varepsilon^2 = e^2/4\pi\varepsilon_o$. $\varepsilon_o$ is the dielectric constant. $\mathbf{r}_i$ is the position of electron $i$ while all other constants have their traditional meaning. Depending on the boundary conditions used for the external potential, systems with arbitrary dimensions like atoms or clusters, wires, slabs, or bulk materials can be described (Fig. 1) Atoms and clusters are considered to be quasi one-dimensional and are finite in all spatial directions. Wires are confined in two directions and are translational invariant in the third, slabs are finite in one direction and periodically repeated in the other two directions, and bulk systems are translationally invariant in all spatial directions.

Density functional theory (Hohenberg and Kohn 1964, Kohn and Sham 1965, Sham and Kohn 1966) constitutes the main underlying basis for the solution of this problem. In the generalization of density functional theory to magnetic systems (Rajagopal 1980, Hedin and Lundqvist 1971, Barth and Hedin 1972, Moruzzi *et al.* 1978, Gunnarsson and Lundqvist 1976, Gunnarsson *et al.* 1972), the so-called spin density functional theory, one distinguishes between two types of electrons, namely the majority electrons ($\sigma = +$) and the minority electrons ($\sigma = -$) whose spin is in and opposite to the direction of magnetization, respectively. In addition to the Coulomb potential of the nuclei the electrons experience an extra contribution $\pm\mu_B H$ due to an external field $H$. the spin degeneracy is lifted. As a consequence the majority electrons are more attracted than the minority electrons. Contributions from orbital momenta and from spin–orbit coupling are neglected, giving an adequate approximation for itinerant magnetism.

The two types of particles are represented by spin-dependent densities $n^+(\mathbf{r})$ and $n^-(\mathbf{r})$, leading accordingly to the following functional for the ground state energy

$$E[n^+,\ n^-] = T[n] + \int d^3r V_{\text{ext}}(\mathbf{r}) n(\mathbf{r}) + U[n] + E_{\text{xc}}[n^+,\ n^-] \quad (2)$$

where $T[n]$ is the functional of the kinetic energy for a set of $N$ noninteracting electrons of density $n(\mathbf{r})$. $U[n]$ is the classical Hartree energy

$$U[n] = \frac{1}{2}\int d^3r n(\mathbf{r}) \int d^3r' n(\mathbf{r}')\,\frac{\varepsilon^2}{|\mathbf{r} - \mathbf{r}'|} \quad (3)$$

and $E_{\text{xc}}[n^+, n^-]$ the exchange-correlation energy which includes all many-body interactions, exchange and correlation, in an effective way. The total density is given by

$$n(\mathbf{r}) = n^+(\mathbf{r}) + n^-(\mathbf{r}) \quad (4)$$

and the magnetization density is given by

$$m(\mathbf{r}) = n^+(\mathbf{r}) - n^-(\mathbf{r}) \quad (5)$$

Clearly, the ground state energy is a functional of both spin-dependent densities, $E[n^+, n^-]$. Using spin-dependent densities in terms of single-particle wave functions $\varphi_k^\sigma(\mathbf{r})$

$$n^\sigma(\mathbf{r}) = \sum_k |\varphi_k^\sigma(\mathbf{r})|^2 \quad (6)$$

the variation of the ground state energy yields the spin-dependent Kohn–Sham equations

$$\left[-\frac{\hbar^2}{2m}\frac{\partial^2}{\partial \mathbf{r}^2} + V^\sigma(\mathbf{r})\right]\varphi_k^\sigma(\mathbf{r}) = E_k^\sigma \varphi_k^\sigma(\mathbf{r}) \quad (7)$$

and, by analogy with the spin-independent case an effective though spin-dependent potential follows as

$$V^\sigma = V_{\text{ext}}(\mathbf{r}) + \int d^3r' n(\mathbf{r}')\,\frac{\varepsilon^2}{|\mathbf{r} - \mathbf{r}'|} + V_{\text{xc}}^\sigma(\mathbf{r}) \quad (8)$$

with

$$V_{\text{xc}}^\sigma = \frac{\delta E_{\text{xc}}}{\delta n \pm (\mathbf{r})}$$

Under the local spin density approximation (LSDA), the exchange-correlation energy (Barth and Hedin 1972, Moruzzi *et al.* 1978) is written as Eqn. (9)

$$E_{\text{xc}}[n^+,\ n^-] \approx \int d^3r (n^+(\mathbf{r}) + n^-(\mathbf{r})) \times \varepsilon_{\text{xc}}^{\text{hom}}(n^+(\mathbf{r}),\ n^-(\mathbf{r})) \quad (9)$$

and

$$V_{\text{xc}}^\sigma \approx \left[\frac{\partial}{\partial n^\pm}(n^+ + n^-)\ \varepsilon_{\text{xc}}^{\text{hom}}(n^+, n^-)\right]_{n^\sigma = n^\sigma(\mathbf{r})} \quad (10)$$

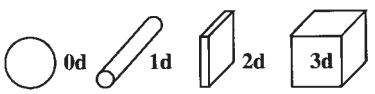

***Figure 1***
Dimension of the systems under consideration. Zero-dimensional clusters, one-dimensional wires, two-dimensional slabs, and three-dimensional bulk systems.

Different approximations of the local density and the local spin density functional (Hedin and Lundqvist 1971, Barth and Hedin 1972, Moruzzi *et al*. 1978, Vosko *et al*. 1980) have been used. They lead to variations within the error of the local density or spin density approximation itself.

## 2. *Stoner Model of Ferromagnetism*

The one-particle nature of the Kohn–Sham equation (Eqn.(7)) allows a Stoner-like model to be derived for ferromagnetism (Vosko and Perdew 1975, Gunnarsson 1976, Janak 1977, Stoner 1938, Blügel 1995). Starting from the assumption that the magnetization density $m(\mathbf{r})$ is a small parameter compared to the density $n(\mathbf{r})$, the exchange and correlation potential $V_{\mathrm{xc}}^{\sigma}$ can be expanded in powers of $m(\mathbf{r})$. The linear approximation yields

$$V_{\mathrm{xc}}^{\pm} = V_{\mathrm{xc}}^{0} \mp m(\mathbf{r})\tilde{V}(n(\mathbf{r})), \quad \tilde{V} > 0 \tag{11}$$

where $V_{\mathrm{xc}}^{\sigma}$ is the exchange-correlation potential for the nonmagnetic case. As a consequence, the majority of electrons experience a more attractive potential as minority electrons. In the Stoner model this potential shift is expressed in terms of a constant

$$V_{\mathrm{xc}}^{\pm} = V_{\mathrm{xc}}^{0} \mp \tfrac{1}{2}IM, \quad M = \int_{V_{\mathrm{atom}}} \mathrm{d}\mathbf{r} m(\mathbf{r}) \tag{12}$$

with the local atomic moment $M$ and the Stoner parameter $I$. In the case of ferromagnetism $M$ is the same for all atoms. As a consequence of the constant potential shift in Eqn. (12), the single particle wave functions $\varphi_k^{\sigma}(\mathbf{r})$ (Eqn. (7)) do not change with respect to the nonmagnetic wavefunctions, while the eigenvalues $E_k$ are shifted rigidly downwards or upwards

$$\varphi_k^{\pm}(\mathbf{r}) = \varphi_k^{0}(\mathbf{r}) \quad \text{and} \quad E_k^{\pm} = E_k \mp \tfrac{1}{2}IM \tag{13}$$

This is the so-called spin–split bandstructure (Fig. 2). The symmetric energy shift is transferred to the spin-dependent density of states

$$n^{\sigma}(E) = n(E \pm \tfrac{1}{2}IM) \tag{14}$$

with respect to the density of states of the nonmagnetic system $n(E)$ (Fig. 2). Integration over all occupied states up to the Fermi energy $E_{\mathrm{F}}$ gives the number of electrons

$$N = \int^{E_F} \mathrm{d}E(n^0(E + \tfrac{1}{2}IM) + n^0(E - \tfrac{1}{2}IM) \tag{15}$$

and the moment per atom

$$M = \int^{E_F} \mathrm{d}E(n^0(E + \tfrac{1}{2}IM) - n^0(E - \tfrac{1}{2}IM)) \tag{16}$$

Since the density of the nonmagnetic system $n^0$ and the number of electrons $N$ are known, the Fermi energy $E_{\mathrm{F}}$ and the moment $M$ can be obtained from the self-consistent solution of Eqns. (15) and (16). As a sufficient condition for a ferromagnetic solution the Stoner criterion

$$In^0(E_{\mathrm{F}}) > 1 \tag{17}$$

can be derived. Large Stoner parameters or exchange integrals $I$ and large density of states at the Fermi energy $n^0(E_{\mathrm{F}})$ favor ferromagnetism. The corresponding parameters deduced from a nonspin-polarized calculation are shown in Table 1 (Gunnarsson 1976, Janak 1977). Obviously, the Stoner criterion is only fulfilled for Fe, Co, and Ni, precisely those metals that show ferromagnetism. Fig. 3 shows the densities of states for Fe, Co, and Ni computed by means of a spin-density functional calculation. The results show the dominating contribution of the 3d electrons. The density of states is exchange split and otherwise very complicated. The spin-up and spin-down densities of states remain, however, very similar which confirms the validity of a Stoner model.

The corresponding spin moments in comparison to experimental results for spin moments and total moments are given in Table 2. The exchange integral $I$ is an interatomic property that depends on the type of

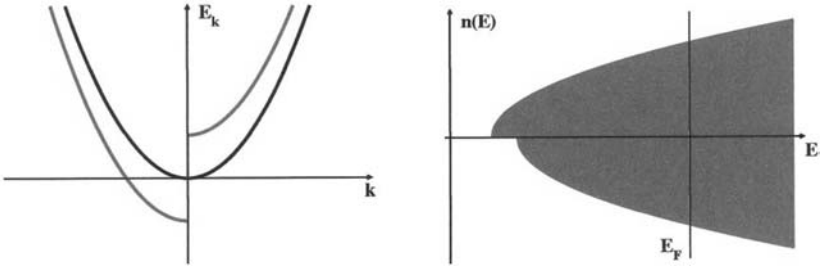

***Figure 2***
Spin–split band structure and density of states for free electrons; majority and minority bands are shifted downwards and upwards, respectively.

***Table 1***
Density of states $n(E_F)$ (in $eV^{-1}$) at the Fermi energy calculated for nonmagnetic systems, Stoner parameter $I$ (in eV), and $In(E_F)$ (Gunnarsson 1976, Janak 1977).

| Metal | Na | Al | Cr | Mn | Fe | Co | Ni | Cu | Pd | Pt |
|---|---|---|---|---|---|---|---|---|---|---|
| $n(E_F)$ | 0.23 | 0.21 | 0.35 | 0.77 | 1.54 | 1.72 | 2.02 | 0.14 | 1.14 | 0.79 |
| $I$ | 1.82 | 1.22 | 0.76 | 0.82 | 0.93 | 0.99 | 1.01 | 0.73 | 0.68 | 0.63 |
| $In(E_F)$ | 0.41 | 0.25 | 0.27 | 0.63 | 1.43 | 1.70 | 2.04 | 0.11 | 0.78 | 0.50 |

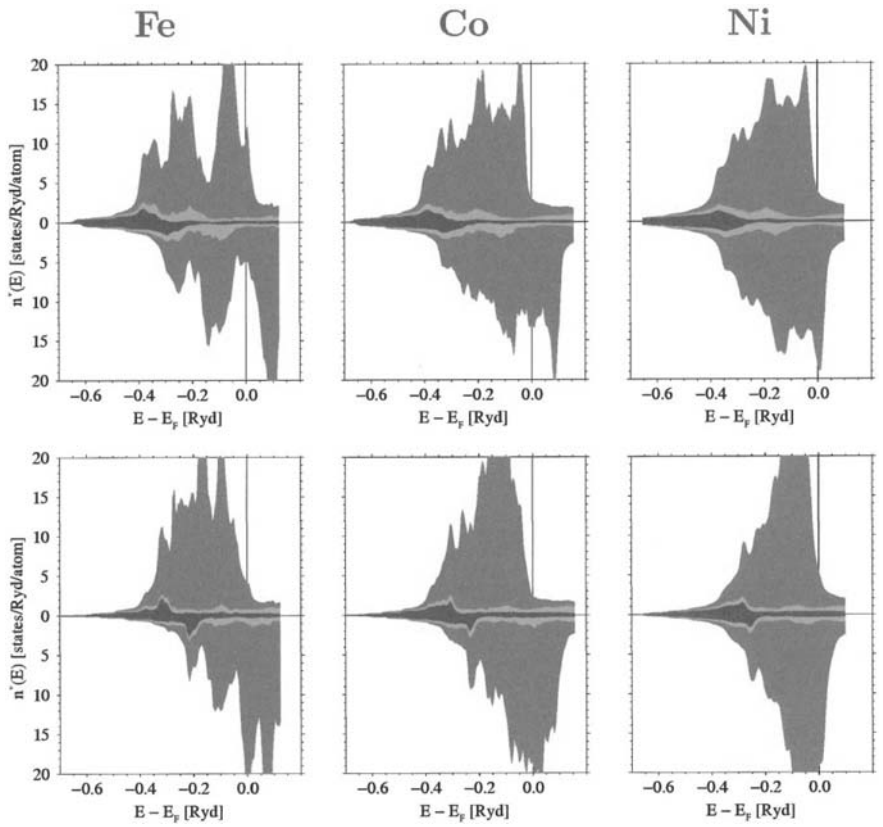

***Figure 3***

***Table 2***
Magnetic moments ($\mu_B$ atom) for Fe, Co, and Ni calculated in the LSDA approximation (Moruzzi *et al.* 1978) in comparison to experimental values for the spin moment and the total moment.

| Metal | $M_{LSDA}$ | $M_{spin}$ | $M$ |
|---|---|---|---|
| Fe | 2.15 | 2.12 | 2.22 |
| Co | 1.56 | 1.57 | 1.71 |
| Ni | 0.59 | 0.55 | 0.61 |

atom but is independent on structure and environment. According to Gunnarsson (1976) and Janak (1977) the exchange integrals of the transition metals have the following trend

$$I_{3d} > I_{4d} > I_{5d} \tag{18}$$

The density of states at the Fermi level is reciprocal with the bandwidth

$$n(E_F) \sim W \tag{19}$$

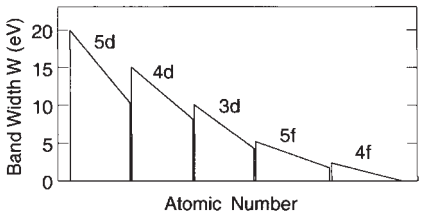

***Figure 4***
Trend in the bandwidth of the transition metal, lanthanides and actinides as a function of the atomic number.

The stronger the electrons are localized, the smaller the bandwidth, the larger is the density of states. The bandwidth is zero in the atomic limit. The Stoner criterion is always fulfilled. The magnetic moment is determined by Hunds rule. If we restrict our further considerations to the tightly bound d electrons of transition metals, the bandwidth can be expressed by means of a tight-binding model

$$W_{\mathrm{d}} = 2\sqrt{N_{nn}}h_{\mathrm{d}}(R_{nn}) \tag{20}$$

According to this approximation the bandwidth depends on the overlap integral or hopping matrix element $h_{\mathrm{d}}$ of the d electrons and the number of nearest neighbor atoms or coordination number $N_{nn}$. The overlap integral $h_{\mathrm{d}}$ is element specific, is determined by the overlap of the d wavefunctinos, and, of course, is reciprocal with the nearest neighbor distance $R_{nn}$. The trend in the transition metals follows the relation

$$\begin{aligned} h_{3\mathrm{d}} < h_{4\mathrm{d}} < h_{5\mathrm{d}} \;&\Rightarrow\; W_{3\mathrm{d}} < W_{4\mathrm{d}} < W_{5\mathrm{d}} \\ &\Rightarrow\; n_{3\mathrm{d}} > n_{4\mathrm{d}} > n_{5\mathrm{d}} \end{aligned} \tag{21}$$

In Fig. 4 the general trend of the bandwidths of transition metals, lanthanides, and actinides is shown (Blügel 1995).

## 3. *Magnetism in Reduced Dimensions*

Understanding magnetism in low-dimensional systems looks rather straightforward. The simplest low-dimensional system is the isolated atom, for which it is known that nearly all transition metal atoms have magnetic moments. The magnetism is well described by Hund's rules. On the other hand, it is known that among the transition metals only five remain magnetic in their bulk crystalline phase: Co and Ni are ferromagnetic, Cr is antiferromagnetic, and Mn and Fe are ferromagnetic or antiferromagnetic depending on their crystal structure. Low-dimensional transition metals, that is interfaces, surfaces, ultrathin films, and monolayers, should behave between these two extremes. As a consequence an enormous number of ab initio calculations have been performed in this field in the 1990s (Blügel 1995, Weinert and Blügel 1993, Asada *et al*. 1999).

Following the considerations above a reduction of the coordination number $N_{nn}$ would cause band narrowing and would enhance the tendency towards magnetism due to the Stoner criterion.

The reduction of the coordination number, however, can be achieved by a reduction in the dimension of the system under consideration. An fcc crystal has a coordination number of $N_{\mathrm{fcc}} = 12$, an atom of the (100) surface of the same crystal is surrounded by eight atoms $N_{(100)} = 8$, and the monolayer atoms have only four nearest neighbors, $N_{\mathrm{ML}} = 4$. Keeping the nearest neighbor distance and the overlap integrals fixed, the density of states and the bandwidths would obey the following relation

$$\begin{aligned} n_{\mathrm{fcc}} : n_{(100)} : n_{\mathrm{ML}} &= \frac{1}{W_{\mathrm{fcc}}} : \frac{1}{W_{(100)}} : \frac{1}{W_{\mathrm{ML}}} \\ &= 1 : 1.22 : 1.73 \end{aligned} \tag{22}$$

The reduction in the coordination number is hence the origin of the enhancement of magnetism at interfaces, surfaces, and for monolayers or ultrathin films. As a consequence these systems offer the opportunity to find totally new magnetic materials.

For the ab initio description of surfaces and ultrathin magnetic films, different geometries are used. In a superlattice the metallic films are separated by vacuum layers but otherwise are periodically repeated in all spatial directions. Surface geometry consists of semi-infinite metal and vacuum parts whereas slab geometry is a freestanding metal film embedded in vacuum layers (Fig. 5).

Figure 3 shows the local densities of states for Fe, Co, and Ni (100) surfaces computed by means of a spin-density functional calculation. The comparison of bulk (upper panel) and surface (lower panel) density of states illustrates the effect of band narrowing clearly. Enhancement of the magnetic moments at the surface in comparison to the bulk material is given in Table 3.

***Figure 5***
Superlattice, semi-infinite surface system, and slab.

***Table 3***
Magnetic moments ($\mu_B$ atom) for Fe, Co, and Ni calculated in LSDA approximation (Blügel 1995) for (100) and (110) surfaces in comparison to bulk moments (Moruzzi *et al.* 1978).

| Metal | $M_{LSDA}$ | $M_{(100)}$ | $M_{(110)}$ |
|---|---|---|---|
| Fe | 2.15 | 2.88 | 2.43 |
| Co | 1.56 | 1.85 | — |
| Ni | 0.59 | 0.68 | 0.74 |

The magnetic moment of the Ni (110) surface is higher than for the (100) surface. The results for Fe are opposite. This behavior is related to the surface orientation, which determines the coordination number and the next nearest neighbor distance between the surface atoms. The largest magnetic moment will be obtained for the most open surface. Ni is an fcc system: the low-index surface (110) is the most open, (100) is intermediate, and (111) is the closed packed surface. The trend for bcc systems is opposite. Fe is a bcc system.

It is implied in the discussion so far that the coordination number is the crucial feature in interface magnetism but this is not the whole truth. The following features have to be taken into account to achieve a quantitative description. First of all, the point symmetry of a surface is lower in comparison to the bulk system. Symmetry reduction causes level splitting, changes the shape of the density of states, and is unfavourable for magnetism. Second, the relaxation of the charge density at the surface changes hybridization at the surface and causes a redistribution of spectral density. As a consequence, a relative shift of the sp band against the d band and/or a change of spectral weight is obtained (see Fig. 3). The number of d states is changed. As a result magnetism can be enhanced or reduced (see Ni). The neglect of these interplaying effects have caused confusion in the past in the field of surface and interface magnetism. But they are readily included in self-consistent electronic structure calculations.

## 4. Ground State Magnetic Order

Based on the calculation of the total energy (Eqn. (10)), ab initio electronic structure calculations provide a perfect tool for investigating the magnetic order. Comparison of the total energy for different magnetic configurations $\Delta E$ allows a systematic search of the magnetic order in the ground state.

As an example, the magnetic order of 3d transition metal monolayers on top of a Cu substrate was investigated (Blügel 1995). The total energy of a ferromagnetic configuration $E^F$ is compared to the total energy of an antiferromagnetic configuration $E^{AF}$ (Fig. 6). The energy differences

$$\Delta E = E^{AF} - E^{F} \tag{23}$$

are shown in Fig. 7. Fe, Co, and Ni layers prefer ferromagnetic, whereas V, Cr, and Mn prefer an antiferromagnetic order.

This is an arbitrary example chosen to demonstrate the method. Similar calculations can be applied to various other problems concerning the magnetic configuration, for example surface steps and edges or

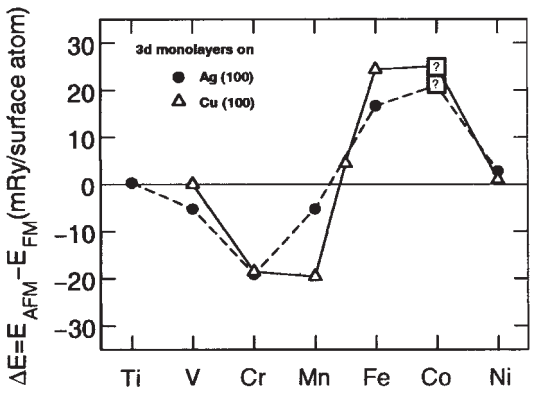

***Figure 7***
Total energy difference per atom for a ferromagnetic and antiferromagnetic phase for 3d monolayers on a △, Cu (100) and ●, Ag (100) substrate.

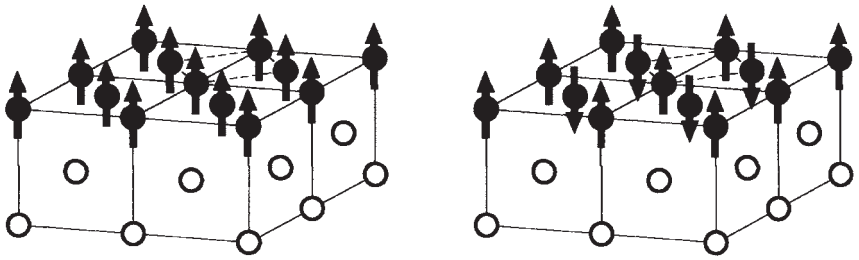

***Figure 6***
Schematic representation of ferromagnetic and c $(2 \times 2)$ antiferromagnetic order of a monolayer film grown as an overlayer on a fcc (001) substrate.

surface alloys (Freyss *et al*. 1996) also including non-collinear magnetic order (Sandratskii 1998)

The capability of this method was nicely confirmed by experimental observation of the local magnetic order in surface alloys by means of spin-polarized scanning tunneling spectroscopy (Heinze *et al*. 2000).

## Thin Film Magnetism: PEEM Studies

A Photoemission Electron Microscope (PEEM) images photo and/or secondary electrons, which are generated at the surface of a solid sample by the absorption of x-ray or ultraviolet (UV) radiation. Depending on the wavelength of the radiation different contrast mechanisms are present, providing information on the elemental and chemical composition, and the electronic and magnetic properties of the material. Magnetic domain imaging is a major application of the PEEM technique, exploiting strong x-ray magnetic dichroism effects, e.g., at the L edges of the magnetic 3*d* transition metals (e.g., Cr, Mn, Fe, Co, Ni). For a comparison with other domain imaging techniques see *Kerr Microscopy*, *Magnetic Materials: Transmission Electron Microscopy*, *Magnetic Force Microscopy*, and references therein.

The PEEM technique stands out against other magnetic imaging techniques through its surface sensitivity and element specificity, making PEEM an ideal tool for the investigation of ultra-thin magnetic films, multi-layers, and alloys. In contrast to other high resolution, magnetic imaging techniques, PEEM is also sensitive to antiferromagnetic order. The spatial resolution of PEEM for magnetic domain imaging is typically about 50–100 nm, which positions PEEM between Transmission Electron Microscopy and optical techniques, such as Kerr Microscopy.

### *1. Photoemission Electron Microscopy*

PEEM was first used in the 1930s and has since then matured into an established surface science technique (Stöhr *et al*. 1993, Tonner *et al*. 1995, Stöhr *et al*. 1998, Anders *et al*. 1999). PEEM is closely related to the Low Energy Electron Microscope (LEEM) and the Spin-polarized Low-energy Electron Microscope (SPLEEM), which were pioneered by Bauer (1994) and Duden and Bauer (1998). All three techniques utilize low-energy electrons to form an image representing physical properties of the sample surface. LEEM and SPLEEM image diffracted low-energy electrons and thereby provide information on the local crystallographic (LEEM) and magnetic (SPLEEM) structure of the surface of a crystalline sample. PEEM, in contrast, images electrons generated by photoionization and therefore is not limited to the study of crystalline samples (see also *Photoemission: Spin-polarized and Angle-resolved*). As light sources, UV gas discharge lamps, UV lasers, and synchrotron radiation sources have been used. Synchrotron radiation offers the important advantage of tunability of the wavelength of the illumination, thereby allowing a selection between various mechanisms of contrast. X-ray PEEM thus combines aspects of spectroscopic and microscopic methods and is called a spectromicroscopy technique.

A typical PEEM setup using synchrotron radiation from a bending magnet is shown in Fig. 1 (Anders *et al*. 1999, Scholl *et al*. 2002). X rays pass through a moveable aperture, which selects the polarization of the radiation. A spherical grating monochromator and an exit slit monochromatize and focus the beam onto the sample. A schematic kinetic energy spectrum of the emitted electrons after x-ray absorption is shown in Fig. 2(a). Photoemission lines appear at high kinetic energy, followed by a broad tail of secondary electrons which peak at low energies close to the work function cut-off. PEEM microscopes usually accept the total electron yield without prior

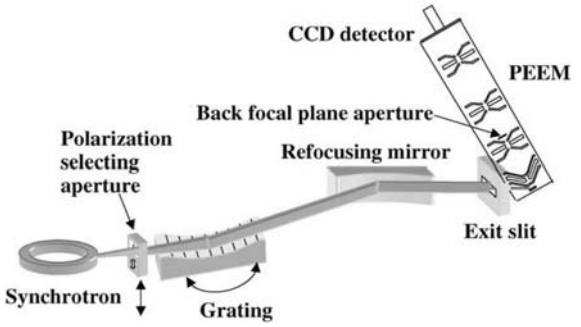

***Figure 1***
PEEM-2 Photoemission Electron Microscope and x-ray beamline at the Advanced Light Source, USA. X rays are monochromatized by a spherical grating and focused into a $30 \times 30\ \mu m^2$ spot on the sample. The electron microscope column produces a magnified image of the local x-ray absorption on a phosphor, which is imaged by a slow-scan CCD camera.

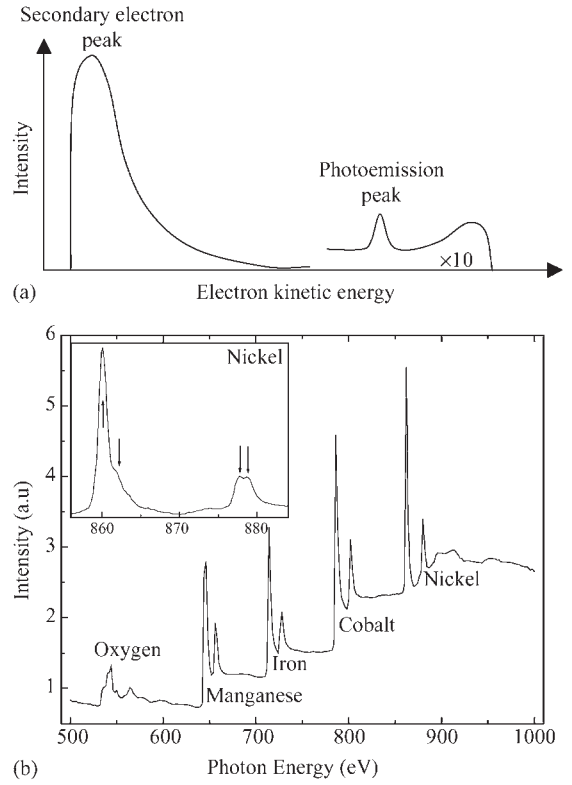

***Figure 2***
(a) Energy spectrum of emitted electrons after the absorption of x-rays. (b) X-ray absorption spectrum measured in total electron yield of a Co/FeMn/NiO sample. The absorption fine structure at the Ni $L_2$ peak (inset) results from the presence of nickel oxide.

energy discrimination. The sampling depth of PEEM correlates with the mean free path of low energy electrons in the studied material and lies typically between 2 nm and 5 nm for metals.

The emitted electrons are accelerated in the strong electric field between the sample and the first microscope lens ($\sim 10^4$ V mm$^{-1}$), and are then imaged with magnification by electron optics, consisting of typically 2–4 electrostatic or magnetic lenses. A back focal plane aperture limits the angular spread of the transmitted electrons and also acts as a simple energy filter, reducing the chromatic and spherical aberrations of the microscope. Projector lenses magnify and focus the image onto the electron detector, typically an electron sensitive phosphor and/or a channelplate detector, producing a visible image. Deflector and stigmator elements in the microscope steer the electron beam and correct for eventual mechanical misalignments. Using synchrotron radiation microscopes, has achieved a spatial resolution close to 20 nm (Anders *et al*. 1999).

## 2. *Contrast Mechanisms*

Contrast in PEEM results from local variations in the light absorption, the work function, and the topography of the sample. Topographic structures such as edges, bulges, and holes locally distort the electric field close to the sample and modulate the image intensity. Work function contrast arises from inhomogeneities in the surface composition and thereby the work function. This contrast mechanism is particularly strong using UV radiation close to the work function cut-off.

Chemical, magnetic, and elemental contrast arises from Near Edge X-ray Absorption Fine Structure (NEXAFS), which is discussed in more detail in *Surface Chemistry: Electron Yield Spectroscopy* (Ormerod 2001). As an example, an x-ray absorption spectrum of a Co/FeMn/NiO multi-layer is shown in Fig. 2(b). Different elements in a material can be identified by their characteristic core hole binding energies and absorption edges. The fine structure close to the absorption edge—the inset shows the Ni $L_{2,3}$ edge—can be further analyzed, providing information about the chemical and magnetic state of the material. For example, the multiplet structure at the L edges, marked by arrows in Fig. 2(b), is characteristic for nickel oxide (Regan *et al*. 2001).

PEEM microscopes are typically used in three modes of operation: (i) full-field imaging, (ii) local spectroscopy, and (iii) spectromicroscopy. In the full-field imaging mode images are acquired at fixed photon energy. In the local spectroscopy mode local x-ray absorption spectra are acquired in predefined regions by scanning the photon energy and using the spatial resolution provided by the PEEM electron optics. In the spectromicroscopy mode, stacks of

PEEM images are acquired as a function of photon energy, generating a three-dimensional dataset with two lateral and one energy dimension.

### 3. *X-ray Magnetic Linear and Circular Dichroism*

X-ray Magnetic Circular Dichroism (XMCD) and X-ray Magnetic Linear Dichroism (XMLD) are established spectroscopic x-ray techniques, which are widely used for the investigation of ferromagnetic and antiferromagnetic surfaces and thin films (Thole *et al*. 1985, Schütz *et al*. 1987, Alders *et al*. 1998, see also *Magnetism: Applications of Synchrotron Radiation*). Both methods probe the modification of the electronic structure of a material in the presence of magnetic order, resulting in an intensity variation of the near edge x-ray absorption fine structure. X-ray magnetic dichroism has been extensively used at $2p$ to $3d$ transitions ($L_{2,3}$ edge) in $3d$ transition metals, exploiting the strong spin–orbit interaction of $2p$ core levels and the strong exchange splitting of $3d$ valence levels (Schütz *et al*. 1987). More recently XMLD has been applied in studies of collinear antiferromagnets (e.g., Alders *et al*. 1998). In order to illustrate the appearance of both dichroism effects, x-ray absorption spectra are shown in Fig. 3, measured in single microscopic magnetic domains on a $Co/LaFeO_3$ bilayer.

The sample was grown by molecular beam epitaxy (MBE) on a $SrTiO_3(001)$ substrate (Scholl *et al*. 2000). The relative in-plane orientation of the photon polarization and the sample magnetization are shown on the right. The size of the XMCD effect in ferromagnetic Co, which appears as a variation of the $L_3$ and $L_2$ resonance intensities, depending on the relative orientation of the sample magnetization **M** and the circular x-ray polarization direction **P**, is a measure for the element specific, atomic, spin, and orbital moment and the angle enclosed by the magnetization and the polarization vector: $\Delta I \sim |\mathbf{M}| \cos \angle (\mathbf{M}, \mathbf{P})$ (Fig. 3(a)). Alternatively, XMLD is particularly useful for the investigation of collinear antiferromagnetism because it probes an anisotropic electronic structure. Ideal antiferromagnets do not show XMCD because they are magnetically compensated. The absorption spectrum of the antiferromagnetically ordered Fe atoms in $LaFeO_3$ shows a change in the relative intensity of the $L_3$ and $L_2$ multiplet peaks due to XMLD, depending on the relative orientation of the $LaFeO_3$ magnetic axis and the linear x-ray polarization (Fig. 3(b)). The size of the effect is again a measure for the element specific, atomic, magnetic moment **M,** and the angle enclosed by the spin axis **A** and the linear polarization vector **E**: $\Delta I \sim \left|\mathbf{M}^2\right| [1 - 2\cos^2 \angle (\mathbf{A}, \mathbf{E})]$.

XMCD was first applied to ferromagnetic domain imaging in a pioneering work in 1993 (Stöhr *et al*. 1993). More recently, microscopic antiferromagnetic

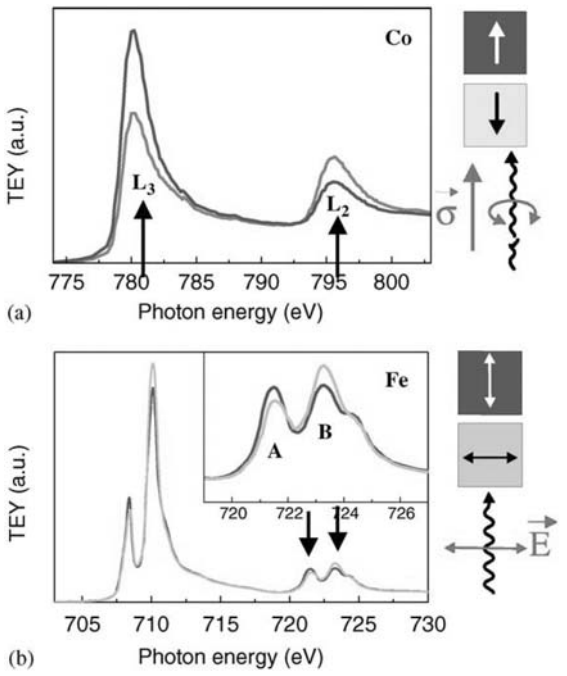

***Figure 3***
(a) X-ray Magnetic Circular Dichroism (XMCD) and (b) Linear Dichroism (XMLD) spectra of 1.2 nm Co/40 nm $LaFeO_3/SrTiO_3(001)$. The $LaFeO_3$ spectrum was acquired at the Fe edge. The spectra show opposite dichroism effects (a) at the $L_3$ and $L_2$ resonance in the ferromagnet Co (XMCD) and (b) at the $L_2$ multiplet peaks A and B in the antiferromagnet $LaFeO_3$ (XMLD).

domains have been imaged for the first time using XMLD (Scholl *et al*. 2000, Nolting *et al*. 2000). For the study of ferromagnetic domains in transition metal ferromagnets, e.g., Co, images are acquired with the photon energy tuned to the peak of the $L_3$ and $L_2$ resonances. The ratio image acquired with circular polarization is the XMCD image (Fig. 4(a)). Alternatively, images acquired with opposite polarization can be divided. Dividing PEEM images acquired with linear polarization at the magnetically sensitive peaks A and B at the $L_2$ edge of the antiferromagnet $LaFeO_3$ generates the XMLD image, representing the antiferromagnetic domain structure of a material (Fig. 4(b)).

Different colors in the XMCD and XMLD image correspond to different directions of the magnetic moment. In Co (top) we distinguish three classes of domains, which have magnetizations pointing up (shown here as the darkest shade), down (lightest shade), and left or right (medium shade, not distinguished in this measurement geometry). The XMLD image of $LaFeO_3$ shows two classes of domains with the in-plane projection of the atomic magnetic

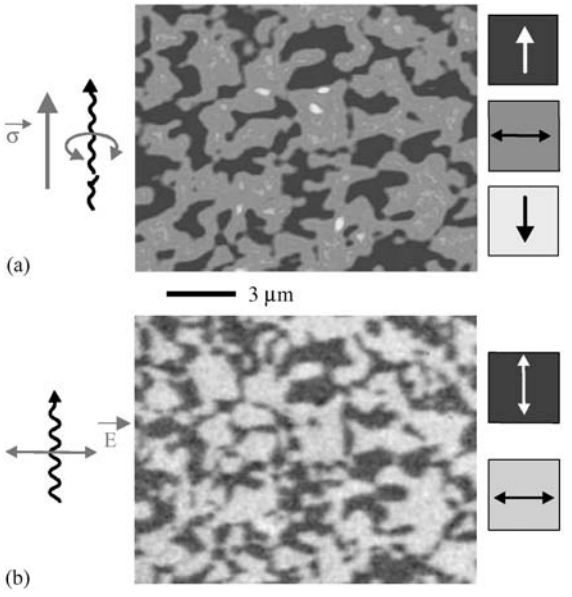

***Figure 4***
X-ray magnetic dichroism images of (a) the ferromagnetic domain structure in Co and (b) the antiferromagnetic domain structure in $LaFeO_3$ in a $Co/LaFeO_3/SrTiO_3(001)$ multilayer sample. Different shades refer to different domain orientations as indicated in the boxes. The images demonstrate a parallel orientation of the in-plane component of the Fe and Co moment due to interfacial exchange coupling.

moments pointing up down (darker shade) and left-right (lighter shade). Note that the shown images were acquired at identical sample positions, making use of the element specificity of x-ray PEEM. The correspondence between the two domain structures indicates a uniaxial interface exchange coupling of sufficient strength, aligning the magnetization in the ferromagnet with the in-plane component of the magnetic axis in the antiferromagnet.

## 4. *Imaging of Local Exchange Bias*

One important application of domain imaging using the PEEM technique is the study of exchange biased thin film systems. Exchange bias at a ferromagnet/antiferromagnet interface leads to a unidirectional anisotropy of the ferromagnetic layer, pinning its magnetization into a preferred direction (Meiklejohn and Bean 1956); see also *Magnetic Films: Anisotropy*. This pinning is employed in magneto-electronic devices for stabilization of the magnetization in a magnetic reference layer. The major application of this effect is in magnetic hard disk heads containing a read element based on the giant magnetoresistance phenomenon (see *Giant Magnetoresistance* and *Magnetic Recording Technologies: Overview*). The unique combination of elemental specificity, surface sensitivity, and ferro- and antiferromagnetic contrast of PEEM allows studying the magnetic structure directly at the interface between two coupled layers, providing crucial insight into the microscopic coupling mechanism (Ohldag *et al.* 2001). The unidirectional pinning of the magnetization in a ferromagnet in contact with an antiferromagnet can be made visible by PEEM as shown in Fig. 5.

XMCD images of a ferromagnetic Co layer on $LaFeO_3$ were acquired in remanence as function of the applied magnetic field. Figure 5 shows a subset of a field series, containing about 30 images. The strong uniaxial interface coupling to the AFM prevents a permanent rotation of the horizontally oriented magnetic domains (gray), which have a magnetization oriented perpendicular to the field direction. Vertically

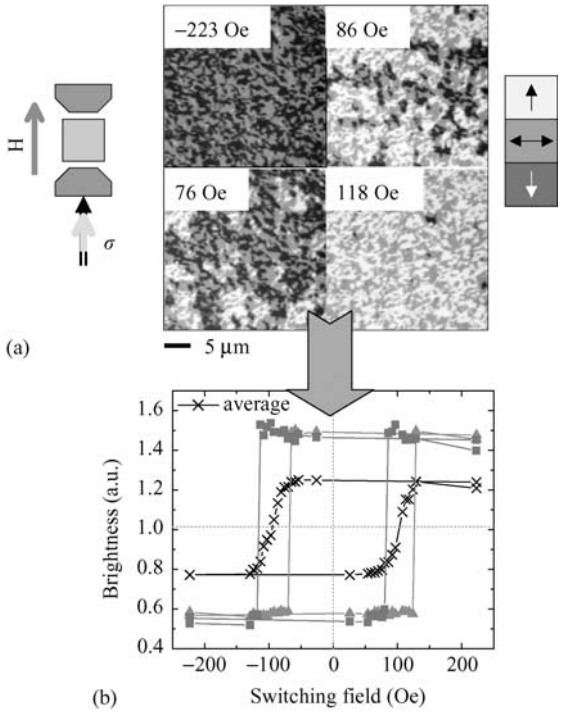

***Figure 5***
(a) Magnetization reversal of Co layer pinned by $LaFeO_3$ underlayer. The images were acquired in remanence after applying magnetic field pulses of increasing strength. The correspondence of magnetization direction to domain brightness is illustrated on the right. (b) Local hysteresis loops were calculated in single domains, showing exchange bias of opposite sign (triangles/squares). The average loop (crosses) was acquired by averaging the XMCD intensity over the whole PEEM field of view.

oriented domains, which have an easy axis along the magnetic field, switch from black to white at about 100 Oe, indicating the reversal of the magnetization parallel to the applied field. Remanent hysteresis loops of two individual domains are shown at the bottom of Fig. 5. The two representative loops show a relative shift of the plus/minus and minus/plus switching fields of about 50 Oe. This corresponds to a positive (negative) exchange bias field in the triangles (squares) domain of $+25$ ($-25$) Oe. Averaging over a large number of domains yields the average loop (black).

### 5. *Conclusion*

In comparison to other domain imaging techniques x-ray PEEM stands out by its ability to separately study the chemical, electronic, and magnetic properties of different materials in a layered or alloyed material. The moderate surface sensitivity of the technique permits the investigation of ultrathin multilayers but at the same time PEEM is sufficiently sensitive to detect sub-monolayer amounts of magnetic moments. The spatial resolution of PEEM can be further improved by aberration correction. Implementation of correction techniques promises an improvement of the spatial resolution close to the physical limit of 1–2 nm. Another future application of PEEM is the investigation of dynamical magnetic processes, such as spin precession and magnetization reversal, utilizing the pulsed structure of synchrotron sources.

## Thin Films, Multilayers and Devices, Superconducting

Thin films are an essential part of all electronic technologies. This is particularly true for superconducting instrumentation, sensors and electronics, in which the active devices themselves are made from deposited films, often a sequence of films made as a multilayer structure. This is in contrast to some semiconductor technologies, in which devices are often created by doping of bulk single crystals, say silicon or GaAs, and are then linked together with interconnects and to passive components (capacitors, resistors) that are made from deposited films. In the most highly developed superconducting technology, namely Josephson junction circuits operating at 4.2 K, the entire circuit of junctions, resistors, capacitors, insulators and interconnects is made from films that are deposited at room temperature (a significant difference from semiconductor processing, which is carried out at high temperatures). Thus, the control of thin-film processes

is especially critical to the success of superconducting electronics technologies. The important film synthesis methods, the properties of superconducting films and the devices made from them are the subjects of this article, which therefore forms a link between articles that are concerned predominantly with different materials or physical phenomena and articles that deal with low-current applications.

The very significant differences between low-temperature superconducting (LTS) materials and high-temperature superconducting (HTS) materials have already resulted in some divergence in the approaches being used to make, understand and use LTS and HTS films. In each section of this article LTS films will be described first, then the differences in the HTS cases will be identified. It is important to note that LTS film studies and technology date from the late 1950s and are, hence, well established, whereas HTS films are very recent and the field is subject to rapid change.

## 1. Thin Films

### 1.1 Thin-film Synthesis

The various deposition methods that are available to make thin films of all kinds can be readily used for superconductors. These methods are thermal and electron-beam evaporation and sputtering. Many elemental superconductors that have been used for both science and applications studies (e.g., lead, tin, indium, aluminum, zinc) can be made as films by the simplest methods, which is thermal evaporation in a moderate vacuum ($10^{-4}$ Pa or $10^{-6}$ torr) onto a substrate at room temperature. The nature of the substrate is not critical, glass is quite adequate. Alloys of these elements can be made by evaporation from two sources or sometimes (e.g., PbBi) from a single source.

Films of greater technological interest (e.g., niobium, tantalum and their alloys with other transition metals) are not easy to evaporate thermally, but electron-beam evaporation and sputtering are straightforward for such materials. Magnetron sputtering sources have become the method of choice for the niobium films used in Josephson circuits. Alloys can be made from a sputtering target of the appropriate composition. The superconducting properties of transition metals are more sensitive to impurities, such as oxygen, than the *s–p* metals and a better vacuum system must be used, say $\leqslant 10^{-6}$ Pa ($10^{-8}$ torr). The transition metals make excellent getters, so placing a liquid-nitrogen-cooled surface near the substrate very effectively lowers the system pressure. The substrate temperature can be 300 K for niobium film deposition, but the resistance ratio of clean films made at this temperature will be limited by the grain size. Higher substrate temperatures are needed for some transition metals (e.g., tantalum) and to increase the grain size of niobium. In particular, high-quality epitaxial films with long electronic mean free paths, such as those used in SIS particle detectors, and epitaxial superlattices with mean free paths extending over many layers (see later) are grown at temperatures as high as 800 °C.

To form films of compounds based on niobium which have higher critical temperatures, such as NbN, NbCN and the family of A15 compounds $Nb_3Sn$, $Nb_3Ge$, $Nbj_3Al$ (see *Superconducting Materials; Types of* ) somewhat more complicated methods are used. The nitrides and carbonitrides, which are important materials for Josephson circuits operating at 8–10 K, are made by sputtering niobium targets in argon plus nitrogen or nitrogen plus methane onto substrates at 100–1000 °C (Braginski and Talvacchio 1990). The A15 compounds have generally been made by coevaporation from electron-beam sources, say niobium and tin, but cosputtering from multiple targets or sputtering from a single mixed target can also be used. The geometry of the evaporation sources (see Fig. 1) creates a spread of compositions across an array of substrates (Hammond 1975). This allows measurements to explore the effects of stoichiometry on the physical properties of the films. To form the crystalline structure of the compound, a heated substrate has to be used. Typical optimum temperatures are 880 °C for $Nb_3Sn$, 900 °C for $Nb_3Ge$. These high deposition temperatures have limited the interest in A15 compounds for electronics applications, although values over 700 °C are now accepted as necessary for HTS films.

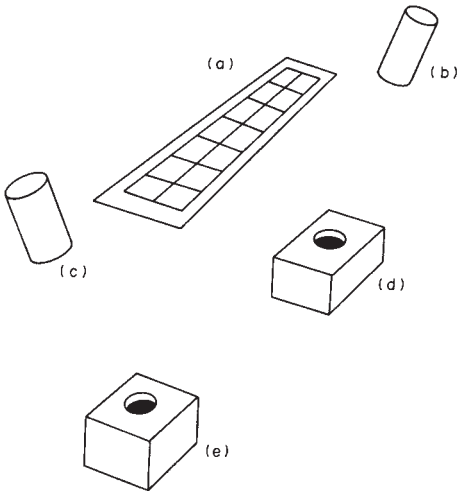

***Figure 1***
Arrangement of sources and substrates to achieve a spread of compositions: (a) array of substrates heated to 800 °C; (b) niobium deposition-rate monitor; (c) tin deposition-rate monitor; (d) niobium electron-beam source; and (e) tin electron-beam source.

To prepare films of the HTS materials, many of the techniques described in this section are being used (see *High-temperature Superconductors: Thin Films and Multilayers*). The presence of three elements plus oxygen in the HTS materials leads to increased complexity of the deposition systems, particularly those for cosputtering, sequential sputtering (a fraction of a monolayer of each material is deposited sequentially and repeated many times), coevaporation (MBE) and sequential evaporation. Two comparatively simple methods have quickly become popular and reproducibly yield very-high-quality films. These are off-axis sputtering (Eom *et al*. 1989) and laser ablation (Inam *et al*. 1988). As in the case of A15 compounds, HTS films are deposited at high temperatures (600–750 °C) with the best films being made at $\geqslant 700$ °C. Unlike the transition metals, HTS films are deposited in high oxygen pressures (sometimes 250 Pa) and, hence, the base pressure of the vacuum system is less relevant. One film process that is widespread for semiconductors, chemical vapor deposition (Li *et al*. 1991), is being tried for HTSs with some success. It has the potential to be a commercial process for films of large area. At present typical film substrate sizes are 4 in or 5 in diameter wafers for niobium circuits, with plans in one laboratory to move to 8 in and 2 in diameter for HTS devices.

A very significant difference between LTS and HTS films is in the choice of substrates. Epitaxy between the substrate and film is essential for HTS materials, hence, a very much more limited choice of substrates is available. Because of the high deposition temperatures, substrates for both HTS and A15 films must not react chemically with the film at temperatures up to around 800 °C. For most LTS films this is not a consideration, but for those applications requiring epitaxial films with long electronic mean free paths, the substrate again must be chosen to have a good lattice match and to be nonreactive.

### *1.2 Film characterization*

Given the possibility that impurities introduced into films during deposition will change their properties from those exhibited by bulk samples of the same material, characterization is an important part of thin-film research. Important measurements include: the resistivity of the film at 300 K, which will be increased by impurities and disorder; the resistivity ratio between 300 K and (say) 10 K, which is strongly reduced by impurities and electron scattering from the film surfaces; the transition temperature $T_c$, which is generally decreased by impurities but can sometimes be increased by disorder; the critical current density $J_c$, which can be most easily measured by making a constriction in the film; the stoichiometry, which can be determined by Rutherford backscattering, inductively coupled plasma spectroscopy or energy/wavelength dispersive x-ray analysis; and the crystalline perfection, which is studied by x-ray scattering or channelling techniques.

Of these characterization techniques, one of the simplest and most informative is the measurement of resistivity and resistivity ratio $(\rho_{300K}/\rho_{10K})$. For example, $\rho_{300K} \simeq 15\ \mu\Omega\,\text{cm}$ for niobium implies an electronic mean free path of 3 nm. As phonon scattering is reduced with decreasing temperature, scattering from grain boundaries and lattice defects (or the film surface) becomes dominant, for films deposited in a poor vacuum system scattering by included impurities becomes important. Thus, a resistivity ratio of 7 implies a mean free path at 10 K of 21 nm, whereas 50 implies 150 nm. The ratios of 7 and 50 are typical of niobium films made on room-temperature and heated substrates. If the film thicknesses are larger than the mean free path, the resistivity ratio is an immediate indicator of film quality. In some epitaxial niobium films, resistivity ratios as large as 300–400 in 2 μm thick films have been reported. For many materials (e.g., silver, niobium, molybdenum, tin, gallium) precision deposition techniques enable films to be deposited with mean free paths that are so long at low temperatures that the resistance ratio is generally limited by surface scattering, unless the films become very thick.

These measurements are commonly used for both LTS and HTS superconducting films. In the HTS case, an important additional parameter of interest is the surface impedance $R_s$ at frequencies in the range from 1 GHz to 100 GHz. The importance of microwave applications of HTS films has created the need to measure $R_s$ from 4.2 K to at least 77 K (see *Superconducting Microwave Applications: Filters*). As $R_s$ for good HTS films is at least an order of magnitude below that of copper, a copper cavity cannot be used for the measurements at 77 K. A niobium cavity can be used at 4.2 K. No standard measurement method exists, but a technique which determines the Q of a resonator made of two HTS films facing each other is becoming popular (Taber 1990).

### *1.3 Physical Properties of Films*

Many of the properties of superconducting films are discussed in other articles, in that they are identical to those of the bulk material. However, thin films are often used in preference to single crystals or polycrystalline samples, for three reasons. First, they allow certain experiments to be carried out more easily. Examples are high-frequency properties, where a film can be prepared with a smooth clean surface more easily than the bulk; nonequilibrium properties, where the sample volume can be made small; Josephson effects in weak links (see *Electrodynamics of Superconductors: Weakly Coupled*), which are most easily defined in films; tunnelling spectroscopy for

which tunnel junctions are prepared by oxidizing clean film surfaces; and proximity effect studies, in that films can easily be made with thickness comparable to a coherence length (at least in LTS materials).

The second reason for using films for scientific studies is that they can be made to exhibit properties that are different from those of the same bulk material. These differences can arise because of dimensional effects, as films can be grown very thin in the dimension normal to the substrate and can be patterned to be small in the plane. When the thickness of the film is less than the coherence length, it becomes two dimensional, in that its properties cannot vary in the direction normal to its surfaces. These dimensional (including dimensional crossover effects) effects will be discussed in Sect. 2.

Another difference between film and bulk materials can be created because the structure and electronic properties of the film are changed by the deposition process. This is generally a result of crystalline disorder (see *Superconducting Materials: Irradiation Effects*). If the film is deposited on a substrate that is too cold to allow ordering to occur, a very-small-grained or even amorphous film can result (see *Amorphous Superconductors*). An early example was the nonsuperconducting semimetal bismuth, which became superconducting up to 6 K when deposited on a substrate held at 4.2 K. The $T_c$ of gallium is similarly raised from 1.1 K to 8.5 K by such "quench condensation." Such films were the first amorphous metals (Brandt and Ginzburg 1960, Buckel Gey 1963). Aluminum films can have a $T_c$ up to 6 K compared to the bulk 1.2 K, the $T_c$ depending largely on the conditions of deposition and the strain induced by the substrate. Such changes in $T_c$ are due to modification of both the phonon spectrum and the density of electronic states of the material. In crystalline transition metals, with their well known dependence of $T_c$ on electron-to-atom ratio (see *Superconducting Materials: Types of*), a remarkably different dependence is observed when films are deposited at low temperatures to make them amorphous. Such quench-condensed films have high resistivities and small resistance ratios (close to 1).

A third reason for using films is for superconducting applications in devices and electronics, as described later in this article and in other more specific contributions on particular application areas.

The same reasons for interest in the physical properties of LTS films apply to HTS materials. However, the radically different properties of the HTS oxides do create some different results. For example, the oxides have anisotropic and very short coherence lengths. Most HTS films are grown with the *c*-axis normal to the substrate, with the copper oxide sheets in the plane of the substrate. The *c*-axis coherence length is only a few tenths of nanometers. Thus, the surfaces of HTS films, unlike their LTS counterparts, are most unlikely to have properties representative of the bulk material (even those properties along the *c* axis). This is because any change in stoichiometry, for example loss of oxygen, or disorder, including that due to surface reconstruction of the lattice, can affect a surface layer whose thickness is comparable to, or greater than, a coherence length. Thus, any experiments that are surface sensitive, such as tunnelling, proximity effects and photoemission studies, are unlikely to measure bulk properties of HTS materials in measurents on *c*-axis films. Recently, films with other orientations have been deposited (see *High-temperature Superconductors: Thin Films and Multilayers*); measurements on these films are likely to reveal more of the bulk properties of HTS materials. In LTS materials the coherence length is generally much longer than the thickness of any surface layer, although niobium and A15 films can exhibit problems of surface degradation unless care is taken.

Effects of dimensionality are also different in HTS materials, in that even in the bulk they are strongly anisotropic and can be considered pseudo two dimensional. It is also not possible to produce films thinner than the coherence length along the *c* axis. The coherence length is only 4 nm in the *a–b* plane of YBCO, so even *a*-axis films are difficult to make thin compared to this length. The effect on physical properties of making the films thin is most easily studied in superlattices (see Sect. 2) but remarkably thin HTS films have been made that remain superconducting to quite high temperatures.

The properties of both films and bulk HTS materials can differ significantly from optimum values, particularly due to loss of oxygen, to crystalline disorder and to doping effects. The trend of these effects is to decrease $T_c$ and increase resistivity until the material becomes insulating at low temperatures (Greene and Bagley 1990).

There is one parameter that is very different in films compared to bulk single crystals, especially in the case of YBCO. This is the value of critical current $J_c$. All good HTS films with $T_c$ close to 90 K, independent of their method of preparation, have $J_c$ values at all temperatures $< T_c$ much higher than those for single crystals. It appears that a pinning center is rather readily produced in thin films that is difficult to reproduce in crystals and that this defect is common to all "high quality" YBCO films to date.

## 2. *Superlattices*

As an object of scientific study, multilayers or superlattices are an interesting class of "engineered" materials in the fields of semiconductors, magnetism (see *Thin Film Magnetism: PEEM Studies*), optics, x-ray optics and superconductivity (Shinjo and Takeda 1987). They are made by sequentially depositing two or more materials many times (e.g., ABABAB…).

The individual film thicknesses of A and B approach one atomic layer in some cases. This repetition of the film sequence distinguishes them from the multilayer device structures to be discussed later.

In semiconductors the long electron wavelength ($\sim$10 nm) implies that the bulk electronic band structure can be radically changed in the direction normal to the layers of a superlattice, once the individual layers have thickness comparable to this wavelength. This regime is relatively straightforward to reach with current growth capabilities such as MBE. Thus, semiconductor superlattices have become a field of intense activity, for both their research interest and device potential. In metals, the short electron wavelength (a few tenths of nanometers) implies that such band structure changes cannot be observed. When metals become superconducting, however, the electron wavelength is replaced by the coherence length as the important length parameter. In LTS materials, it is easy to make superlattices with layer thickness much less than coherence lengths (typically tens of nanometers). Hence, there is scientific interest in superconducting superlattices, in which the components A and B can be superconductor (A) with another superconductor, metal, semiconductor or insulator (B).

It is important to note that in HTS superlattices, at least those with *c* axis normal to the substrate, it is again not possible to make the layer thickness thinner than the coherence length, which is only a few tenths of nanometers. If the HTS materials were strictly two dimensional, layering them into a superlattice should have no effect on $T_c$ unless structural effects occurred (see later).

Unlike semiconductor superlattices, at present there are no important devices made from superconducting superlattices (in contrast to multilayer device structures), although the Nb/Al–Al oxide–Nb trilayer process that is now the metallization of choice for Josephson circuits was a direct result of studies of tunnelling in niobium–aluminum superlattices (Geerk *et al.* 1982).

### 2.1 Superlattice Synthesis

The vacuum equipment that is commercially available makes it relatively easy to prepare superconducting superlattices. A substrate is exposed to alternating sources of materials, for example by moving shutters in front of electron-beam sources, or by rotating or oscillating the substrate in front of two sputtering sources. Magnetron sputtering sources are particularly suitable because of the stability of their deposition rate. It is often important to heat the substrate, as the resulting films (e.g., niobium, tantalum) will then have larger grain size, longer electron mean free path and longer coherence lengths. Superlattices of HTS materials have been made by the same methods. Obviously a heated substrate ($\sim$700 °C) is always necessary. In addition, laser deposition lends itself ideally to the synthesis of HTS superlattices. Two targets are moved alternately into the focus of the laser beam and the layer thickness is controlled by the number of laser shots allowed to impinge on each target (Lowndes *et al.* 1990).

### 2.2 Superlattice Characterization

As a superlattice has an additional periodicity of the structure in the growth direction, which is superimposed on the crystal lattice spacing, an important measurement is the standard $\theta$–$2\theta$ x-ray scan. An example is shown in Fig. 2, where the subsidiary maxima are due to x-ray reflections from the superlattice (Somekh *et al.* 1989). The position of these maxima can be used to determine the superlattice wavelength (the sum of the A and B layer thicknesses) and their intensities are related to the interfacial roughness between layers.

Another important measurement is simply the net resistivity of the superlattice (in the case of two metals). If the electron mean free path is long, that is, the electrons move freely through the interfaces between A and B, then the resistivity will have a value between the values of A and B in their bulk form. However, if the electrons are scattered at the interfaces, or if the films themselves become structurally disordered due to the layering process or to strain, then the resistivity will be higher than the values of A or B. Even in superlattices of superconductors with other materials (insulators, semiconductors), or in HTS superlattices, the resistivity and resistance ratio are very important parameters to measure.

Transmission electron microscopy can yield elegant pictures of superlattices and can be used to give the orientation of the individual layers or grains

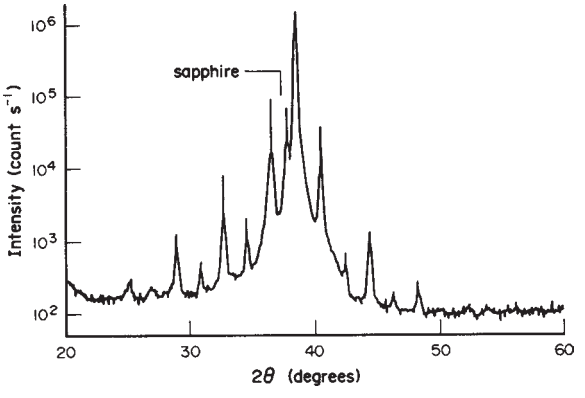

***Figure 2***
CuK alpha x-ray trace of niobium–tantalum epitaxial multilayer (4.9 nm wavelength) grown on A-plane sapphire to give (110) niobium–tantalum epitaxy; from the superlattice intensities the interface roughness can be estimated at 0.22 nm (after Somekh *et al.* 1989).

within the layers. In the HTS materials, the layered nature of the oxide structure gives even more striking results. One example shows that within the one layer there is a very abrupt change from YBCO to PrBCO, presumably the result of ledge growth of the layers of unit cell dimensions, that is, the layer was growing as one unit cell of YBCO say when the source was changed to PrBCO, which continued the growth to complete the layer. This ledge growth is also clearly evident in scanning tunnelling microscope profiles of the surface of YBCO films (not superlattices), in which the layers of one unit cell in height are shown around screw growth dislocations.

### 2.3 *Physical Properties of Superlattices*

The superconducting property of LTS superlattices that has received by far the greatest attention is the upper critical field $H_{c2}$, measured with the field applied parallel to the layers. This is because the dimensionality of the superconducting state is readily determined from the form of the dependence of $H_{c2}$ on temperature $T$.

As an example, consider the specific case of a superlattice of niobium–germanium (germanium films are insulators at low temperatures) (Ruggiero *et al.* 1982). If the niobium layers are thick ($t \gg \xi$), then the superlattice behaves like bulk niobium, that is, it is three dimensional. If the niobium layers are thin ($t \ll \xi$), and the germanium is thick, then the niobium layers are isolated from each other and are two dimensional. However, if the niobium layers are again, thin, and the germanium layers are thin enough to allow appreciable coupling by tunnelling between the niobium layers, then bulk three-dimensional behavior is again recovered, as the superlattice appears again as uniform material over the length scale of $\xi$. Interesting crossover effects have been observed as a function of temperature, in that the coherence length is much longer near $T_c$ than it is at lower temperatures. Hence, it is possible to find two regimes, one at higher temperatures where $\xi > t$ and three-dimensional behavior is observed and another at low temperatures with $\xi < t$ that exhibits two-dimensional behavior. As these two regimes have different temperature dependences of $H_{c2}$, namely $H_{c2} \simeq T_c - T$ for three dimensions and $H_{c2} \simeq (T_c - T)^{1/2}$ for two dimensions, the crossover between them is observed in the plot of $H_{c2}$ vs $T$ (see Fig. 3). These regimes can be thought of as the situations where the cores of the flux vortices either extend across multiple layers as Abrikosov vortices (three dimensional) or sit between the niobium layers in the germanium layers as Josephson vortices (two dimensional).

A second type of superlattice utilizes superconducting and normal metals (e.g., SNSNSN…). The coupling between the S layers is by the proximity effect induced in the N layer. A widely studied example is niobium–copper superlattices, in which one unusual

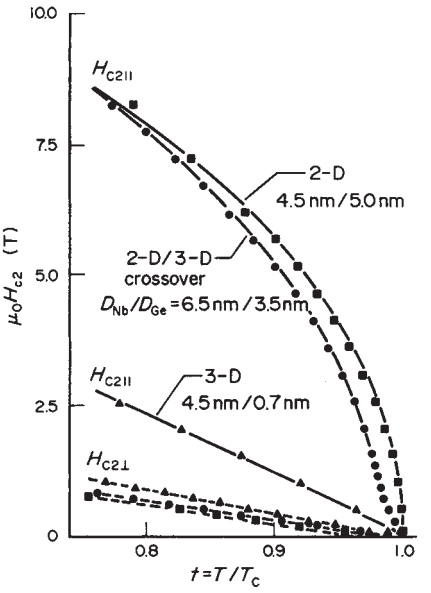

***Figure 3***
Upper critical fields near $T_c$ for Nb–Ge multilayers. Systematically varying the germanium thickness between the two-dimensional niobium layers effects a progression from anisotropic three-dimensional behavior $[H_{c2\parallel}(T) \sim (T_c - T)]$ to "crossover" behavior and finally to decoupled two-dimensional behavior $[H_{c2\parallel}(T) \sim (T_c - T)^{1/2}]$ (after Ruggiero *et al.* 1980).

effect occurs for small periods ($\lesssim 2$ nm). Both the niobium and copper layers appear to become disordered, with a strong increase in resistivity, a decrease in resistance ratio and decrease in the $T_c$ of the niobium. Dimensional crossover effects can also be observed in SN superlattices as the N layer becomes longer than its effective coherence length, which in copper in niobium–copper superlattices was demonstrated to be about 20 nm (Banerjee *et al.* 1983).

More recently, a further novel transition was predicted (Takahashi and Tachiki 1986) and observed (Karkut *et al.* 1988) in superlattices of two superconductors with very similar $T_c$ but with very different mean free paths, for example, niobium and a niobium–titanium alloy. In this case two crossover transitions were observed. Near $T_c$ the vortices are located in the niobium–titanium but are large enough to extend across the niobium (three dimensional, $H_c \simeq (T_c - T)$). At a lower temperature $\xi_{Nb}$ becomes less that $t_{Nb}$ and the vortices relocate into the niobium layers and are confined within them (two dimensional, $H_{c2} \simeq (T_c - T^{1/2})$) (see Fig. 4). At even lower temperatures, $\xi_{NbTi}$ becomes $< t_{NbTi}$ and the vortices become two dimensional within the niobium–titanium layers, which have a very high $H_{c2}$.

Work on HTS superlattices is naturally at an earlier stage, although the layered nature of the oxide

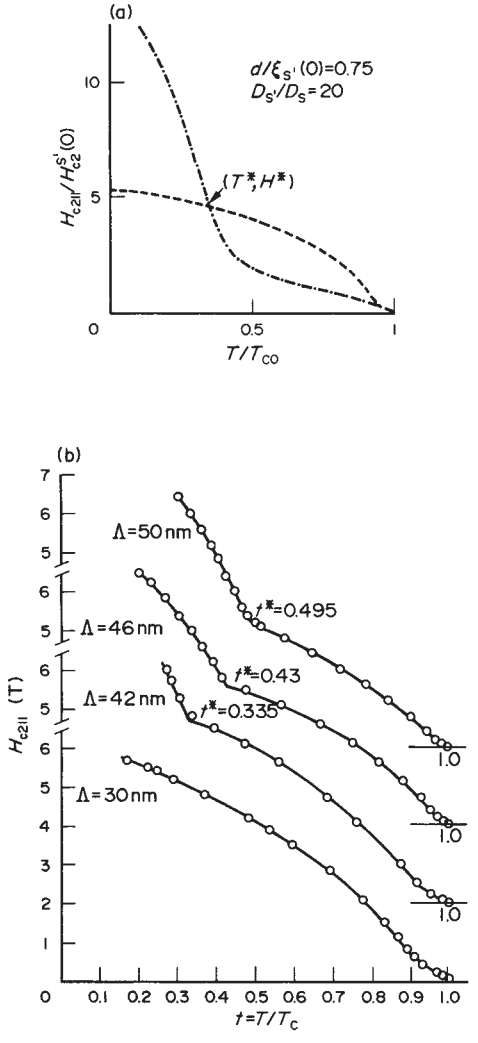

*Figure 4*
(a) Theoretical temperature dependence of the parallel critical fields for a multilayer SS′SS′SS′… . The dashed and dash-dotted curves indicate the upper critical fields when the superconducting order parameter nucleates in the S and S′ layers respectively. The observable $H_{c2\parallel}$ is the higher one of the two critical fields at each temperature. The point ($T^*$, $H^*$) is a multicritical crossover point, $d$ is the layer thickness and $D$ is the diffusivity (after Takahashi and Tachiki 1986). (b) Resistive measurements of $H_{c2\parallel}$ vs $t(=T/T_c)$ for Nb/NbTi superlattices with layers of equal thickness showing behavior at $t^*$ for samples with different wavelength Λ (after Karkut *et al.* 1988).

materials has allowed superlattices of very impressive perfection to be grown. Perhaps the most interesting question to be answered to date is the value of $T_c$ as the individual HTS layers are made thinner and as

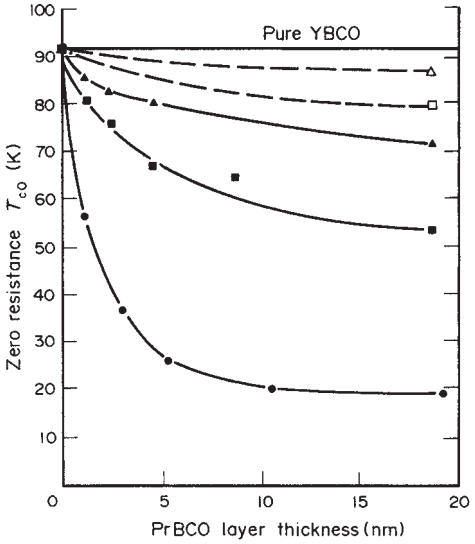

*Figure 5*
Critical temperature of $(YBCO)_M/(PrBCO)_N$ superconducting multilayers ($m=1$ to 8 unit cells thick) vs the separating PrBCO layer thickness: Δ, eight-cell YBCO; □, four-cell YBCO; ▲, three-cell YBCO; ■, two-cell YBCO; ●, single-cell YBCO (after Lowndes *et al.* 1990).

the coupling across an intermediate layer is made weaker. The intermediate layer is, for example, PrBCO which is a lattice-matched oxide that is a Mott insulator that exhibits high electrical resistivity at low temperatures. The results of Fig. 5 show that even layers of YBCO that are one unit cell thick have a $T_c$ of 20 K when widely separated (Lowndes *et al.* 1990). The $T_c$ increases as the coupling increases, reaching 56 K when the PrBCO is one unit cell thick.

It is evident that HTS materials with a pronounced perovskite layer structure behave in many respects as intrinsic atomic-scale multilayers, the alternating layers being the copper oxide planes (S) and the redox spacer layers (N or I) (see *Superconducting Materials: Types of*). In the more complex HTS materials the doping levels on the two types of layer may be varied independently, their character changing from …SNSNSN… to …SISISIS… depending on the preparation conditions. The interpretation and modelling of HTS materials as intrinsic multilayer structures is currently an active area of considerable importance both for their basic physical properties and for their behavior in magnetic fields.

## 3. Superconducting Device Structures

Superconducting devices are rather simple structures compared to those that are commonplace in semiconductor technology. This perhaps reflects the orders

of magnitude difference in commitments of time, personnel and funds to the two fields since the mid-1940s, which are themselves measures of the relative commercial importance of the two fields to date. Some superconducting devices can be made in a single film of material, the most common uses two films and the most complex requires only three. Despite this, they perform logic functions faster than the most advanced semiconductor devices and at a level of power dissipation which is orders of magnitude smaller (see *Thin Films, Multilayers and Devices, Superconducting*). Whether they will ever become more complex, or indeed need to do so, is an open question.

### *3.1 Tunnel Junctions and Weak Link Structures*

Superconductors are affected strongly by magnetic fields and only weakly by electric fields. This magnetic field sensitivity is the basis for many electronic devices. In a superconducting film, or film adjacent to a superconductor, a local region is produced where the superconducting state can be controlled by external magnetic fields. The cryotron (Buck 1956), which was the earliest superconducting electron device, used this principle. This device, which was invented in 1954 and therefore predates the Josephson effect, used two films (see Fig. 6) separated by an insulator. A current through the control film created a magnetic field which switched the second film from its superconducting to its normal state. Recovery from the normal state was not fast (by modern standards). With the discovery of the Josephson effect (see Josephson 1962) a much faster device became possible. The Josephson junction (see Fig. 7) consists of two superconducting films separated by a thin insulator ($<1.5$ nm thick). This insulator allows the tunnelling of pairs of electrons (the Josephson current) and single electrons (the quasiparticle current). These result in the tunnelling currents shown in Fig. 8 as a function of the voltage across the insulator. For an ideal junction there would be a discontinuous jump at $2\Delta/e$ and an exponentially small subgap tunnelling current proportional to $\exp(-\Delta/k_BT)$ (Van Duzer and Turner 1981). In real systems there is a smearing due to lifetime effects and nonuniformity in the films. In addition there is invariably a subgap leakage current. The sources of subgap leakage vary from device to device and depend very

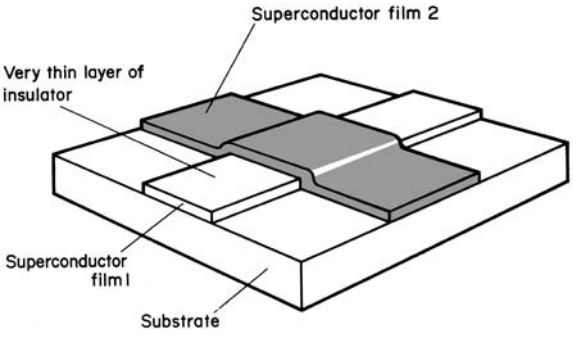

***Figure 7***
Josephson junction (SIS tunnel junction).

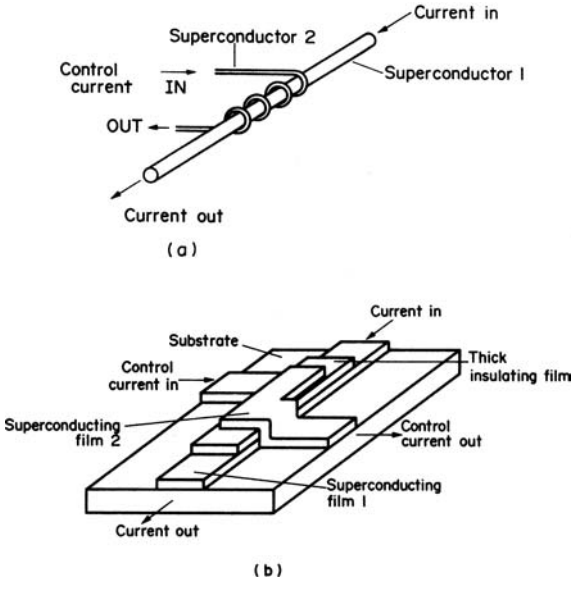

***Figure 6***
Cryotron types: (a) wire-wound type, (b) thin-film type.

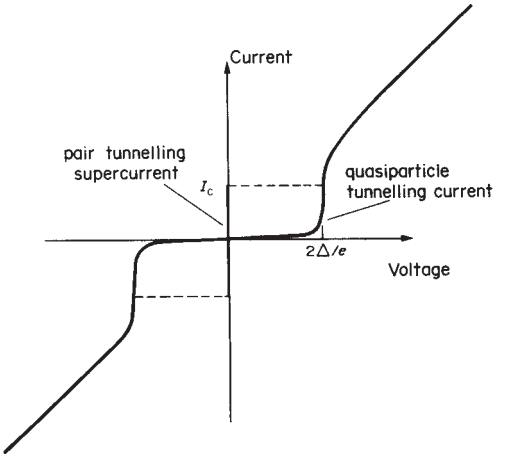

***Figure 8***
*I–V* characteristic of Josephson junction for the case where the two superconducting films have the same energy-gap parameter $\Delta$, the characteristic shows some subgap leakage current.

much on the fabrication of the device. Leakage can for instance arise from electron states within the tunnel barrier, or pinholes in the barrier itself. At low temperatures for very-high-quality low-leakage barriers, small subgap currents due to two-particle or many-particle tunnelling can be observed (Kirk *et al.* 1991). If a small magnetic field is applied to the junction parallel to the films, the Josephson current is reduced to zero when one quantum of magnetic flux is in the area given by the width of the junction multiplied by the sum of the London penetration depths of the two films (Rowell 1963). In practical devices, this is about 0.1–1 mT. It is important to realize that, in contrast to the cryotron, it is only the Josephson current that is switched off by the magnetic field. The two films comprising the junction remain entirely superconducting at these low magnetic fields. In addition to control by magnetic field, the junction can also be switched by increasing the current until the maximum Josephson current is exceeded.

The Josephson tunnel junction has become the device of choice for LTS electronic, instrument and sensor applications (Ruggiero and Rudman 1990). It is fast and consumes little power. Its modern form, made from Nb/Al–Al oxide–Nb, is described in detail in *SQUIDs; Biomedical Applications; SQUIDs: The Instrument; Josephson Voltage Standard; Josephson: Junctions: Low-$T_c$*

Soon after the theoretical discovery and experimental verification of the Josephson tunnel junction, it was realized that Josephson effects could be observed in many even simpler structures, which are now collectively known as weak links (Anderson and Dayem 1964). No tunnelling occurs in any of these structures, they rely instead on creating a region of weak coupling between two superconductors by various means other than an oxide layer. Some examples are shown in Fig. 9. The simplest is a contact between a pointed wire of one superconductor and a second bulk superconductor (''point contact''). The thin-film version is a small constriction defined in a film (a ''weak link'', ''bridge'' or ''microbridge''). A ''variable thickness bridge'' has the constriction both thinner and narrower than the surroundings (banks). The coupling region can also be made from a normal metal, which is made weakly superconducting by the proximity effect (SNS junction).

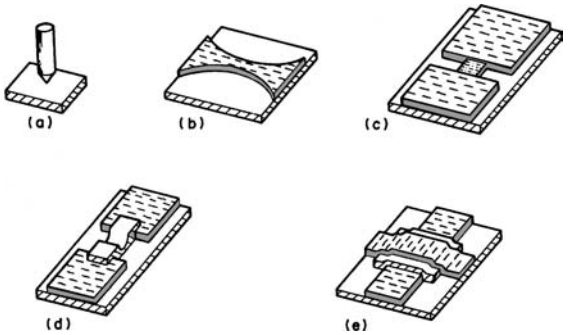

***Figure 9***
Josephson weak link structures: (a) point contact, (b) constriction, (c) variable thickness bridge, (d) SNS planar and (e) SNS sandwich.

In all these Josephson weak link devices, the length of the coupling region must be comparable to the superconducting coherence length in that region. In LTS materials and normal metals, standard film growth and lithographic techniques can produce features of the sizes required (generally $\lesssim 1\,\mu m$). In HTS materials, this is obviously not possible.

Unlike the semiconducting transistor, superconducting devices do not have gain. At a fixed current level, they simply switch between the zero voltage and finite voltage states with application of magnetic field. A few three-terminal devices have been investigated that are more transistorlike in design, but not yet in operation (Kleinsasser and Gallagher 1990). One example is the superconducting FET (see Fig. 10), in which two closely spaced superconducting contacts induce a weak coupling region on the surface of a semiconductor by the proximity effect. This superconducting channel is then switched on and off by application of an electric field from the gate. To date, large gate voltages are required to achieve switching and the devices are not practical.

As of mid-1991, the device scene in HTS materials is one of great activity and some uncertainty. All the devices made in LTS materials are being investigated, with varied levels of success. It is clear that the short coherence lengths of the HTS materials creates a real challenge in device design and processing. It does seem likely that junctions of the weak link type will emerge as more important than tunnel junctions, at least in those HTS materials with $T_c > 77\,K$. The reasons for this will be given later.

One HTS device has been created which has no LTS counterpart. A control line modulates the flux density in a weakened region of a second film (channel). It can be called a flux-flow cryotron (Martens *et al.* 1991) in that the channel is switched from zero resistance into its flux flow state, rather than into its normal state. Its value in interface circuits has already

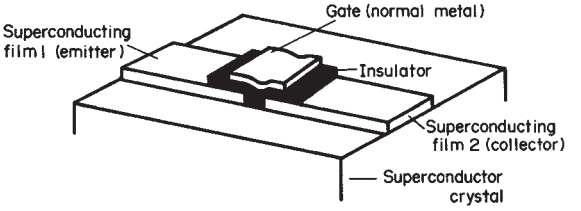

***Figure 10***
Superconducting three-terminal device (FET type).

been demonstrated, in that its output voltage is quite large (tens to hundreds of millivolts).

### 3.2 Device Processing: LTSs

The LTS weak link devices are relatively easy to make with current lithographic techniques. Optical, electron-beam and ion-beam patterning have all been used to create the weak regions of dimensions 1 μm or less in a variety of materials. The details will not be discussed here.

Tunnel junctions exhibiting quasiparticle tunnelling were first made in the late 1950s by the very simple process of evaporating a strip of aluminum film using a shadow mask, exposing it to the air for a short time ($\sim$1 min), then evaporating a crossing strip of lead to produce an Al–Al oxide–Pb tunnel junction (Giaever 1960). The brief exposure to air grows the required thickness of aluminum oxide ($\sim$1.5 nm) which completely covers the aluminum film even over relatively large areas of a few square millimeters. It is important that there are no defects or "pinholes" in the oxide, otherwise a metallic short circuit occurs. This basic oxidation process has been used for the vast majority of tunnel junctions made on many different materials, and is used in the current commercial process.

Other materials that have been used to make oxide tunnel junctions include lead, tin, niobium, tantalum and the alloys and A15 compounds of niobium. In some cases the oxidation is not so easy as it is for aluminum and heating in oxygen is required. Because of its relatively high $T_c$ (7.2 K), lead and its alloys received many years of study as the metallizations for Josephson circuits. The problems that were encountered illustrate the difference between the research mode of making a few successful junctions for scientific study, and a manufacturing mode of reproducibly making circuits that require many thousands of junctions. The variation of critical current density across these junctions must be small and they must survive both shelf storage and many thermal shocks as they are cycled from 300 K to 4.2 K and back to 300 K. Because of the failure of lead, no satisfactory metallization for Josephson circuits existed for 20 years (1963–1983). Niobium was an obvious choice ($T_c = 9.2$ K), but oxidation of niobium itself produces a mixture of oxides with insulating, semiconducting and even metallic properties. There is probably also degradation of the niobium film surface. This problem was finally solved by immediately depositing a thin layer ($<10$ nm) of aluminum on top of the niobium film in the same vacuum system, then oxidizing the aluminum to form an aluminum oxide, rather than niobium oxide, tunnel barrier (Geerk *et al.* 1982).

Such "artificial" barriers have been used for a number of other materials that do not readily oxidize themselves. The best known example is MgO, which is deposited as a thin layer on top of NbN to form NbN–MgO–NbN tunnel junctions (Shoji *et al.* 1985). The different types of "sandwich" tunnel junctions are shown in Fig. 11.

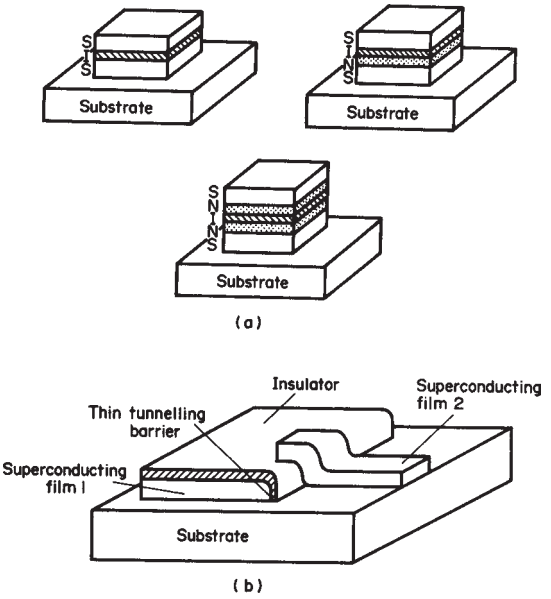

***Figure 11***
(a) Three types of multilayer sandwich structure Josephson junction, SIS, SNIS and SNINS; (b) edge-type Josephson junction.

The sizes of sandwich junctions can be as small as 1 μm × 1 μm using standard optical lithography and submicrometer sizes using deep-UV sources. Another way to make very small junctions is to oxidize the edge of a film that has been cut by ion milling. Such an "edge junction" is shown in Fig. 11. The small capacitance of such structures makes them suitable for high-frequency SIS detectors used in radio astronomy studies.

### 3.3 Device Processing: HTSs

The new oxide materials with $T_c > 77$ K are demanding the invention of a new device technology. They readily form tunnel junctions with counterelectrodes of low-$T_c$ materials (Geerk *et al.* 1988), either because their surfaces lose oxygen and become insulating, or because the counterelectrode itself (e.g., lead) removes the oxygen to form the insulator. However, such junctions have no technological value. Obviously there is no Josephson current until the temperature is below $T_c$ of the counter electrode and, at least to date (1991), none of them exhibits the $I$–$V$ characteristic of Fig. 8 with well-defined Josephson current and energy gap. This comment applies to all the

anisotropic oxides. Whether it is an intrinsic property remains to be seen.

The isotropic oxides (e.g., BaPbBi oxide, BaKBi oxide) are strikingly different. A "classical" *I–V* characteristic of the type shown in Fig. 8 has been observed by simply touching a BKBO single crystal to a BKBO film and work is underway to produce similar results in a thin-film sandwich structure. At

present, the maximum $T_c$ in an isotropic oxide superconductor is about 30 K. However, this would allow a Josephson technology similar to that developed for niobium to be used at 12–15 K, well within the range of closed cycle refrigerators of reasonable cost. Thus, these isotropic oxides might become important metallizations for electronics applications.

In the absence of any useful tunnel junctions in HTS materials, the weak link devices are of more importance than they were in the LTS field (although it is true that most of the SQUID-based LTS magnetometers that have been sold have in fact used such weak links rather than tunnel junctions). A great variety of device structures are being investigated at present (mid-1991). Many of them make SQUIDs operating at 77 K. Whether any of them will become the basis of a genuine circuit technology remains to be seen. They include SNS devices where the N layer can be silver (or silver–gold alloy). In one geometry the silver covers a break in the HTS film induced by a step in the substrate. Other N layers are semiconducting and "metallic" oxides, in various geometries (Simon 1991). The possible presence of a proximity effect in such oxides is an interesting issue.

To define a weak link constriction, or region of reduced $J_c$ and $T_c$, of a size comparable to the very short coherence lengths, is difficult in HTS materials. However, electron-beam writing and focused ion-beam milling have been used with some success, and the use of patterning by a scanning tunnelling microscope has been proposed. In one structure nature itself seems to provide a structure of the correct dimensions, namely a boundary between two grains in the film. The cleanest examples of such devices are grain boundary junctions grown on substrates that were cut and deliberately misaligned in the plane by

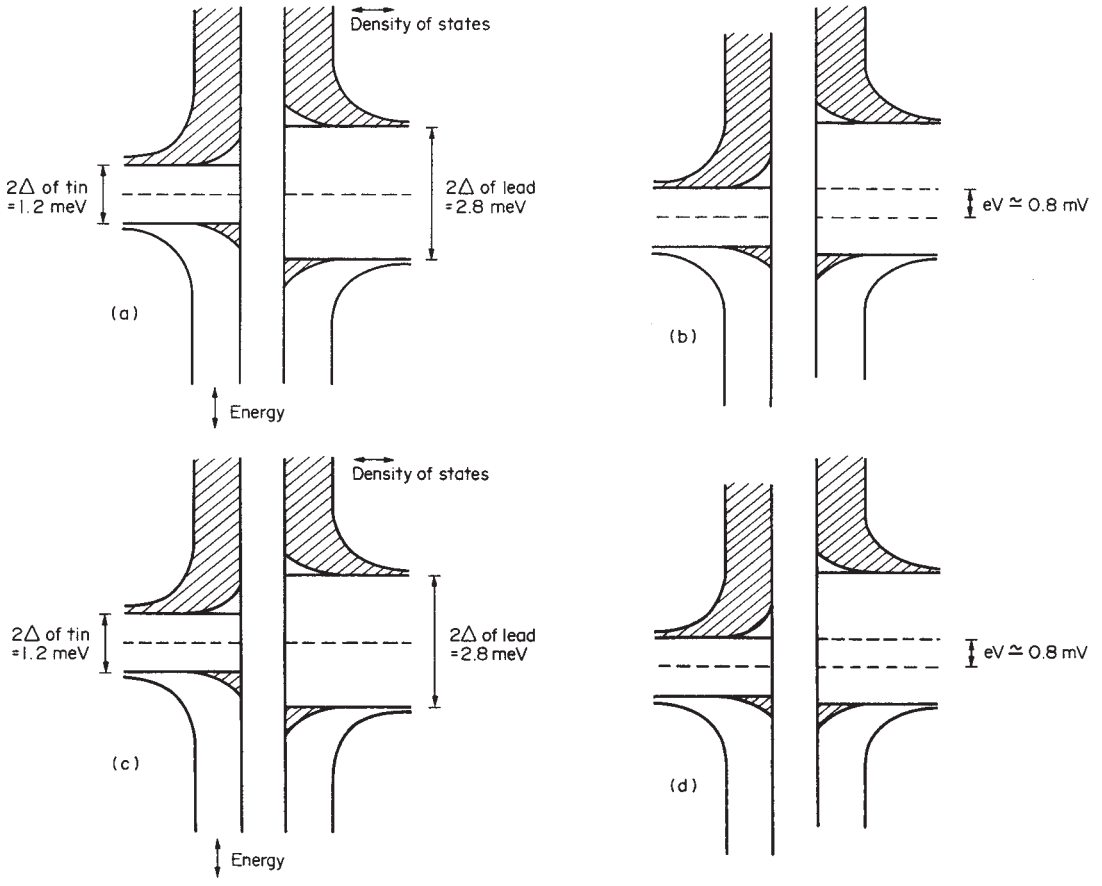

*Figure 16*
The density of filled and empty quasiparticle states for lead and tin superconducting layers on each side of a tunnel barrier. An applied voltage $V$ leads to a relative displacement of the density of state diagrams, the voltage corresponding to the gap $2\Delta$ is $2\Delta/e$: (a) zero applied voltage; (b) $eV = \Delta_{Pb} - \Delta_{Sn} \simeq 0.8$ mV; (c) $\Delta_{Pb} - \Delta_{Sn} < eV < \Delta_{Pb} + \Delta_{Sn}$, $eV \simeq 1.4$ mV; and (d) $eV = \Delta_{Pb} + \Delta_{Sn} \simeq 2.0$ mV.

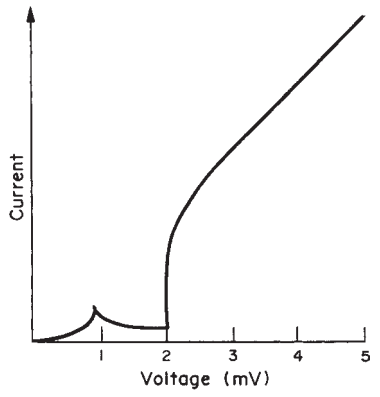

***Figure 17***
The current–voltage characteristic for the tunnelling of quasiparticles in an Sn–I–Pb junction.

various tilt angles (Gross *et al.* 1990a). The film, growing epitaxially, replicates the orientation of the substrate. On yttria-stabilized zirconia substrates, the critical current drops exponentially with angle, by four orders of magnitude as the angle is increased from 0 to 40° (see Fig. 12) (Ivanov *et al.* 1991). SQUIDs of YBCO showing modulation with magnetic field up to 87 K have been produced with such grain boundary junctions (Gross *et al.* 1990b). (See Fig. 13, which shows the structure, Fig. 14 demonstrating the modulation and also the article *Josephson Junctions: High-$T_c$*.)

A step geometry has also been used to form weak link HTS junctions (see Fig. 15). If the angle of the step is steep ($\theta > 45°$) single or multiple grain boundaries form at the discontinuity in the substrate surface (Fig. 15a,b). For shallow junctions ($\theta < 35°$) the epitaxy is preserved at the step and an SNS junction can be formed by depositing a heteroepitaxial layer of normal PrBCO (Fig. 15c) (Gao *et al.* 1991). In this junction films are grown with the *c* axis normal to the substrate so that the tunnelling current is in the *ab* plane, the direction with longest coherence length.

An alternative process called biepitaxy creates a grain boundary in the film by control of the in-plane epitaxy using seed and buffer layers (Char *et al.* 1991a), rather than by changing the substrate orientation. This process could allow complex circuits of grain boundary junctions to be demonstrated, as the junction can be located at any point on a single-crystal substrate. The first integrated SQUID magnetometer fabricated on one chip used such biepitaxial grain boundary junctions (Char *et al.* 1991b).

### *3.4 Properties of Devices*

The ideal BCS current–voltage characteristic of LTS tunnel junctions can be readily understood by the use of semiconductorlike diagrams in which the filled and

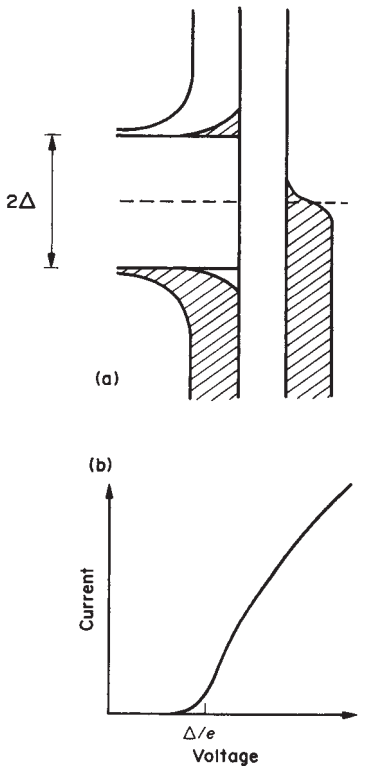

***Figure 18***
SIN tunnel junction: (a) density of filled and empty states at zero applied voltage, and (b) current–voltage characteristic at finite temperature.

empty quasiparticle states are shown at an energy $2\Delta$ apart and have $(E^2-\Delta^2)^{1/2}$ energy dependencies of the density of states (see Fig. 16). The superconducting pairs are shown at the Fermi level, the midpoint of the gap. The effect of an applied voltage $V$ is simply to slide the Fermi levels and thus the whole gap structures relative to each other by a distance $eV$. The effect of temperature is included by a thermal distribution over only the quasiparticle states.

The most interesting case is that of two superconductors with different energy gaps, say tin and lead to be specific. The $T_c$ values are 3.7 K and 7.2 K, and the energy-gap parameters $\Delta = 0.6$ meV and 1.4 meV, respectively or $2\Delta = 1.2$ meV and 2.8 meV. The density of states diagrams are then as shown in Fig. 16a at zero voltage and a temperature significantly below the $T_c$ of tin. As the voltage is increased, a maximum in current occurs at $eV = \Delta_{Pb} - \Delta_{Sn}$ (Fig. 16b), but the current then decreases for larger voltages. This is because the current is the integral over the filled and empty states that are aligned with each other, which is smaller in Fig. 16c than in Fig. 16b. A sudden increase in current occurs for $eV = \Delta_{Pb} + \Delta_{Sn}$ in Fig. 16d. In theory, this should be a discontinuous

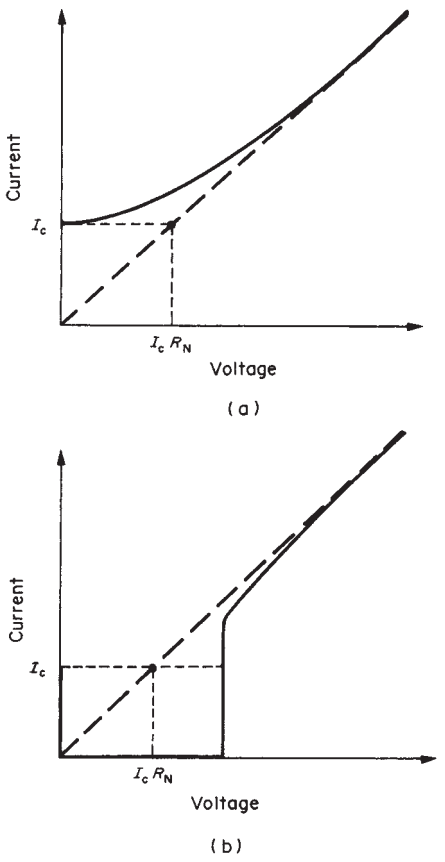

***Figure 19***
(a) The current–voltage characteristic for a weak link with a resistively shunted junction RSJ type transition, the $I_C R_N$ product for the weak link is indicated; and (b) $I_C R_N$ product for Josephson tunnel junction.

jump in current at any temperature, but in practice it has a slight width due to lifetime effects and nonuniformities in the films.

At high voltages, the current–voltage characteristic approaches that of the normal state. The quasiparticle branch of the characteristic is shown in Fig. 17; the complete characteristic, including the Josephson current of pairs flowing at $V = 0$ exhibits the main features of Fig. 8. Another interesting case is the S–I–N junction, where N is a normal metal, for which the density of states diagram and $I$–$V$ characteristic are shown in Fig. 18. The reader should be able to recreate the $I$–$V$ characteristics by following the process of sliding the density of states as described.

In weak link devices, as there is no tunnelling, there is no signature of the energy gap in the $I$–$V$ characteristic. In many such devices, the $I$–$V$ characteristic resembles that for a tunnel junction with a low-resistance shunt across it, the resistively and capacitatively shunted junction (RCSJ) (see *Electrodynamics of Superconductors: Weakly Coupled*). The $I$–$V$ characteristic then appears as in Fig. 19.

An important "figure of merit" for both LTS and HTS devices of both tunnelling and weak link types is the $I_C R_N$ product, which is the voltage defined in Fig. 19. It is related to the signal voltage that is available in a SQUID or circuit. Obviously it should be large (millivolts). It can be $\leqslant 3$ mV in niobium tunnel junctions, but in many HTS devices, especially the SNS type, it is very small (e.g., tens of microvolts). This makes such structures less interesting for practical applications.

A second figure of merit, used for tunnel junctions, is a measure of the subgap leakage current that flows for voltages less than the energy gap compared with the current that would flow at the same voltage in the normal state. This can be expressed as the ratio $R_S/R_N$ calculated at some defined voltage (e.g., 2 mV for niobium devices), or as a voltage $V_m$ defined as $R_S$ times the critical current $I_c$. In an ideal junction, this current is only due to quasiparticles that are thermally excited above the gap. Hence, at temperatures small compared with $T_c$, it should be very small. For example, for Pb–I–Pb junctions at 1 K values for $R_S/R_N$ of $10^5$ have been observed. For Nb–I–Nb at 4.2 K most of the subgap current is thermally excited and the ratio is about 20–25. Values lower than this indicate a poor quality junction with some non-tunnelling leakage paths for the excess current. The most obvious possibility is a small pinhole in the tunnel barrier.

## *4. Concluding Remarks*

The discovery of the HTS oxides raises interesting questions of how LTS and HTS junction technologies will be used, assuming that the latter can be developed. There are strong signs that this will happen. In some areas of application, it seems likely that HTS and LTS technologies will compete with each other, as they do with silicon and GaAs in some cases.

In one example, the most sensitive SQUIDs for measuring magnetic signals from the brain might well remain at 4.2 K, whereas for other measurements, where portability of the equipment is needed (e.g., nondestructive evaluation of pipes) 77 K operation will be favored.

The majority of the digital circuits that have been built with niobium tunnel junctions employ "voltage state logic," in which the two states of the junction are at zero voltage and about 2.9 mV. Power dissipation is the product of the current and this voltage for the time that the junction remains switched. If HTS junctions of the same type could be made, the advantages of the low power dissipation of superconducting technology would be partly lost. The voltage (gap) would be ten times larger, and the current also ten times larger (to scale with the operating temperature); hence, the power would be 100 times larger.

However, there is a class of superconducting circuits, known as QFP (quantum flux parametron) or SFQ (single flux quantum) circuits, that avoid this problem and, hence, regain the advantage of the very low power dissipation of Josephson technology, even at temperatures up to 77 K. The basic circuit element is the SQUID and power is dissipated only when a quantum of flux (which is the bit of information in QFP) moves in or out of the SQUID loop. The momentary voltage pulse is the bit of information in SFQ circuits. Such circuits do not need Josephson junctions of the type shown in Fig. 8; in fact they can use weak link devices. Thus, they appear to be the most likely candidates for initial demonstrations of HTS high-speed electronics.

Another divergence between LTS and HTS that is already becoming apparent is the extensive use of fully epitaxial multilayer devices in HTS. In this materials aspect, HTS begins to resemble III–V semiconductor technology much more than it does conventional superconductor (niobium) technology. As an example, an integrated HTS SQUID magnetometer has been fabricated which utilized 15 epitaxial oxide layers of superconductors and insulators, plus a final silver contact layer (see Char *et al*. 1991a). Indeed, the field of superconducting thin films, multilayers and devices is changing and progressing rapidly.

# Thin Films: Domain Formation

Soft magnetic films and nanostructures are of interest for applications as sensors and storage material. Most desirable are single-domain structures that switch their magnetization at a certain field by fast coherent rotation. These ideal films, so far, have not been produced; the films tend to break up into domains along the magnetization loop. The formation of domains in soft magnetic films and nanostructures has to be understood for the discussion of the magnetic properties of the films and nanostructures and how to select them for applications.

A desirable ideal state of the magnetization in thin ferromagnetic films is the single-domain state in which at remanence the magnetization is directed along an easy axis. Application of an external field should cause coherent rotation of the magnetization towards the applied field. Magnetization reversal is expected by spontaneous switching at a critical field. Nature does not follow these idealized assumptions.

For discussing the static equilibrium state of the magnetization in a real sample one has to consider the integral minimum of all magnetic energies: the Zeeman energy $\varepsilon_H = -\vec{H}\vec{M}$ of the sample in an applied field; the crystalline anisotropy energy $\varepsilon_K$; the uniaxial anisotropy energy $\varepsilon_{K_u}$; the magnetostrictive anisotropy energy $\varepsilon_\sigma$; the exchange anisotropy $\varepsilon_{ex}$; the external demagnetizing self-energy $\varepsilon_{dext} = -(1/2)\vec{H}_{dext}\vec{M}$, where $\vec{H}_{dext}$ is the demagnetizing field from magnetic poles at the film boundaries; the intrinsic demagnetizing self-energy $\varepsilon_{dint} = -(1/2)\vec{H}_{dint}\vec{M}$, where $\vec{H}_{dint}$ is the demagnetizing field resulting from intrinsic magnetization divergencies; the surface anisotropy $\sigma_s$; and the wall energy $\sigma_w$ (Kittel 1949, Craik and Tebble 1965).

All of these energy densities have to be integrated over the volume of the film. Their minimum gives the stable state of magnetization distribution in the film. This problem is treated in the field of micromagnetism.

Experimental observation of domains gives a first indication of how to approximate this difficult problem, which is then reduced to the domain theory, in which the domains are separated by walls and homogeneous magnetization is assumed within domains (Kittel 1949).

The methods of domain observation have increased in sensitivity and resolution over the years. They include the Bitter pattern, magneto-optical Faraday and Kerr rotation, Lorentz microscopy, spin polarized photoemission of electrons, and x-ray dichroism (Hubert and Schäfer 1998). These methods will not be discussed in this article.

Why is the single-domain state of a film not a state of lowest energy? Why does the film break up into domains?

(i) The film size is finite. Magnetic poles at the boundaries cannot be avoided in the single-domain state, leading to strong magnetic self-energy. The total magnetic energy is decreased when this self-energy is decreased by domain formation. The additional increase in energy owing to domain wall energy is smaller than the decrease of the self-energy.

(ii) Nonideal films, for instance polycrystalline films, show fluctuation of the direction of the local magnetization around the mean direction, the so-called magnetization ripple (Hoffmann 1968). In some cases this ripple is responsible for nucleation of domains. The ripple prevents a coherent switching of single domains.

Domain formation in thin films is many and varied. It can be explained in the best way by discussing soft magnetic thin films with uniaxial magnetic anisotropy, which are applied as magnetic sensors. The uniaxial anisotropy results from film deposition in the presence of a magnetic field parallel to the film plane or from field annealing below the Curie temperature of the deposited film. In both cases the direction of the applied field introduces an easy axis of the magnetization parallel to the applied field. Permalloy ($Ni_{91}Fe_{19}$) is the typical material used for soft magnetic uniaxial films.

## *1. The Single-domain Theory of Stoner and Wohlfarth*

The magnetization reversal of ideal uniaxial films is theoretically described by the Stoner–Wohlfarth single-domain theory (Stoner and Wohlfarth 1948, Cohen 1969, Prutton 1964), in which an ideal uniaxial film with homogeneous in-plane magnetization is assumed.

The in-plane magnetization loops with applied field in the easy or hard direction are calculated from the minimum of the Zeeman energy, $-\vec{M}\vec{H}$, and the

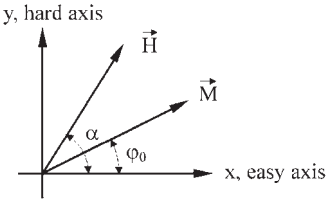

***Figure 1***
System of coordinates and angles.

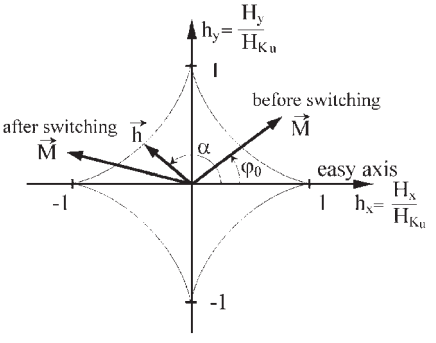

***Figure 2***
Stoner–Wohlfarth astroid.

uniaxial anisotropy energy, $K_u \sin^2 \varphi_0$ (Fig. 1), leading to

$$\frac{\partial \varepsilon}{\partial \varphi_0} = \frac{\partial}{\partial \varphi_0}[-HM \cos(\alpha - \varphi_0) + K_u \sin^2 \varphi_0]$$
$$= -HM \sin(\alpha - \varphi_0) + 2K_u \sin\varphi_0 \cos \varphi_0 = 0 \quad (1)$$

for the equilibrium state.

Introducing the anisotropy field $H_{K_u} = 2K_u/M$, which is characteristic for uniaxial films, the equilibrium state is given by

$$h \sin(\alpha - \varphi_0) + \cos \varphi_0 \sin \varphi_0 = 0 \quad (2)$$

The field $h = H/H_{K_u} = HM/2K_u$ is the applied field in units of $H_{K_u}$, which will be used in the following discussions.

The effective field, $h(\alpha)$, in units of $H_{K_u}$, is given by

$$\frac{1}{2K_u} \frac{\partial^2 \varepsilon}{\partial \varphi_0^2} = h(\alpha) = h \cos(\alpha - \varphi_0) + \cos 2\varphi_0 \quad (3)$$

which determines the stability of the magnetization. Stable states require $h(\alpha) > 0$; instability, i.e. switching, occurs for $h(\alpha) = 0$ (Hoffmann 1966, 1968).

The equation

$$h(\alpha) = h \cos(\alpha - \varphi_0) + \cos 2\varphi_0 = 0 \quad (3a)$$

describes the well-known Stoner–Wohlfarth astroid (Fig. 2) (Stoner and Wohlfarth 1948, Cohen 1969, Prutton 1964).

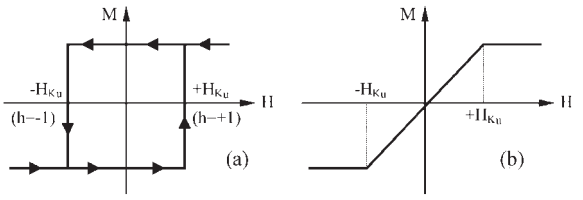

***Figure 3***
Magnetization loops of uniaxial films: (a) easy axis; (b) hard axis.

On applying a field $\vec{H}$ at an angle $\alpha$ to the easy axis, for which the magnetization at $H = 0$ was originally saturated, the magnetization is coherently rotated by an angle $\varphi_0$ from the easy axis. As soon as the applied field $\vec{H}$ crosses the astroid, the magnetization switches spontaneously by coherent rotation into a new stable state (Fig. 2).

In the special case of applying the field along the easy axis, the magnetization remains stable in the original state, until at $H = -H_{K_u}$ it switches spontaneously to the antiparallel direction by coherent rotation (Fig. 3(a)). These two stable states, switched at $H_{K_u}$, make uniaxial films desirable for magnetic storage. Unfortunately, in reality, coherent switching along the easy axis is not observed. Instead, the magnetization of the films breaks up into domains, and magnetization reversal is completed by domain wall motion with coercive force $|H_c| < |H_{K_u}|$ (see Figs. 10(a) and (b)).

In the special case of applying the field along the hard axis, the magnetization rotates continuously from the easy axis against the direction of the applied field, until at $H = H_{K_u}$ the magnetization is saturated in this direction. The expected magnetization loop is given in Fig. 3(b). In this way the uniaxial film is used as a field sensor (see also *Coercivity Mechanisms*).

## 2. *Magnetization Ripple*

In discussing magnetization reversal in real polycrystalline films or in single-crystalline films, including defects, one has to include inhomogeneous local anisotropies, such as crystalline anisotropy and magnetostriction of the crystallites. These local anisotropies lead to deviations, $\varphi$, of the local direction of the magnetization from the mean direction $\varphi_0$. The magnetization is no longer homogeneous over the entire film. The fluctuations are coupled in elliptical areas over many crystallites. The major axis of the coupling ellipse is always directed perpendicular to the mean magnetization and is determined by dipolar coupling. The minor axis, parallel to the mean magnetization, is determined by the exchange length.

The fluctuation $\varphi$ can be seen in images obtained by Lorentz microscopy (Fig. 4). This "magnetization ripple" (Hoffmann 1966, 1968, Cohen 1969) dominates

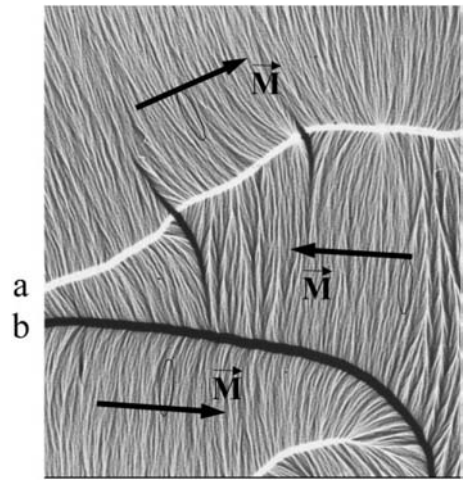

***Figure 4***
Lorentz image with magnetization ripple, Bloch wall, and cross-tie wall (courtesy of J. Zweck).

the magnetization reversal in fields along the hard axis and is responsible for the formation of domains. The model of homogeneous magnetization of ideal single-domain films is no longer applicable. The fluctuations, $\varphi$, of the magnetization cause magnetic divergencies, leading to intrinsic demagnetizing fields. Furthermore, exchange energy has to be taken into account. Assuming a two-dimensional thin film with infinite diameter, the total energy density depends on the site $\vec{r}$:

$$\varepsilon(\vec{r}) = \varepsilon_H + \varepsilon_{K_u} + \varepsilon_d(\vec{r}) + \varepsilon_{ex}(\vec{r}) + \varepsilon_{loc}(\vec{r}) \qquad (4)$$

and is now the sum of the Zeeman energy $\varepsilon_H$, the uniaxial anisotropy energy $\varepsilon_{K_u}$, the intrinsic demagnetizing energy $\varepsilon_d$ $(\vec{r})$, the exchange energy $\varepsilon_{ex}$ $(\vec{r})$, and the local energy $\varepsilon_{loc}$ $(\vec{r})$.

Instead of Eqns. (1) and (2), the following variational problems have to be solved. For the equilibrium state:

$$\delta \iiint \varepsilon(\vec{r'}) \mathrm{d}V' = 0 \qquad (5)$$

and for the effective field:

$$h_{eff}(\vec{r}) = \frac{1}{2K_u}\delta^2 \iiint \varepsilon(\vec{r'}) \mathrm{d}V' \qquad (6)$$

Solving Eqn. (5) first gives the mean direction $\varphi_0$ of the magnetization, which is the same as in the single-domain theory.

Furthermore, solution of Eqn. (5) leads to a quantitative description of the ripple angle, $\varphi$, and the ripple wavelength, $\lambda$. The r.m.s. value $\sqrt{\overline{\varphi^2}}$ depends on the local anisotropies and the applied field; $\lambda$ depends on the exchange constant and the applied field. On decreasing the applied field $H$ from saturation towards the Stoner–Wohlfarth astroid, both the ripple angle, $\varphi$, and the ripple wavelength, $\lambda$, increase (Fig. 5).

Solution of Eqn. (6) leads to a quantitative description of the intrinsic demagnetizing field caused by the ripple (Hoffmann 1966). The effective intrinsic demagnetizing field is aligned parallel or antiparallel to the mean magnetization (Fig. 6). This oscillation causes local instabilities as soon as $h_{eff}(\vec{r}) = 0$, leading to ripple blocking. This is most important for domain formation owing to the existence of the ripple. Blocking means that the mean direction of the magnetization no longer follows the Stoner–Wohlfarth single-domain behavior. The film splits into domains and hysteresis is observed.

The blocking curve is now the critical curve (Fig. 7) for magnetization reversal in thin films. On increasing the reversed applied field, the field vector can never approach the Stoner–Wohlfarth astroid (curve a) before crossing the blocking curve (curve b). This is a fundamental statement of ripple theory. The magnetization of a real film with uniaxial anisotropy can never be switched by coherent rotation. The magnetization breaks up into domains. Magnetization reversal is completed by domain wall motion. This theoretical prediction has been confirmed by many experiments. The Stoner–Wohlfarth model can be applied only to the region outside the blocking curve.

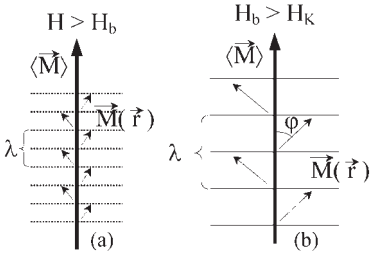

***Figure 5***
Magnetization ripple: (a) free ripple state; (b) ripple at blocking field $H_b$.

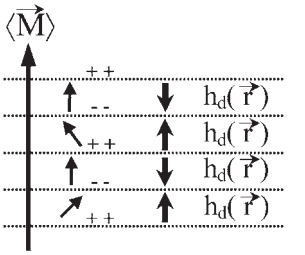

***Figure 6***
Intrinsic demagnetizing field of the ripple.

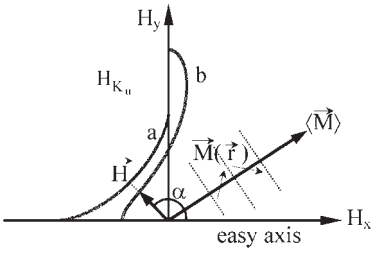

***Figure 7***
Critical curves for magnetization reversal: (a) Stoner–Wohlfarth astroid; (b) blocking curve.

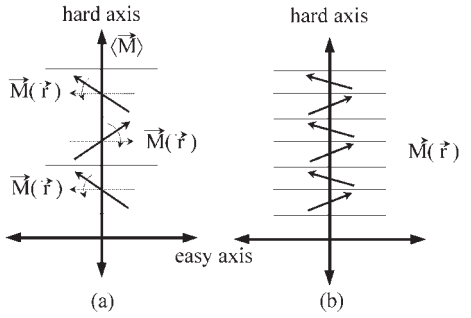

***Figure 8***
Magnetization ripple during reversal along the hard axis. Ripple at the blocking field. Film with (a) low local anisotropies and (b) large local anisotropies.

## 3. *Magnetization Reversal in Fields Along the Hard Axis*

Magnetization reversal along the hard or easy axis is of special interest. In the case of high-quality films (low local anisotropies), the magnetization loop in the hard axis direction may appear as in Fig. 3(b) as a straight line. In this case the intrinsic demagnetizing field is small. The ripple wavelength at blocking, which determines the domain width, is large. Each domain then behaves like a Stoner–Wohlfarth single domain. Reversal occurs by clockwise and counterclockwise rotation of the magnetization within each domain (Fig. 8(a)). The remanence is zero.

In the case of larger local anisotropies the intrinsic demagnetizing field is stronger. The ripple wavelength at blocking is smaller (Fig. 8(b)). Magnetization reversal within the domains is affected by the demagnetizing field. Hysteresis is observed. The remanence is larger than zero.

## 4. *Magnetization Reversal in Fields Along the Easy Axis*

During magnetization reversal along the easy axis some more effects have to be discussed. Owing to the finite size of the films, at saturation magnetic poles at the edge of the film create an external demagnetizing field $H_d$ (Fig. 9(a)), which need not be discussed during hard axis reversal.

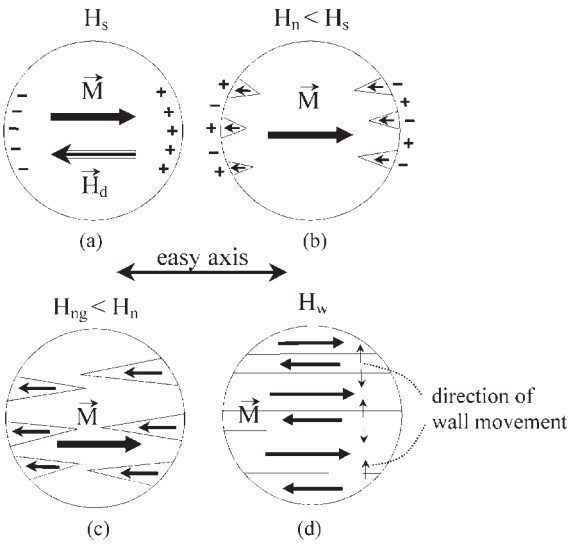

***Figure 9***
Stages of magnetization reversal along the easy axis: (a) saturation in applied field $H_s$; (b) nucleation of reversed domain at decreasing applied field; (c) growth of the nuclei; (d) formation of walls and wall movement.

The demagnetizing field is antiparallel to the magnetization. It is strongest at the film edge. Decreasing the applied field below the saturation field leads to nucleation of reversed domains at the nucleation field $H_n$ (Fig. 9(b)). This reduces the total demagnetizing field and consequently the demagnetizing self-energy.

On decreasing the applied field further, the reversed nuclei grow (at $H_{ng}$) (Fig. 9(c)) and finally form domains (Fig. 9(d)). The magnetization reversal is finalized by domain wall movement that starts at $H_w$. The reversal always starts with nucleation at $H_n$. The shape of the magnetization loop depends on the strengths of $H_n$, $H_{ng}$, and $H_w$. The ripple is present in all cases but the mentioned fields dominate the domain formation and the magnetization reversal, since these fields are effective before ripple blocking occurs.

Two characteristic types of magnetization loops are observed, depending on the geometry and quality of the film:

(i) $H_n > H_{ng} > H_w > H_c$, which leads to a magnetization loop in the easy axis direction as shown in Fig. 10(a); and

(ii) $H_n <$ all other fields, which leads to a magnetization loop as shown in Fig. 10(b); in this case the applied field $H$ has to be reversed from the saturation direction to nucleate the reversed domains, which immediately grow to larger domains and saturate the magnetization by domain wall movement.

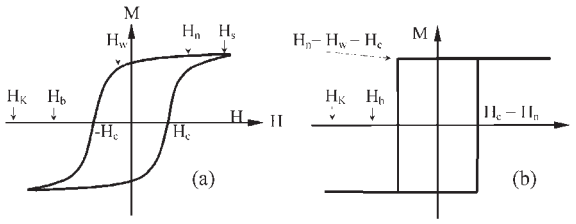

***Figure 10***
Magnetization loops dominated (a) by the field necessary for wall movement and (b) by the nucleation field.

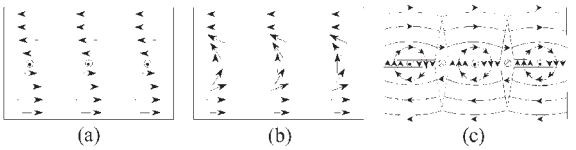

***Figure 11***
Domain walls in thin films: (a) Bloch wall; (b) Néel wall; (c) cross-tie wall.

The magnetization loop of Fig. 10(b) is similar to that along the easy axis of the Stoner–Wohlfarth single-domain theory (Fig. 2(a)) where magnetization reversal is given by coherent switching. In real films coherent switching at $H_{K_u}$ can never occur, as explained by the blocking curve (Fig. 7). Domains are formed and magnetization reversal occurs by domain wall movement. This is very clearly seen, since $|H_c| < |H_{K_u}|$ in all cases. The magnetization reversal in isotropic films with zero uniaxial anisotropy is the same as described above for the easy axis reversal.

In general, the single-domain theory is valid only outside the blocking curve (Fig. 7). The films can be used as sensors without hysteresis, as long as the magnetic field vector does not cross the blocking curve. Coherent switching is impossible.

## 5. *Domain Walls*

Three types of walls are observed in thin films, depending on the film thickness (Kittel 1949, Hubert and Schäfer 1998, Middelhoek 1961). Examples are given below for permalloy films.

(i) Bloch wall, film thickness $d > 50$ nm (Fig. 11(a)). Inside of the walls the magnetic moments rotate around the normal of the walls, avoiding magnetic divergences and stray fields parallel to the film plane. Stray fields perpendicular to the film plane result from magnetic poles at the film surface.

(ii) Néel wall, film thickness $d < 25$ nm (Fig. 11(b)). For thinner films the magnetic self-energy of poles at the film surface is too strong. Within the wall the magnetic moments rotate in the film plane, avoiding the magnetic poles at the surfaces. Instead, the wall creates magnetic divergencies, which increase the wall energy.

(iii) Cross-tie wall, film thickness $\sim 25$–$50$ nm (Fig. 11(c)). This type of wall is a transition between the Néel and Bloch walls.

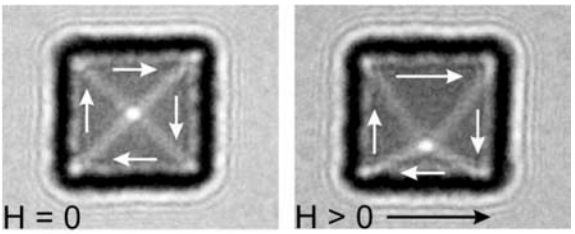

***Figure 12***
Landau–Lifshitz configuration of domains of a squared nanostructure, observed by Lorentz microscopy: (a) remanence; (b) in an applied field (courtesy of M. Schneider).

## 6. *Magnetization Reversal in Nanostructures*

Domain formation in nanostructures is governed by the external demagnetizing field from the film edge. In the remanent state domains are formed to avoid the demagnetizing field.

### *6.1 Rectangular Nanostructures*

Rectangular nanostructures show in the remanent state the ideal Landau–Lifshitz domain configuration that is shown in the Lorentz image of Fig. 12(a). Applying a magnetic field causes an increase of the domain with magnetization parallel to the field and a decrease of the domain with antiparallel magnetization. The vortex in the center of the film is shifted perpendicular to the applied field (Fig. 12(b)).

### *6.2 Circular Nanostructures*

To avoid the demagnetizing field from the edges of the circular nanostructures in the remanent state the magnetization forms a circular flux closure with a vortex in the center of the nanostructure. Figures 13(a) and (b) show the Lorentz image of rotation of the magnetization. Increasing an applied field shifts the vortex perpendicular to the applied field with respect to the film edge (Fig. 13(c)). At the saturation field $H_s$ the vortex collapses. This saturation field is larger than the demagnetizing field $H_d$ at saturation. Decreasing the applied field to zero again leads to circular flux

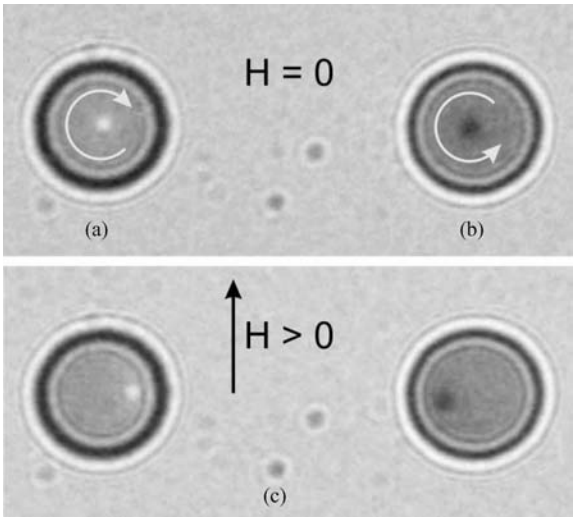

***Figure 13***

closure with a vortex in the center of the structure (see Figs. 13(a) and (b)).

### *6.3 Elliptical Nanostructures*

The shape anisotropy of elliptical nanostructures leads to an easy axis along the major axis. After saturation along the easy axis the structure remains in a single-domain state at zero field (Fig. 14(a)). On applying a reverse field the magnetization breaks up into domains (Fig. 14(b)). Saturation in the reverse field occurs by domain wall motion. These structures are of interest for magnetic storage. For this purpose the formation of domains during magnetization reversal has to be avoided. Much work is in progress to overcome this reversal problem.

## *7. Conclusion*

The interest in ferromagnetic films is rapidly growing because of their application as field sensors in various modes, as magnetic storage material for floppy disks, as nanostructures in MRAMs, and as giant magnetic resistance elements in many applications. In cases of single-domain behavior stability at remanence and after switching the magnetization from one stable state to another is desired. Difficulties arise because of domain formation in the films and nanostructures. This article shows that in any nonideal soft magnetic film domain formation is unavoidable. Future investigations will try to overcome this problem instead of neglecting it.

# Thin Films: Giant Magnetostrictive

Interest in giant magnetostrictive materials in thin film form has grown rapidly over the past few years, owing to their potential as actuators for powerful transducer systems in microsystems, e.g., laser scanners,

micropumps, and ultrasonic motors (Quandt 2000). The development of the corresponding room temperature giant magnetostrictive thin film materials is based on rare earth–transition metal alloys. In general, the rare earth iron-based alloys offer the best chance of developing giant magnetostriction at room temperature or above, since the highly aspherical 4*f* orbitals of the rare earths remain in an oriented state, owing to the strong coupling between the rare earth and the iron moments, resulting in this large room-temperature magnetostriction.

An important task in developing giant magnetostrictive materials has been optimization of magnetostriction to magnetic anisotropy ratio, in order to attain large strains at moderate magnetic fields. In bulk materials it was achieved by using cubic compounds—the rare earth–$Fe_2$ Laves phases—in which the second order anisotropy constant vanishes, also by Tb–Dy alloying in order to compensate the fourth order anisotropy constant (Clark 1980). In the case of thin films, amorphous $(Tb,Dy)_x(Fe,Co)_{1-x}$ films (Duc *et al*. 1996) or especially novel TbFe/FeCo multilayers (Quandt and Ludwig 1999) represent the most promising approaches to combine soft magnetic and giant magnetostrictive properties.

Special attention has to be paid to the sign of the magnetostriction. While terbium-based materials exhibit positive magnetostriction, which means that this material expands in the direction of the external field, samarium-based materials behave in the opposite way, thus allowing an easy design of magnetostrictive bimorphs, which enables the realization of stress- or temperature-compensated bending actuators while further enhancing the overall effect.

The fabrication of giant magnetostrictive thin films was originally realized only by PVD techniques, the most prominently used being magnetron sputtering (Quandt 2000) with either mosaic-type or composite targets as well as multitarget arrangements. Other PVD techniques include electron beam evaporation, laser ablation and ion beam sputtering. The amorphous films are generally deposited onto unheated or cooled substrates, while for crystalline films heated substrates for a single-step process are used as an alternative to a post-deposition crystallization treatment.

For applications, the orientation of the magnetic easy axis and of the domains in the demagnetized state is of special importance, because maximum magnetostriction is only obtained by 90° rotations of the magnetic domains while 180° rotations do not result in any magnetostrictive strain. Considering that magnetostrictive thin film actuators are in general driven by a single magnetic field, the direction of which is fixed in relation to the actuator and in-plane in order to avoid large demagnetization losses, the optimized demagnetized state should consist of domains with an in-plane easy axis being oriented perpendicular to the driving field direction. This initial state can be obtained by a post-deposition annealing process under an in-plane magnetic field which is oriented under 90° towards the driving field direction (Ludwig and Quandt 2000).

Another possibility to influence the direction of the magnetic easy axis of a magnetostrictive film is directly related to the film's stress. Considering the minimum of the magnetoelastic energy for an isotropic ferromagnet

$$E_{\mathrm{me}} = -\tfrac{3}{2}\sigma\lambda_{\mathrm{s}}\cos^2\alpha$$

the orientation of the magnetic easy axis ($\alpha$: angle between the directions of the magnetization and of the application of the stress) depends on the sign of the film stress $\sigma$ for a material with a given saturation magnetostriction $\lambda_{\mathrm{s}}$. This equation implies an in-plane magnetic easy axis for a positive product $\sigma\lambda_{\mathrm{s}}$, while a negative product results in a perpendicular anisotropy. Therefore, in the case of positive magnetostrictive-like terbium-based or FeCo films, tensile stress is required for in-plane anisotropy, whereas negative magnetostrictive samarium-based films should be deposited with compressive stress to result in the same anisotropy. As the sign and the magnitude of the film's stress can be controlled by the fabrication conditions, the thermal expansion coefficient of the substrate, or by stress annealing, an in-plane magnetic easy axis can be adjusted, in general, for all thin film materials.

The in-plane magnetoelastic coupling coefficient $b$ or the magnetostriction $\lambda$ can be measured by the common cantilevered substrate technique using the formula of du Trémolet de Lachesserie and Peuzin, resulting in:

$$b = \frac{\alpha}{L}\frac{h_{\mathrm{s}}^2}{h_{\mathrm{f}}}\frac{E_{\mathrm{s}}}{6(1+\nu_{\mathrm{s}})};\ \lambda = \frac{-b(1+\nu_{\mathrm{f}})}{E_{\mathrm{f}}}$$

where $\alpha$ is the deflection angle of the cantilever as a function of applied field, $L$ is the free length of the cantilever, $E_{\mathrm{s}}$ and $\nu_{\mathrm{s}}$ are the Young's modulus and Poisson's ratio for the substrate, and $h_{\mathrm{s}}$, $h_{\mathrm{f}}$ are the thicknesses of the substrate and film, respectively.

In the following sections, amorphous, nanocrystalline and multilayered state-of-the-art giant magnetostrictive materials in thin film form with positive and negative magnetostriction and applications of these materials are discussed.

## *1. Amorphous Films*

Use of amorphous materials is an important approach to lowering macroscopic anisotropy. In amorphous magnetic rare earth–iron alloys, the contribution of the rare earth–iron interaction results in the formation of a sperimagnetic structure with an ordering temperature above room temperature. In the case of positive magnetostrictive materials, TbFe thin films have been fabricated in a wide composition

range. It was found that increasing the rare earth content compared to the Laves phase composition results in the highest low-field magnetostriction in amorphous thin film materials. Assuming the same local environment in the amorphous compared to the crystalline state, a further approach to reduce the remaining anisotropy should be achievable by Tb/Dy substitution, which was investigated for a wide composition range for rare earth–iron or rare earth–cobalt thin film materials. This approach leads to a further reduction in the magnetic saturation field, but the lower Curie temperature due to the dysprosium alloying leads to a significant reduction in the saturation magnetostriction resulting in no or only a very small gain in low-field magnetostrictive strain of these ternary films.

Since the Curie temperature of amorphous TbFe is still quite low and is thus detrimental to giant magnetostriction to be obtained at higher temperatures, another interesting approach is related to the amorphous TbCo or TbFeCo alloys. Although the crystalline Laves phase $TbCo_2$ orders below 300 K, the ordering temperatures in amorphous TbCo alloys are raised up to 600 K depending on the composition, owing to a strongly ferromagnetically coupled cobalt sublattice with a sperimagnetic structure. In particular, amorphous films of the system Tb–Dy–Fe–Co exhibit very high room temperature magnetostrictions, exceeding $1000 \times 10^{-6}$. Comparison with other amorphous terbium-based thin film materials is shown in Fig. 1.

While $SmFe_2$ bulk materials are normally not considered as actuator materials, owing to the tensile stress required in these materials in order to achieve a suitable alignment of the magnetic domains, this situation is different in thin film bending transducers, which can easier be stressed with different signs. Therefore, amorphous Sm–Fe and Sm–Fe–B thin

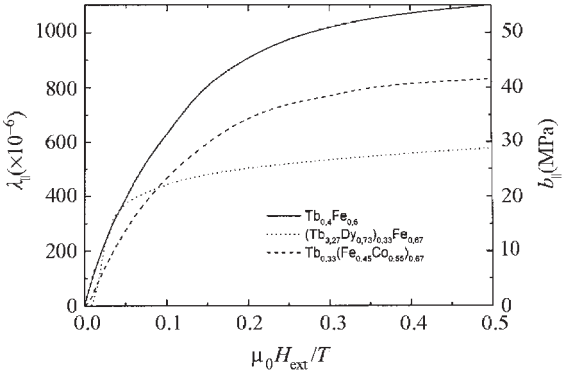

*Figure 1*

films have been investigated over a wide compositional range, showing interesting giant magnetostriction at low external fields, especially in the case of Sm–Fe–B with a boron content of approximately 0.8 at.% (Lim *et al.* 1998), which is shown in Fig. 2 in comparison to an amorphous SmFe thin film.

## 2. *Nanocrystalline Materials*

The major drawback of all amorphous materials are their low Curie temperatures, leading to a limited temperature range of use and to large temperature coefficients of the magnetostriction at room temperature. Since the Laves phase $TbFe_2$ orders at 711 K (Clark 1980), crystallized films of the composition $(Tb_{0.3}Dy_{0.7})Fe_2$ have been investigated in some detail. In general, it has been found that crystallization is accompanied by a coercivity of at least 70 mT, thus requiring large magnetic driving fields. A possibility to overcome these limitations is related to the control of the grain size of the magnetic thin film material, as the random anisotropy model predicts a decrease of the coercivity with the grain size provided that the grain size is smaller than the ferromagnetic exchange length (Winzek *et al.* 1999).

Therefore, giant magnetostrictive materials with nanocrystalline grain structure should allow the combination of high Curie temperatures with soft magnetic properties. In particular, three approaches to realize a nanocrystalline grain structure have been reported: control of the crystallization temperature, addition of additives to enhance grain nucleation, and the use of multilayer structures to limit the grain growth in normal direction. The most promising result has been obtained for TbDyFe/Nb multilayers having a Curie temperature of 560 K and a saturation magnetostriction of $550 \times 10^{-6}$. Their hysteresis is significantly reduced compared to crystalline single

layer materials (Fig. 3), but still reaches 35 mT under optimized preparation conditions.

## 3. Multilayers

Since the magnetic saturation field is proportional to the ratio of the anisotropy and the saturation magnetization, an alternative approach is based on an increase of the saturation magnetization of these materials. The amorphous rare earth transition metal materials used up to now have rather low magnetizations, owing to their ferrimagnetic nature. For the compositions of interest the rare earth moments dominate and thus any decrease of their content will further reduce the magnetization, while an increase results in a lowering of the Curie temperature and consequently a lowering of the room temperature magnetization. However, using multilayers it is possible to engineer new composite materials with properties which overcome these limitations (Quandt and Ludwig 1999).

To create such a composite, two materials have to be combined: one material is the giant magnetostrictive amorphous TbFe alloy, while the other is magnetically soft and has a very high magnetization and, preferably, a considerable magnetostriction itself (e.g., FeCo). Fabricating these layers with thicknesses smaller than the ferromagnetic exchange length and the domain wall width, domain wall formation at the interfaces is prevented and the magnetic properties of such an exchange-coupled multilayer system are determined by the average of those of each individual layer. Although it was found that the layers couple anti-parallelly, an enhancement of the overall magnetization is achievable for certain thickness ratios. Together with the reduction in anisotropy this increase in magnetization results in a significant reduction in the magnetic saturation field. Figure 4 compares the low field magnetoelastic coupling coefficient of an optimized TbFe/FeCo multilayer with a state-of-the-art amorphous TbFe single layer film.

Furthermore, these types of multilayers show two effects which are of interest for the realization of smart actuators: both a significant change of the Young's modulus and of the electrical resistivity with the magnetic field. The Young's moduli of the mulilayers exhibit a distinct increase with the applied magnetic field, of approximately 20% in the case of an annealed TbFe/FeCo multilayer, while this effect is smaller and requires higher magnetic fields in the case of the corresponding amorphous TbFe single-layer materials. The magnetoresistive effect is approximately 0.2% being developed in the same field range as the films' magnetostriction.

## 4. Applications

Giant magnetostrictive materials in thin film form have predominantly been used as various micro-actuators for applications in microsystem technology (Ludwig and Quandt 2000). Their working principle is based on a bending transducer which consists of a film/substrate compound with the substrate being, in general, non-magnetostrictive. Different geometries and boundary conditions are common, the most important being cantilevers, membranes and plates. Upon magnetization the magnetostriction in the film causes the film/substrate compound to bend, similar to the bending of a bimetallic transducer. Commonly, the most important feature of these micro-actuators is their remote-controlled operation. In the following, some examples of these magnetostrictive thin film transducers are explained in more detail.

In the case of cantilevers different applications have been realized, normally by using silicon micro-machining for the fabrication of the cantilevers. The large

bending or deflection of these cantilevers was applied for fluid jet deflectors controlling up to 500 $mls^{-1}$, for magnetic field measurements by detecting the deflection of the cantilever optically, as well as for optical two-dimensional micro-mirrors which employ bending and torsional vibrations driven by two differently oriented magnetic fields. Furthermore, special attention was paid to the development of thermal drift-free actuators either realized by a special design of the micromachined substrate or by combining positive and negative magnetostrictive materials in a bimorph structure.

Magnetostrictive membranes have been used for fluidic micro-components such as micro-valves or micro-pumps, whereas the deflection of the membrane is used either to close or to open the valve outlet or to induce a pressure rise in the pumping chamber. Free plates with magnetostrictive coatings have been employed for the realization of travelling machines or for ultrasonic motors. Both linear and rotating standing wave motors were realized with micro-machined silicon or titanium substrates using a propulsion mechanism of vibrating teeth on a friction layer. The ultrasonic motors were operated by a.c. magnetic fields in combination with a magnetic bias field.

As a completely different application, giant magnetostrictive thin films can be used in scanning probe microscopy for magnetic field imaging. This technique has been demonstrated in the case of the magnetic field distribution of a hard-disk read–write head by coating this device and measuring the magnetic field induced change in the thickness of the coating due to the magnetostriction.

These different applications demonstrate the potential that giant magnetostrictive thin film materials have for the realization of micro-actuators and micro–sensors. It is expected that further application areas can be addressed by using the novel giant magnetostrictive multilayers, owing to their higher magnetostrictive susceptibility, their higher Curie temperature and their additional features, e.g., their change of resistivity and Young's modulus in a magnetic field.

## Transition Metal Oxides: Magnetism

For practical applications the most important magnetic transition metal oxides are ferrites. In addition, manganites with perovskite structure and chromium dioxide are also important. Oxides in which magnetism is connected with the presence of *f* electrons are discussed elsewhere (see *Localized 4f and 5f Moments: Magnetism*).

A convenient feature of ferrites is that their magnetic properties can be well controlled. This is connected with the fact that the magnetic part of the free energy has a good approximation in a single ion character, i.e., it is a sum of the contributions of individual ions present in the system. As a rule there are several crystallographic sublattices occupied by cations with a large number of possible combinations of cation types and concentrations. By choosing the proper combination the desired properties may be then achieved.

There are numerous reviews of magnetism and the properties of transition metal oxides. A good review with an accent on applications was written by McCurrie (1994). Ferrites with the spinel structure were considered by Krupička and Novák (1982) and Brabers (1995), while those with the garnet and magnetoplumbite structure were discussed by Winkler (1981) and Kojima (1982), respectively. Recent experimental results for the mixed valence manganites were reviewed by Ramirez (1997).

### *1. Basic Interactions of Localized Electrons*

In most of the magnetic oxides the 3*d* electrons of the iron group transition metal ions may be treated as localized. The exceptions are usually connected with the mixed valence, i.e., with the presence of two different valence states of the same atom on crystallographically equivalent sites. Even in these cases, however, the localized picture provides a convenient starting point. The interactions important for the

magnetism of systems with localized $3d$ electrons are discussed below.

### *1.1 Intra-atomic Coulomb Interaction*

This interaction makes the occupation of an orbital state by two electrons with opposite spins energetically unfavorable. A consequence is the First Hund's rule according to which the ground state of a free ion corresponds to the maximal total spin $S$. Between terms having the same $S$, the term with the maximum total angular momentum $L$ is energetically most stable (Second Hund's rule). The energy intervals between terms characterized by their $L$ and $S$ values are of the order of electron volts. In particular the ground state of the $Fe^{3+}$ ion is $^6S$ ($S=5/2$, $L=0$) and the first excited term $^4G$ ($S=3/2$; $L=4$) is at $\sim 4\,\text{eV}$.

### *1.2 Crystal and Ligand Field*

In crystals the electrons of a magnetic ion are subjected to the electrostatic crystal field and due to the covalency the $2s$ and $2p$ electrons of oxygen ligands are transferred to the empty states of the magnetic ion. Both these effects lead to the splitting of the energy levels of the ion. The corresponding interaction has a single electron character and it is described by an effective Hamiltonian:

$$\hat{H}_{\text{CF}} = \sum_{k=0}^{2l} \sum_{q=-k}^{k} B_{k,q} \hat{t}_{k,q} \tag{1}$$

where $B_{k,q}$ is the crystal field coefficient and $\hat{t}_{k,q}$ is the one electron irreducible tensor operator, which can be expressed in terms of the electron orbital momentum operator $\hat{l}$. The Hamiltonian $\hat{H}_{\text{CF}}$ reflects the local symmetry of the ion site. For the $d$ electrons ($l=2$), in the important case of the octahedral symmetry, Eqn. (1) reduces to:

$$\hat{H}_{\text{CF}} = \frac{B_4}{60}[35\hat{l}_z^4 - 30l(l+1)\hat{l}_z^2 + 25\hat{l}_z^2 - 6l(l+1) + 3l^2(l+1)^2 + \tfrac{5}{2}(\hat{l}_+^4 + \hat{l}_-^4)] \tag{2}$$

which splits a quintuplet of $d$-orbital states into a lower lying triplet, denoted as $t_{2g}$, and doublet $e_g$. The splitting between the doublet and the triplet is of the order of electronvolts and $\hat{H}_{\text{CF}}$ is thus comparable to the intra-atomic Coulomb interaction. In the tetrahedral symmetry the quintuplet is again split into a doublet $e$ and a triplet $t_2$, with the doublet having a lower energy. If the local symmetry is lower than cubic, more terms are present in $\hat{H}_{\text{CF}}$ causing additional splitting of the orbital states.

### *1.3 Spin-orbit Coupling*

The spin-orbit coupling is an intra-atomic relativistic interaction, which couples the electron spin with its orbital momentum. It may be approximated by:

$$\hat{H}_{ls} = \zeta(\vec{l}\ \vec{s}) \tag{3}$$

For the iron group ions the spin-orbit coupling parameter $\zeta$ is of the order of $1\times10^{-2}$–$1\times10^{-1}\,\text{eV}$ and $\hat{H}_{ls}$ is thus smaller compared to the intra-atomic Coulomb and crystal field interactions.

### *1.4 Vibronic Interaction, Jahn–Teller Effect*

The vibronic (electron–lattice) interaction is especially important for ions, which have the orbitally degenerate ground state in the given crystal environment. As shown by Jahn and Teller a coupling term, linear in displacement of ions (''force''), then appears in the Hamiltonian. In the static treatment, which neglects the kinetic energy of ions, the local symmetry is then lowered by a spontaneous distortion of the environment (static Jahn–Teller effect). The static treatment is appropriate for systems with a large concentration of Jahn–Teller ions, where the co-operative interaction leads to lowering of the crystal symmetry. If a Jahn–Teller ion is isolated in an otherwise ideal lattice, the symmetry of its environment remains unchanged. However, in wave functions the electron and lattice coordinates become inexorably mixed, leading to a significant modification of the behavior observed, e.g., the spin-orbit coupling is quenched (dynamic Jahn–Teller effect).

Examples of ions exhibiting strong Jahn–Teller effects are $Mn^{3+}$, $Cr^{2+}$, and $Cu^{2+}$ ions in the octahedral co-ordination and the tetrahedral $Fe^{2+}$ ion.

### *1.5 Exchange Interaction*

The dominant mechanisms of the exchange interaction in magnetic oxides are connected with the transfer of electrons between the magnetic ions via the intervening oxygen ligands. Such ''supertransfer'' depends on the mutual orientation of the spins and on the occupations of the electron orbitals. Owing to the Pauli principle, the transfer can occur in the case of half-filled orbitals only for antiparallel spins, hence the antiparallel spin orientation is favored. This is the strongest exchange mechanism in ferrites leading to ferrimagnetism or antiferromagnetism. If one of the orbitals in question is empty, transfer of electrons with both spin orientations is allowed, but, because of the intra-atomic exchange interaction (First Hund's rule), the parallel orientation is preferred. This mechanism thus leads to ferromagnetic ordering. A particular case of the latter interaction occurs when the two orbital states have the same energy, as in the manganite perovskites with mixed $Mn^{3+}$–$Mn^{4+}$ valence. The $Mn^{3+}$–$Mn^{4+}$ pair may be treated as $Mn^{4+}$–$Mn^{4+}+e^-$ with the $Mn^{4+}$ centers being equivalent. The tendency to ferromagnetism is then

strong, and the interaction is in this case called the double exchange (e.g., Kubo and Ohata 1972).

The exchange interactions listed above are isotropic and the corresponding effective Hamiltonian has the Heisenberg form:

$$\hat{H}_{\text{ex}} = -\sum_i \sum_{j \neq i} J_{ij} \vec{\hat{S}}_i \vec{\hat{S}}_j \tag{4}$$

For the double exchange this form is only a rough approximation, because the biquadratic and higher-order terms are important too. The exchange integral $J_{ij}$ is a sensitive function of the angle between the $M_i$-oxygen and the $M_j$-oxygen bonds in the $M_i$-oxygen-$M_j$ triad and it also depends on the orbital states in question. In particular, if either the $M_i$ or the $M_j$ cation has an orbitally degenerate state, $J_{ij}$ must be treated as an operator in the orbital space.

In combination with the spin-orbit and crystal-field terms the exchange interaction (Eqn. (4)) yields anisotropic terms in the effective Hamiltonian, which may be expressed in the pseudodipolar or/and Dzyaloshinski–Moriya form:

$$\hat{H}_{\text{psdip}} = \vec{\hat{S}}_i \bar{T} \vec{\hat{S}}_j; \quad \hat{H}_{\text{DM}} = D[\vec{\hat{S}}_i, \vec{\hat{S}}_j] \tag{5}$$

where $\bar{T}$ is a traceless tensor (e.g., Kanamori 1963).

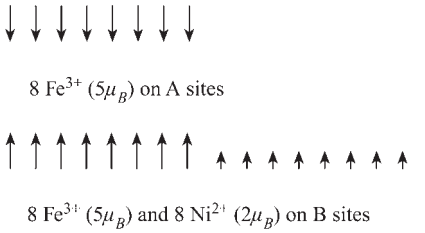
## 2. *Crystal and Magnetic Structure*

A convenient representation of the crystal structures of the magnetic oxides is provided by the interconnected polyhedra as showed in Figs. 1(a)–(d). The centers of the polyhedrons (tetrahedrons, octahedrons, dodecahedrons, or bipyramids) are occupied by the cations, while the oxygen ligands are situated in their corners.

### 2.1 *Spinels*

Spinel ferrites $MFe_2O_4$ have a cubic crystal symmetry with eight formula units in the unit cell. There are two cation sublattices—tetrahedral (A) and octahedral (B). In spinel ferrites with a normal structure (e.g., $Zn^{2+}[Fe_2^{3+}]O_4$)$M^{2+}$ ions occupy the A sublattice, while the B sublattice is filled by the $Fe^{3+}$ ions. In the inverse spinel ferrites the $M^{2+}$ ions are in the B sublattice (M = Ni, Co, or Fe). For M = Mn, Mg, or Cu the M ions are in both the A and B sublattice and their distribution may be influenced by the thermal treatment. The $Fe^{3+}$ ions may be substituted by other trivalent magnetic ($Mn^{3+}$, or $Cr^{3+}$) or nonmagnetic ($Ga^{3+}$, or $Al^{3+}$) ions. Other possibilities are represented by the Li-ferrite, $Fe^{3+}[Li_{0.5}^{1+}Fe_{1.5}^{3+}]O_4$, and maghemite, $\gamma$-$Fe_2O_3$-$Fe^{3+}[\square_{1/3}Fe_{5/3}^{3+}]O_4$ (where $\square$ represents the cation vacancy).

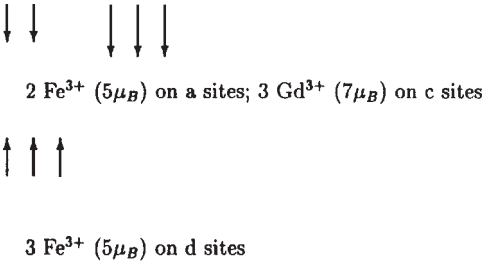
The dominating magnetic coupling in the spinel ferrites is the antiferromagnetic A–B superexchange interaction, leading to ferrimagnetic ordering. The magnetic structure of nickel ferrite is thus:



### 2.2 *Garnets*

The ferrites with the garnet structure $R_3Fe_5O_{12}$ (R may be, for example, yttrium, trivalent rare-earth ion, or bismuth) are cubic compounds with eight formula units in the unit cell. The $Fe^{3+}$ ions occupy 16 tetrahedral (d) sites and 24 octahedral (a) sites. The $R^{3+}$ ions fill 24 dodecahedral (c) sites. The ion distribution is thus $\{R_3^{3+}\}[Fe_2^{3+}](Fe_3^{3+})O_{12}^{2-}$. Iron can be *fully* substituted by some other trivalent cations (e.g., $Al^{3+}$, or $Ga^{3+}$), or *partly* by tetravalent ($Si^{4+}$, or $Ge^{4+}$) or bivalent ($Co^{2+}$, or $Mg^{2+}$) ions. If the substitute is not trivalent, the charge neutrality is maintained by the change of the iron valence. The bivalent cations (e.g., $Ca^{2+}$, $Sr^{2+}$, or $Mn^{2+}$) may also enter the c sublattice.

The dominating magnetic coupling in the garnet ferrites is the antiferromagnetic a–d superexchange interaction, leading to a ferrimagnetic ordering of Fe(a) and Fe(d) spins. The spin of the rare-earth ions on the c sublattice is antiparallel to the Fe(d) spin. The magnetic structure of $Gd_3Fe_5O_{12}$ is:



$Gd^{3+}$ is an *S*-state ion with zero-orbital momentum in the ground state. The exchange interactions in $Gd_3Fe_5O_{12}$ are thus isotropic and the magnetic structure is collinear. In other rare-earth iron garnets the magnetic moments of individual $R^{3+}$ ions are not parallel to the magnetization forming so called umbrella structure.

### 2.3 *Hexagonal Ferrites*

The most important hexagonal ferrites $M_2Fe_{12}O_{19}$ (M = Ba, Sr, or Pb) have the magnetoplumbite structure. The unit cell contains two formula units, and

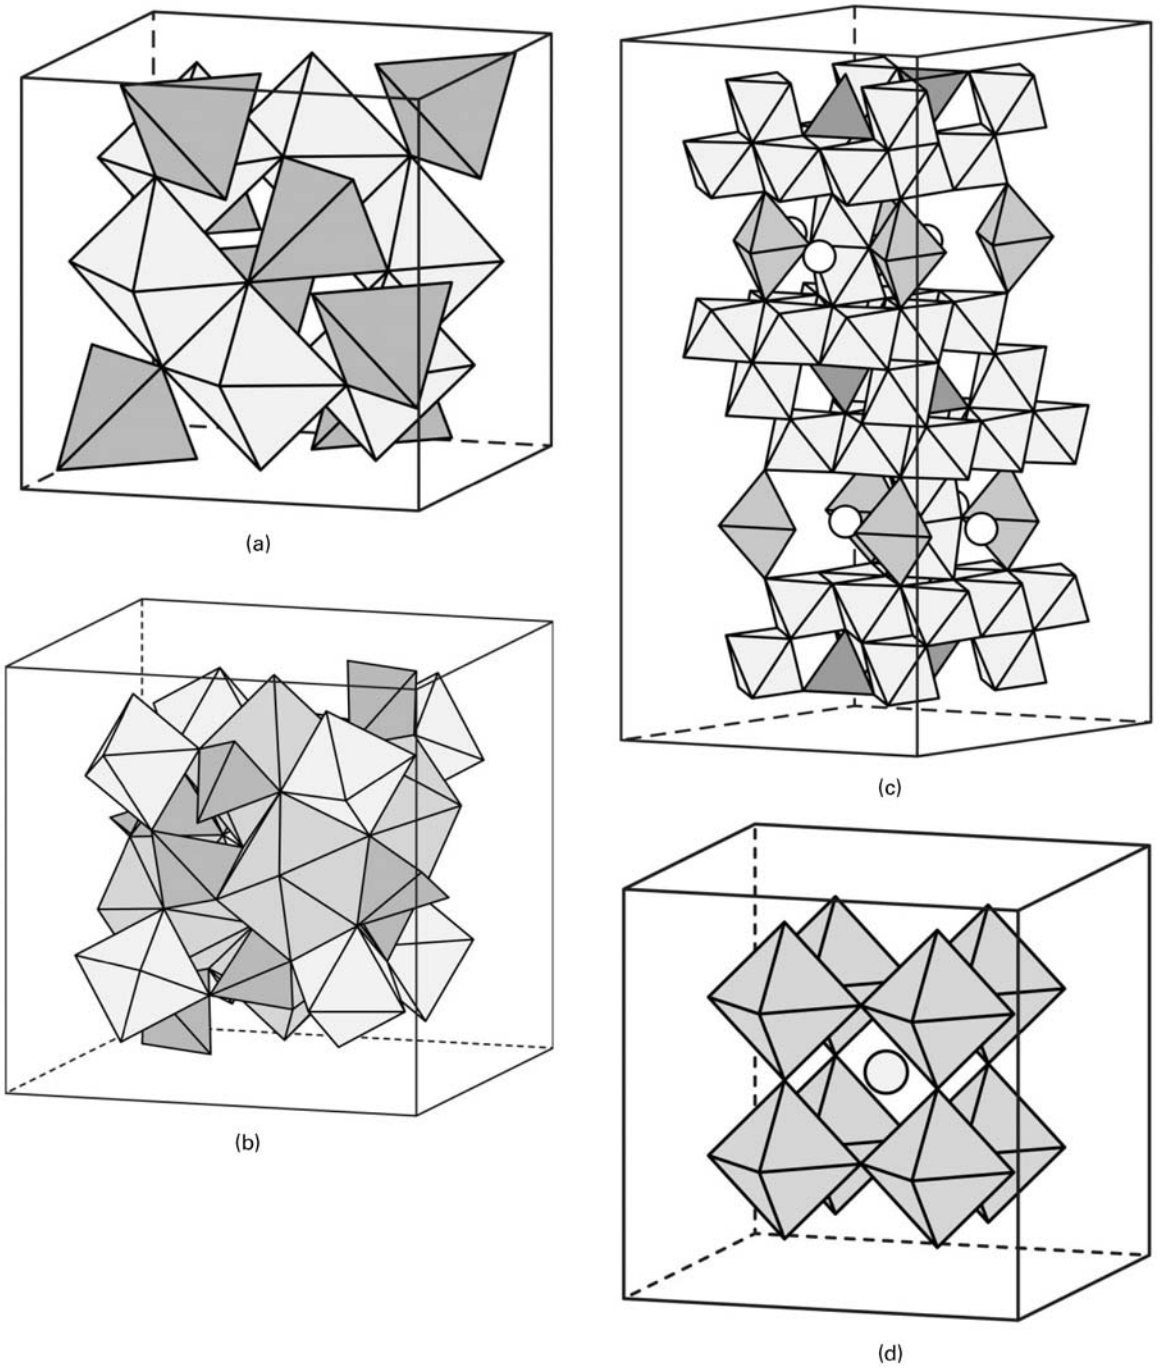


***Figure 1***

| Spin | Up | Up | Down | Down | Up |

can be divided into four blocks designated as **SRS*R***. The **S** block has the spinel structure, while symmetry of **R** is rhombohedral. Asterisk means a rotation of the block by $\pi$ around the hexagonal axis. There are five sublattices occupied by $Fe^{3+}$ ions. The superexchange interactions, all of an antiferromagnetic character (Novák *et al*. 1989), lead to a collinear ferrimagnetic ordering of spins (Table 1). Substitution of various cations in all the Fe sublattices as well as in the M sublattice can be made. Technological applications of these materials are described in *Alnicos and Hexaferrites*.

Hexagonal ferrites with a more complicated structure contain a hexagonal block **T**, in addition to blocks **R** and **S**. Examples are W, Y and Z hexaferrites with the chemical compositions $BaM_2Fe_{16}O_{27}$, $Ba_2M_2Fe_{12}O_{22}$, and $Ba_3M_2Fe_{24}O_{41}$, respectively.

### 2.4 Perovskites

The most important transition metal perovskites are orthoferrites $RFeO_3$ (where R is yttrium or a rare-earth ion) and mixed valence manganites $R_{1-x}M_xMnO_3$ (where M is a bivalent or monovalent cation such as $Ca^{2+}$, $Sr^{2+}$, $Ba^{2+}$, $Pb^{2+}$, $Na^+$, and $K^+$). All these compounds have a distorted perovskite structure. The $Fe^{3+}$, $Mn^{3+}$, and $Mn^{4+}$ ions are octahedrally coordinated while the R and M ions have 12 oxygen ligands. The orthoferrites are basically antiferromagnetic, but there is a weak ferromagnetism due to a canting (about 0.5°) of the antiferromagnetically oriented $Fe^{3+}$ spins.

In manganites containing bivalent M ions the ion distribution is $(R^{3+}_{1-x}M^{2+}_x)(Mn^{3+}_{1-x}Mn^{4+}_x)O^{2-}_3$. If $x$ is smaller than $\approx 0.1$ an antiferrodistortive ordering of the local Jahn–Teller deformations associated with the $Mn^{3+}$ ions exists. The systems are nonmetallic and antiferromagnetic. For higher M concentrations the double-exchange interaction prevails over the superexchange, the systems are then metallic-like and ferromagnetic. The Curie temperature depends on the difference of $R^{3+}$ and $M^{2+}$ ionic radii and it reaches $\sim 370$ K in the (LaSr) system. A rich phase diagram exists for $x \approx 0.5$. Depending on the $R^{3+}$ and $M^{2+}$ cations the system may exhibit a $Mn^{3+}$–$Mn^{4+}$ charge ordering and it is then nonmetallic and antiferromagnetically ordered. In other cases ferromagnetic ordering and the metallic-like conductivity is observed.

### 2.5 Chromium Dioxide

$CrO_2$ has a rutile structure with two formula units per unit cell. It is an unusual transition metal oxide as it is ferromagnetic, rather than ferrimagnetic. The tetravalent state of chromium is expected with the electron configuration $[Ar]3d^2$. The magnetic moment per unit cell is then $4\,\mu_B$ (assuming that the orbital angular momentum is quenched by the crystal field) in reasonable agreement with the experimental data.

## 3. Important Properties

### 3.1 Temperature Dependence of Magnetization

In the molecular field approach the temperature dependence of the sublattice magnetizations of a ferrimagnetic system is calculated from the coupled system of equations:

$$\vec{B}_\alpha = \sum_\beta \lambda_{\alpha\beta}\vec{M}_\beta; \quad M_\alpha(T) = M_\alpha(0)\boldsymbol{B}_{S_\alpha}(x_\alpha);$$
$$x_\alpha = (g_\alpha \mu_B S_\alpha / kT)B_\alpha \qquad (6)$$

where $\vec{M}_\alpha$ is the magnetization of the sublattice $\alpha$, $\lambda_{\alpha\beta}$ are the molecular field coefficients, connected with the exchange integrals $J_{ij}$ (see Eqn. (4)) by:

$$\lambda_{\alpha\beta} = \frac{2z_{ij}J_{ij}}{n_j g_i g_j \mu_B^2} \qquad (7)$$

the site $i(j)$ belongs to the sublattice $\alpha(\beta)$, $z_{ij}$ is the number of neighbors, $n_j$ is the number of $j$-type sites for whatever is the quantity of material to which the magnetization is related. $g_i$, $g_j \approx 2$ are the respective $g$-factors. $\boldsymbol{B}_S$ is the Brillouin function. For a ferrimagnetic system with two magnetic sublattices, three possible types of the $M(T)$ dependence are obtained (Fig. 2).

In systems where the double exchange dominates, the molecular field approach leads to a different set of equations (see Kubo and Ohata 1972). The $M(T)$ dependence is more convex, compared to a system described by the Heisenberg–Hamiltonian.

### 3.2 Magnetocrystalline Anisotropy

The main mechanism which gives rise to the magnetocrystalline anisotropy originates from the interplay

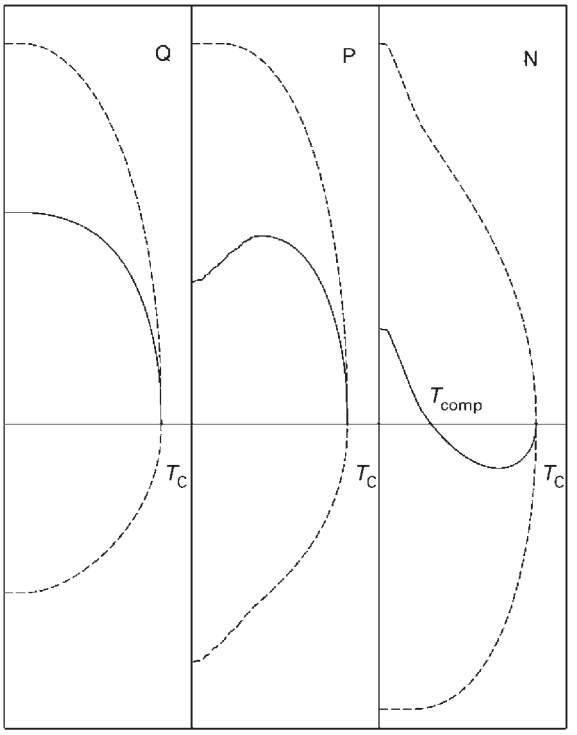

***Figure 2***
Three types of temperature dependence of the magnetization in a two-sublattice ferrimagnet. Dashed curves correspond to the magnetizations of the sublattices. Full curve is the total magnetization. $T_{comp}$ denotes the compensation temperature.

of the crystal field, spin-orbit, and exchange interactions. The anisotropic part of the free energy then has a single ion character, i.e., it may be expressed as the sum of the contributions of individual magnetic ions, present in the system, the same holds also for the anisotropy constants. A large contribution give ions the orbital moment of which is not quenched by the crystal field. Examples are the $Co^{2+}$ and $Fe^{2+}$ ions in the octahedral co-ordination and all trivalent lanthanide ions, with the exception of $La^{3+}$, $Gd^{3+}$, and $Lu^{3+}$.

The temperature dependence of the single ion contribution $k$ to the anisotropy constant follows the $l(l+1)/2$ law:

$$\frac{k(T)}{k(0)} = \left[\frac{m(T)}{m(0)}\right]^{l(l+1)/2} \tag{8}$$

where $m(T)$ is the magnetic moment of the ion at temperature $T$, $l=2$ and 4 for the first anisotropy constant in the axial and cubic symmetry, respectively.

In systems with symmetry lower than cubic the dipolar and anisotropic exchange interactions may also contribute to the magnetocrystalline anisotropy. In many ferrites with nominally cubic symmetry an axial magnetocrystalline anisotropy may be induced by annealing the system in a magnetic field.

### *3.3 Electrical Conductivity and Magnetoresistance*

In many transition metal oxides the same cation may exist in several different valence states. Such a 'mixed valence' situation is connected with the presence of oxygen or cation vacancies and/or caused by cation substitution. An example is the $Y_3Fe_5O_{12}$ garnet (YIG), in which all cations are trivalent, providing the system is ideally stoichiometric. Substitution of $Si^{4+}$ for $Fe^{3+}$ in the tetrahedral sublattice then induces the change of valency of the octahedral Fe ion $Fe^{3+} \rightarrow Fe^{2+}$.

The charge carriers are in most cases described as polarons (electrons or electron holes plus the lattice distortion) moving by hopping or in a band. The electrical conductivity may be of n-type (e.g., YIG:Si) or p-type (e.g., YIG:Ca) and it can be very low in nearly stoichiometric compounds ($10^{-11}$ c in YIG at 300 K, see Winkler 1981). A special case is represented by magnetite $(Fe^{3+})[Fe^{3+}Fe^{2+}]O_3$ with the equal number of ferrous and ferric cations in the octahedral sublattice. The d.c. conductivity of $Fe_3O_4$ is larger than $10^2\,\Omega^{-1}cm^{-1}$ at 300 K.

The importance of the ferromagnetic, metallic-like mixed valence manganites (see Sect.2.4) is increasing. Above $T_C$ the conductivity in these compounds has a hopping character, while below $T_C$ it is metallic-like. At temperatures close to $T_C$ an external magnetic field markedly influences the spin configuration and has a large effect on the electrical conductivity, leading to "colossal" magnetoresistance.

### *3.4 Optical and Magneto-optical Properties*

At long wavelengths $\lambda > 1.5\,\mu m$ the optical absorption in ferrites is mainly caused by the lattice vibrations. Between $\sim 1.5$–$5.0\,\mu m$ the so-called infrared window exists, in which the absorption coefficient $\alpha$ can be very low ($\alpha < 0.03\,cm^{-1}$ for the yttrium iron garnet). At shorter wavelengths the absorption increases due to the electronic transitions between the states of the transition metal ions as well as the charge transfer transitions involving the oxygen ligands. If the rare earth ions are present, characteristic absorption bands appear in the far infrared region. The absorption is also very sensitive to the presence of the charge carriers ($Fe^{2+}$ or $Fe^{4+}$ ions).

The rotation of the plane of linearly polarized light (Faraday effect) was most thoroughly studied in garnet ferrites (see Winkler 1981). The specific Faraday rotation $\theta_F$ lies in the range from $1 \times 10^2$–$1 \times 10^5\,^\circ cm^{-1}$ and it depends on the wavelength of the light beam, temperature, composition of the

garnet, external magnetic field, etc. $\theta_F$ is strongly enhanced by the presence of the $Bi^{3+}$ ion in the dodecahedral sublattice.

## Transparent Rare Earth Compounds: Magnetic Circular Dichroism

Magnetic circular dichroism (MCD) is the difference in molar absorptivities for left and right circularly polarized light, $\Delta\varepsilon = (\varepsilon_{LCP} - \varepsilon_{RCP})$, and is measured as a function of frequency (or wavenumber) on samples placed in a longitudinal magnetic field. In this chapter, MCD spectroscopy of transparent rare-earth compounds in the solid and liquid state is described, with special emphasis on the MCD spectra of trivalent europium ions. The majority of the MCD studies on trivalent rare-earth ions have been devoted to the $Eu^{3+}$ ion. The trivalent $Eu^{3+}$ ion ($4f^6$ electronic configuration) has the advantage of a nondegenerate ground state ($^7F_0$) and the presence of excited states with a small total angular momentum $J$ (e.g. $^5D_1$ and $^5D_2$). This makes the MCD spectrum of $Eu^{3+}$ relatively easy to interpret, in comparison with the MCD spectra of the other trivalent rare-earth ions. The $Eu^{3+}$ MCD spectrum is dominated by signals which have the shape of the first derivative of a Gauss-curve. These signals are the so-called *A*-terms. An *A*-term can have a positive or negative sign. A positive *A*-term has its positive lob at the high wavenumber side of the spectrum.

In this case, the absorption of left circularly polarized light takes place at a higher energy (or wavenumber) than the absorption of right circularly polarized light. For a negative *A*-term, the reverse is true. As will be discussed further, the sign of the *A*-terms in the MCD spectrum depends on the symmetry of the first coordination sphere around the $Eu^{3+}$ ion. The information obtained by MCD is similar to what can be extracted from a classical Zeeman spectroscopy experiment, where the splitting and mixing of energy levels in a magnetic field are studied. However, MCD can also be measured in the case of broad absorption bands. Typical MCD applications are the assignment of electronic transitions, measurement of the Zeeman splitting, investigation of magnetic and symmetry properties of electronic states, polarization studies and testing the reliability of crystal-field wave functions and intensity parameters. An MCD spectrum has a higher information content than the corresponding absorption spectrum, since in addition to the intensity, the MCD signal is characterized by a sign (positive or negative). MCD is an excellent method for detecting the presence of overlapping transitions in the absorption spectrum. The method is very sensitive to changes in the electronic structure, and therefore to changes in the physical structure.

### 1. Measurement of MCD Spectra

The measurement of MCD spectra is rather similar to the measurement of absorption spectra. The primary differences are that the radiation incident on the sample must be circularly polarized and that the sample is placed in a longitudinal magnetic field (magnetic field lines parallel to the light beam). Most magnetic circular dichroism spectrometers are circular dichroism spectrometers extended with a magnet, although some instruments are especially designed for MCD measurements. A permanent magnet, electromagnet or superconducting magnet can be used. The permanent magnet has the disadvantage that the magnetic field is rather weak and that the magnetic field cannot be switched off for CD measurements. An electromagnet is often the best choice, because it can produce a moderate magnetic field (ca. 1 T), it can be switched off and it is simple in use. A superconducting magnet can provide a strong magnetic field (typically 5–7 T), but cooling with liquid helium is necessary. The light beam from the light source is first linearly polarized and then circularly polarized

by a Pockels cell or photoelastic modulator. Typically, MCD instruments have a single-beam setup.

There are some constraints on the samples which can be used in MCD measurements. The circular polarization of the incident light beam may only be altered by sample absorption, resulting in elliptically polarized light. This means that MCD can only be recorded for optical isotropic samples or in an isotropic direction for anisotropic samples. Solutions will give no problems. Cubic crystals and especially glasses have to be checked for the absence of internal stress. Uniaxial crystals can be measured along the unique optic axis. In this case, adequate orientation of the sample is crucial. In principle, MCD spectra of biaxial crystals cannot be measured. Finally, it is difficult to record the MCD spectrum of powdered samples, because of the effects of light scattering.

MCD data are obtained with an MCD spectrometer in terms of *ellipticities* $\theta$ (in millidegrees). The relation between $\theta$ and $\Delta\varepsilon$ is given by the expression:

$$\theta = \frac{33000\Delta\varepsilon}{lC} \tag{1}$$

where $l$ is the optical path length (in cm) and $C$ is the concentration (in molL$^{-1}$).

## 2. Basis MCD Theory

An elaborate discussion of the theory of MCD can be found in the work of Stephens (1970, 1974, 1976) and of Piepho and Schatz (1983). MCD spectra find their origin in the magnetically induced optical activity, due to the Zeeman effect. The Zeeman effect predicts that all the energy level degeneracy is lifted in the presence of a magnetic field. In the case of a rare-earth ion coordinated by ligands according to a defined geometry, the energy levels in question are the levels obtained after introduction of the crystal-field perturbation on the free-ion levels. The Hamiltonian of such a system can be written as:

$$H = H_0 + H'_{\mathrm{ER}} + H'_{\mathrm{SOC}} + H'_{\mathrm{CF}} + H'_{\mathrm{Zeeman}} \tag{2}$$

where $H_0$ is the Hamiltonian in the central-field approximation, $H'_{\mathrm{ER}}$ is the electron repulsion Hamiltonian (the prime indicates that the Hamiltonian describes a perturbation), $H'_{\mathrm{SOC}}$ is the spin-orbit coupling Hamiltonian, $H'_{\mathrm{CF}}$ is the crystal-field Hamiltonian and $H'_{\mathrm{Zeeman}}$ is the Zeeman Hamiltonian. The wavefunctions are those which diagonalize the total Hamiltonian (including the Zeeman effect). In an MCD measurement, the magnetic field is applied parallel to the propagation direction of the light. The propagation direction is called $z$; therefore the magnetic field component to be considered is $\mathbf{H}_z$. In a crystal with the principal site symmetry axis parallel to $z$, the Zeeman levels are described and labeled with respect to this $z$-axis.

According to a notation used by Judd (1962), the Zeeman levels of the ground state can be written as:

$$\langle A_\alpha| = \sum_M \langle 4f^N\ \psi\ JM|a_M \tag{3}$$

where $A$ is a crystal field level with Zeeman component $\alpha$, $a_M$ are coefficients, $4f^N$ indicates the $4f^N$ configuration with $N$ electrons in the valence shell, $\psi$ is an additional quantum number, $J$ is the total angular momentum, and $M$ is the $z$-component of $J$. For the excited state, an analogous expression can be written:

$$|A'_{\alpha'}\rangle = \sum_{M'} a'_{M'}|4f^N\ \psi' J'\ M'\rangle \tag{4}$$

For the discussion of the MCD signals it is sufficient to consider only the $M$ quantum numbers:

$$\langle A_\alpha| = \sum_M \langle M|a_M \tag{5}$$

$$|A'_{\alpha'}\rangle = \sum_{M'} a'_{M'}|M'\rangle \tag{6}$$

If the rare-earth ions are in an uniaxial single crystal with the main symmetry axis parallel to the propagation direction of the light, light absorption only takes place in the $xy$ plane. For an electric dipole transition, the operators are:

absorption of RCP :

$$m_{+1} = \frac{-1}{\sqrt{2}}(m_x + im_y) = -|e|D^{(1)}_{+1} \tag{7}$$

absorption of LCP :

$$m_{-1} = \frac{1}{\sqrt{2}}(m_x - im_y) = -|e|D^{(1)}_{-1} \tag{8}$$

where $m_x$, $m_y$ are the electric dipole operators for light polarized according to the $x$ or $y$ directions, and $|e|$ is the absolute charge of the electron. $D^{(1)}_\rho$ is a tensor of rank 1, with polarization numbers $\rho = +1$ for RCP and $\rho = -1$ for LCP. In the case of a magnetic dipole transition, the operators are:

absorption of RCP :

$$\mu_{+1} = \frac{-1}{\sqrt{2}}(\mu_x + i\mu_y) = \frac{-|e|}{2mc}(L + 2S)^{(1)}_{+1} \tag{9}$$

absorption of LCP :

$$\mu_{-1} = \frac{1}{\sqrt{2}}(\mu_x - i\mu_y) = \frac{-|e|}{2mc}(L + 2S)^{(1)}_{-1} \tag{10}$$

where $m$ is the electron mass, $c$ is the speed of light, $L$ is the orbital angular momentum and $S$ is the spin angular momentum. Since the Zeeman components are characterized by the quantum numbers $M$, one can understand that circularly polarized light induces transitions between Zeeman levels. Depending on the quantum number $M$ of the ground state $\langle A_\alpha|$ and

the quantum number $M'$ of the excited state $|A'_{\alpha'}\rangle$, either left circularly polarized light (LCP, $\rho = -1$) or right circularly polarized light (RCP, $\rho = +1$) can be absorbed preferentially. The conditions for absorption in terms of $M$, $M'$ and $\rho$ can be formulated by *selection rules*.

The relative order of the splitting of a $J$-level by a magnetic field in its $M$ components is defined by the Landé-factor $g$:

$$g = 1 + \frac{J(J+1) - L(L+1) + S(S+1)}{2J(J+1)} \qquad (11)$$

If $g$ is positive, the *sign of the A-term* of $Eu^{3+}$ is determined by the *sign of the M′ quantum number* used to label the Zeeman level to which *left circularly polarized light* is absorbed. If $g$ is negative, the absorption of right circularly polarized light has to be evaluated. For the observable $^{2S+1}L_J$ levels of $Eu^{3+}$, $g$ is always positive.

## 3. MCD Selection Rules

### 3.1 Electric Dipole Transitions

Although no electric dipole transitions can occur for $Eu^{3+}$, it is instructive to start with this case. The classical example to illustrate the MCD signal of an electric dipole transition is the $^1P \leftarrow {}^1S$ transition. In a magnetic field, the $^1P$ state splits into three components: $^1P_{+1}$ ($|M'\rangle = |+1\rangle$), $^1P_0$ ($|M'\rangle = |0\rangle$) and $^1P_{-1}$ ($|M'\rangle = |-1\rangle$). The selection rule, which can be obtained by evaluating 3j symbols in the transition moment integral, is:

$$\Delta M = M' - M = -\rho \qquad (12)$$

When the ground state is characterized by $\langle M| = \langle 0|$, as in the case of $^1S_0$, the selection rule is reduced to:

$$\Delta M = M' = -\rho \qquad (13)$$

In other terms, left circularly polarized light ($\rho = -1$) is absorbed to the upper Zeeman component characterized by $|M'\rangle = |+1\rangle$ ($g$ is positive). For the same reason, right circularly polarized light is absorbed to the lower Zeeman component $|M'\rangle = |-1\rangle$. The corresponding MCD signal will be a positive $A$-term.

### 3.2 Magnetic Dipole Transitions

The same considerations as for an electric dipole transition, lead to the selection rule for a magnetic dipole transition:

$$\Delta M = M' - M = -\rho \qquad (14)$$

which can be rewritten in the case that the ground state is characterized by $\langle M| = \langle 0|$, to:

$$\Delta M = M' = -\rho \qquad (15)$$

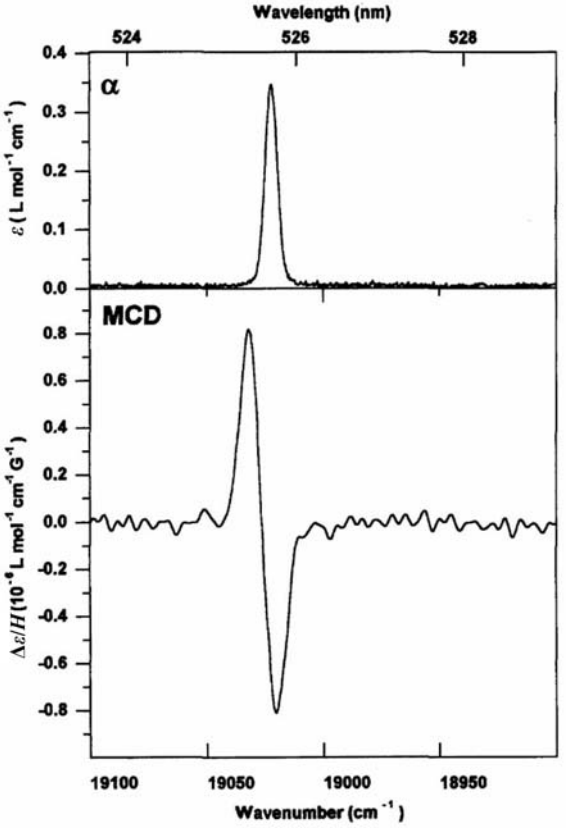

***Figure 1***
MCD and axial absorption spectra of the $^5D_1 \leftarrow {}^7F_0$ magnetic dipole transition of $LiYF_4$:$Eu^{3+}$ at ambient temperature. The $A$-term has a positive sign.

The MCD selection rules for electric dipole and magnetic dipole transitions are thus the same. A positive $A$-term is observed if the Zeeman component $|+1\rangle$ is at a higher energy than the $|-1\rangle$ component. An example is the magnetic dipole transition $^5D_1 \leftarrow {}^7F_0$ in the MCD spectrum of $Eu^{3+}$ (at ca. 19000 $cm^{-1}$), which always shows a positive $A$-term. It has been suggested to use this transition as a sign reference transition, in order to see if the magnetic field lines are parallel or antiparallel to the magnetic field lines (Görller-Walrand 1985). The MCD and axial absorption spectrum of the $^5D_1 \leftarrow {}^7F_0$ transition in $LiYF_4$:$Eu^{3+}$ is shown in Fig. 1.

### 3.3 Induced Electric Dipole Transitions

According to the Judd–Ofelt theory (Judd 1962, Ofelt 1962), the occurrence of intraconfigurational $f$–$f$ transitions is explained by nonsymmetric interactions which mix states of opposite parity into the $4f^N$

configuration. A simple mechanism is the coupling of states of opposite parity by the effect of the odd terms in the crystal-Hamiltonian $H_{CF}$:

$$H_{CF}^{odd} = -|e|\,V^{odd} = \sum_{k,q} B_q^k D_q^{(k)} \qquad (16)$$

where $B_q^k$ is a crystal-field parameter and $D_q^{(k)}$ is a tensor of rank $k$ ($k$ is odd) (Görller-Walrand and Binnemans 1996). The important point is that, depending on the values of $k$ and $q$ which are determined by the first coordination sphere around the lanthanide ion, mixing occurs between states of opposite parity and the Zeeman components, which are characterized by linear combinations of $\langle M|$ functions in the ground state and by linear combinations of $|M'\rangle$ functions in the excited state. The selection rule for an induced electric dipole transition is

$$\Delta M = M' - M = -(\rho + q) \qquad (17)$$

In the case where the ground state is characterized by $\langle M| = \langle 0|$, as for the $^7F_0$ ground state of $Eu^{3+}$, the selection rule is simplified to:

$$\Delta M = M' = -(\rho + q) \qquad (18)$$

The sign of the $A$-term is identical to the sign of the $M'$ value that satisfied the selection rule for $\rho = -1$. Whereas the sign of the $A$-term of an electric dipole transition or a magnetic dipole transition is only dependent on the free-ion properties, the sign of the $A$-term of an induced electric dipole transition depends on the site symmetry of the lanthanide ion (Görller-Walrand and Fluyt-Adriaens 1985; Görller-Walrand *et al*. 1985). The selection rules are valid for the intermediate coupling scheme ($J$ is a good quantum number), but relaxation of the selection rules can occur when $J$-mixing is strong.

## 4. Use of MCD for Site Symmetry Determination

The sign of the MCD-signal of the induced electric dipole transition $^5D_2 \leftarrow {}^7F_0$ (at ca. 21500 $cm^{-1}$) can be used to probe the site symmetry of the $Eu^{3+}$ ion and the type of the idealized coordination polyhedron. A positive $A$-term is found for the $Eu^{3+}$ ion in a $C_{4v}$ symmetry ($q = 0$), whereas a negative $A$-term is expected for $D_{2d}$ ($q = \pm 2$) and $D_{3h}$ symmetry ($q = \pm 3$). It is not possible to discriminate between $D_{2d}$ and $D_{3h}$ symmetry on the basis of the sign of the $^5D_2 \leftarrow {}^7F_0$ transition alone, but in the case of $D_{3h}$ symmetry, the MCD signal of the $^5D_2 \leftarrow {}^7F_0$ transition is twice as intense as the intensity of the MCD signal of the $^5D_1 \leftarrow {}^7F_0$ transition, whereas in the case of $D_{2d}$ symmetry the two MCD signals have an equal intensity. Ideally, $C_{4v}$ is the symmetry of a monocapped square antiprism (coordination number, CN = 9) or of a distorted square antiprism (CN = 8). $D_{3h}$ is the symmetry of a tricapped trigonal prism (CN = 9) and $D_{2d}$ is the symmetry of a dodecahedron (CN = 8). These coordination polyhedra are the most often observed coordination polyhedra of lanthanide complexes.

## 5. Check of the Reliability of Intensity Parameters

The spectral intensities of magnetic dipole transitions can be calculated exactly, provided that a good set of wavefunctions is available. The spectral intensities of induced electric dipole transitions in the absorption spectrum for lanthanide ions in single crystals are commonly parametrized in terms of $B_{\lambda kq}$ or $A_{tp}^{\lambda}$ intensity parameters (Görller-Walrand and Binnemans 1998). Since these parameters are related to the experimental dipole strength by nonlinear equations, solution of the problem is not straightforward. The sign of the parameters is indeterminate: a change of all the signs of the parameters will result in exactly the same calculated dipole strength. The extracted parameter set depends largely on the chosen starting values. Different parameter sets may give the same figure of merit for the calculated dipole strengths. It is very difficult to select the most adequate set of intensity parameters. Simulation of the MCD spectrum can help. Calculation of the MCD signals does not require more parameters than the crystal field and intensity parameters extracted from the absorption spectrum. If these parameters are adequate, they should allow a good simulation of the MCD spectrum. In the past, the MCD spectrum was often described by the Faraday parameters or MCD parameters $A_1$, $B_0$ and $C_0$ (Stephens 1970). In the Stephens-formalism several approximations are made, and these are not always valid for lanthanide systems, especially not for single crystals. An assumption is, for instance, that the Zeeman splitting is small compared to the crystal field splitting within a multiplet. This is not true for small crystal field splittings and a strong magnetic field. The Zeeman effect cannot be considered as a small perturbation compared to the crystal field effect.

Not only do the free ion and the crystal field Hamiltonian have to be included in the total Hamiltonian, but also the Zeeman Hamiltonian (as described in Sect. 2). After diagonalization, the Zeeman levels are directly found, instead of the crystal field levels. The MCD of a transition is calculated as the difference in intensity between the absorption of left circularly polarized to the Zeeman levels of a $^{2S+1}L_J$ term and the absorption of right circularly polarized light (Fluyt *et al*. 1996). The MCD of a transition has to be reported as an intensity difference. A positive sign indicates that left circularly polarized light is absorbed more effectively than right circularly polarized light. A negative sign indicates the opposite. In the case of overlapping bands, the band width of the curves used for the simulation will affect the overall appearance of the MCD signal to a

large extent. For single crystals, a Lorentzian shape function often gives the best results for the graphical simulation.

MCD can sometimes be used to detect transitions that are not resolved in the absorption spectrum. A condition is that the MCD signals of transitions to the closely spaced crystal field levels, which give rise to overlapping absorption bands, have an opposite sign. However, if the MCD signals of the transitions to the nearly degenerate crystal field levels have the same sign, the MCD spectrum is not advantageous.

## 6. MCD of Bioinorganic Compounds and Macrocyclic Complexes

Because lanthanide ions can subsitute for $Ca^{2+}$ in different proteins, it was suggested that MCD spectroscopy of lanthanide-substituted proteins could be used to probe the $Ca^{2+}$ active sites of these proteins. The fact that $Ca^{2+}$ active sites were being probed by luminescence spectroscopy after $Eu^{3+}$ or $Tb^{3+}$ substitution, and the sensitivity of the MCD spectrum towards small changes in the environment of the coordinated lanthanide ions, suggested that MCD could be a good technique to study the metal-ion site structure. In the past, several MCD studies were devoted to lanthanide ions (mainly $Nd^{3+}$) bound to proteins, but these studies were qualitative in nature, pointing to the differences of the MCD spectra of lanthanide ions in aqueous solution and of protein–lanthanide complexes. The use of MCD spectroscopy of lanthanide ions in bioinorganic chemistry has been reviewed (Dooley and Dawson 1984), but there has been little activity in this research field.

# SUBJECT INDEX

The Subject Index has been compiled to assist the reader in locating all references to a particular topic in the Encyclopedia. Index entries are filed in letter-by-letter sequence, and arranged in set-out style with up to three levels of heading. Major coverage of a subject is indicated by ***bold italic*** page numbers. Page numbers followed by *T* (or *F*) refer to Tables (or Figures). *See* references point the user to preferred terms; *see also* references indicate terms of related interest. Every effort has been made to make the index as comprehensive as possible and to standardize the terms used.
